In reporting[1] the results of experiments designed to examine consequences of the theory surrounding the concept of the innate capacity for increase, or Malthusian parameter[2,3], attention was directed to an unexplained discrepancy. From a linear regression of log total numbers on time, the experimental populations increased by an average of 6·082 times per three weeks, with 1 per cent confidence limits of 6·026 and 6·138, whereas age-specific life and fertility data independently obtained suggested that the value should have been 4·478. This discrepancy alone would have meant no more than that the experimental methods used in obtaining the life and fertility data depressed some or all of the rates of development, etc., but, by coincidence as it now seems, another method of evaluating the census observations suggested a value of 4·664, which is in accord with that calculated from the life and fertility table data. This value was obtained as follows: it was assumed that the population growth could be described as a first order process:

$$Mn_t = n_{t+1}$$

where M is a matrix the elements of which are numerical values of the dependence of stage i at time $t + 1$ on stage j at time t ($i, j = 1, 2, \ldots, s$), where there are s morphologically distinguishable stages in the population, and n_t and n_{t+1} are column vectors specifying the number of individuals in each stage at times t and $t + 1$. From census observations made at intervals of 3 weeks, M was estimated for this period by:

$$M = (V^{-1} W)'$$

where V is the variance/covariance matrix between the numbers of individuals at time t and W is the covariance matrix between the numbers of individuals at times t and $t + 1$. The first estimate, that forming the basis of the earlier discussion[1], will be referred to as M_1 and was:

$$M_1 = \begin{bmatrix} 0{\cdot}250 & 1{\cdot}998 & 4{\cdot}734 & -0{\cdot}009 \\ 1{\cdot}596 & 0{\cdot}173 & 25{\cdot}023 & 12{\cdot}021 \\ 0{\cdot}152 & 0{\cdot}042 & -0{\cdot}110 & 1{\cdot}032 \\ -0{\cdot}133 & 0{\cdot}854 & 1{\cdot}022 & -0{\cdot}231 \end{bmatrix}$$

which has a dominant latent root of 4·664 with an associated stable (column) vector of [0·455 0·875 0·055 0·152]'.

Dr. R. W. Howe, of this Laboratory, pointed out to me that this estimate of M used variances and covariances which had been corrected for the mean; if the experimental methods had achieved the results for which they were designed, namely, the removal of harmful 'density' effects, then regressions should pass through the origin, that is, corrections for the means should not be made. A new estimate of M was then made; this will be referred to as M_2. This matrix:

$$M_2 = \begin{bmatrix} 0{\cdot}341 & 1{\cdot}803 & 4{\cdot}119 & -0{\cdot}785 \\ 1{\cdot}203 & 0{\cdot}998 & 27{\cdot}776 & 15{\cdot}309 \\ 0{\cdot}125 & 0{\cdot}101 & 0{\cdot}085 & 1{\cdot}264 \\ -0{\cdot}160 & 0{\cdot}875 & 0{\cdot}919 & -0{\cdot}279 \end{bmatrix}$$

has a dominant latent root of 5·521 with a stable (column) vector of [0·347 0·925 0·058 0·141]'. This latent root is obviously in much closer agreement with the increase implied by the slope of the linear regression estimate of the totals on time.

Since there does not seem to be an algebraic method for the estimation of the standard errors of the latent roots of a matrix, the elements of which have known or estimated variances, it is not clear whether the 1 per cent confidence limits for this latent root include the linear regression estimate. At present, therefore, whether a discrepancy remains is uncertain. Further investigation of the underlying distributions[1,4] and their implications will be necessary before this problem can be solved.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, November 23

INSTITUTE OF ACTUARIES (at Staple Inn Hall, High Holborn, London, W.C.1), at 5 p.m.—Mr. J. R. Ford and Mr. C. M. Stewart: "Population Trends in Great Britain".

BRITISH SOCIETY FOR THE HISTORY OF SCIENCE (in the Council Room of the Science Museum, Exhibition Road, South Kensington, London, S.W.7), at 5.30 p.m.—Dr. Marie Boas Hall: "Henry Oldenburg and the Art of Scientific Communication".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. R. F. Hoskins: "Loop Gain and Return Difference of Transistor Amplifiers".

ROYAL INSTITUTION OF NAVAL ARCHITECTS (at the North East Coast Institution of Engineers and Shipbuilders, Bolbec Hall, Newcastle upon Tyne), at 6 p.m.—Mr. W. D. Horsley: "The High Speed Generator—Eighty Years of Progress" (Sir Charles Parsons Memorial Lecture).

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Lady Williams, C.B.E.: "Vocational Training". (Second of three Cantor Lectures on "A Comparative Study of World Trends in Education".)

INSTITUTION OF MECHANICAL ENGINEERS, MANIPULATIVE AND MECHANICAL HANDLING MACHINERY GROUP (in the Renold Building of the College of Science and Technology, Manchester), at 6.45 p.m.—Discussion on "The Mechanics of High-Speed Weaving".

Tuesday, November 24

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Mr. D. J. Robinson: "A Visit to Venezuela's El Dorado".*

UNIVERSITY OF LONDON (at the Institute of Education, Malet Street, London, W.C.1), at 5.15 p.m.—Dr. Joyce Long: "Universities and Those Outside Them".*

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, London, S.W.1), at 5.30 p.m.—Mr. J. L. Beckett and Mr. H. R. Oakley: "A Combined Scheme of Sewage Disposal and Refuse Composting in Leicester".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Sir Lawrence Bragg, F.R.S.: "Waves and Vibrations". (Afternoon lecture for Sixth Form Boys and Girls from Schools in London and the Home Counties. Further lectures on November 24, and December 1 and 2.)

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, London, S.W.7), at 5.30 p.m.—Prof. E. P. Wohlfarth: "Magnetism in Theory and Practice" (Inaugural Lecture).*

UNIVERSITY OF LONDON (at Queen Elizabeth College, 61–67 Campden Hill Road, London, W.8), at 5.30 p.m.—Dr. P. T. Haskell: "The International Fight Against the Locust".*

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. M. G. P. Stoker: "Tumour Viruses". (Ninth of fourteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

ROYAL AERONAUTICAL SOCIETY (joint meeting with the Institution of Electrical Engineers, at Savoy Place, London, W.C.2), at 6 p.m.—Discussion meeting on "Unconventional Methods of Generating Electrical Power in the Aircraft of the Future".

INSTITUTION OF MECHANICAL ENGINEERS, GRADUATES' AND STUDENTS' SECTION (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6.30 p.m.—Mr. A. J. Barter: "Locomotive Maintenance".

SOCIETY OF CHEMICAL INDUSTRY, PLASTICS AND POLYMER GROUP (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. J. I. Cunneen: "Cis-trans Isomerism in Polyisoprenes".

SOCIETY FOR ANALYTICAL CHEMISTRY, SPECIAL TECHNIQUES GROUP (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 7 p.m.—Twentieth Annual General Meeting, followed by Scientific Films.

Wednesday, November 25

INSTITUTION OF CHEMICAL ENGINEERS (in the Connaught Rooms, Great Queen Street, London, W.C.2), at 9.45 a.m.—Discussion Meeting on "The Economist's View of the Process Industries".

INSTITUTE OF PETROLEUM (in association with the Institution of Heating and Ventilating Engineers, at the Royal Aeronautical Society, 4 Hamilton Place, London, W.1), at 4 p.m.—Symposium on "District Heating".

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Mr. S. Paul Chambers, C.B., C.I.E.: "Statistics and Intellectual Integrity" (Inaugural Address of the President).

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. D. St. J. Seigne: "Marine Electric Propulsion".

CHALLENGER SOCIETY (at the Linnean Society, Burlington House, Piccadilly, London, W.1), at 5.45 p.m.—Dr. T. F. Gaskell: "The Prospects of Oil or Gas from Under the North Sea".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT I.E.R.E.–I.E.E. COMPUTER GROUPS (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Discussion on "Logic Circuit Symbols" opened by Mr. J. A. Lawrence and Mr. J. H. Smith.

INSTITUTION OF MECHANICAL ENGINEERS (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Sir Robert Cockburn: "Materials and the Engineer" (Thomas Hawksley Lecture).

ROYAL METEOROLOGICAL SOCIETY (in the Conference Hall, County Hall, Westminster Bridge, London, S.E.1), at 6 p.m.—Dr. J. Hallett: "The Origins and Growth of Ice in Our Atmosphere".

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP—FOOD ENGINEERING PANEL (joint meeting with the Industrial Water and Effluents Group, at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Mr. A. Henchley and Mr. R. Cunningham: "Effluent Disposal in an Edible Oil Refinery and Margarine Factory".

INSTITUTION OF ENGINEERING INSPECTION (at the South-West Essex Technical College, Forest Road, Walthamstow, London, E.17), at 7.30 p.m.—Mr. J. C. McCullagh: "Inspection in the Radio and Electronics Industry".

Thursday, November 26

FERTILISER SOCIETY (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Prof. J. F. Sutcliffe: "The Absorption of Inorganic Nutrients by Plants" followed by a discussion.

INSTITUTION OF ELECTRICAL ENGINEERS, SCIENCE AND GENERAL DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Colloquium on "Plasma Jets".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. W. Lane-Petter: "Sophisticated Laboratory Animals". (Tenth of fourteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation).*

INSTITUTION OF MECHANICAL ENGINEERS, LUBRICATION AND WEAR GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Standards in Britain for Lubrication and Lubricants".

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (joint meeting with the Heavy Organic Chemicals and Chemical Engineering Groups, at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Dr. Ing. B. Orsoni: "The Italian Heavy Organic Chemical Industry".

Friday, November 27

UNIVERSITY OF LONDON (at the Institute of Neurology, National Hospital, Queen Square, London, W.C.1), at 5.30 p.m.—Prof. W. Feindel (Montreal): "Radio-Isotopic Studies on Cerebral Circulation in Man".*

INSTITUTION OF MECHANICAL ENGINEERS, APPLIED MECHANICS GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion Meeting on "New Pathways with Kinematic Linkages".

BRITISH SOCIETY FOR THE HISTORY OF SCIENCE (in Room 45, Leicester College of Technology, The Newarke, Leicester), at 7 p.m.—Dr. John Butt: "James Young, Scientist, Industrialist, Philanthropist".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. P. H. Greenwood: "Explosive Speciation in African Lakes".

Saturday, November 28

BOTANICAL SOCIETY OF THE BRITISH ISLES (in the Botany Department, British Museum (Natural History), Cromwell Road, London, S.W.7), from 2 p.m. to 5.30 p.m.—Annual Exhibition Meeting.

LONDON COUNTY COUNCIL (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Zoe, Lady Hart Dyke: "The Silk Makers".

GLACIOLOGICAL SOCIETY (joint meeting with the Scott Polar Research Institute, at the Scott Polar Research Institute, Cambridge), at 8.30 p.m.—Mr. John T. Andrews: "Baffin Island".

Monday, November 30

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (joint meeting with the I.E.R.E. Medical and Biological Group, at Savoy Place, London, W.C.2), at 2.30 p.m.—Discussion on "Lasers".

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Anniversary Meeting.

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Dr. T. F. Gaskell and Captain G. S. Ritchie, D.S.C., R.N.: "Beneath the North Atlantic".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURER (graduate, preferably with an interest in microbiology) IN BOTANY—The Principal, Wigan and District Mining and Technical College, Wigan (November 27).

LECTURER (with an M.Sc. or Ph.D. in microbiology or bacteriology, and experience in parasitology) IN MICROBIOLOGY at the University of Nigeria, Nsukka, Eastern Nigeria—The London Representative, University of Nigeria, 33 Craven Terrace, London, W.2 (November 30).

SENIOR LECTURER IN BIOCHEMISTRY; LECTURERS IN CIVIL ENGINEERING (2); a SENIOR LECTURER IN RESEARCH (Physics); and a SENIOR LECTURER IN RESEARCH (Electrical Engineering)—The Principal, Nottingham Regional College of Technology, Burton Street, Nottingham (November 30).

CHAIR OF SOCIOLOGY—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (December 1).

LECTURER or ASSISTANT LECTURER IN PHARMACOLOGY—The Secretary, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (December 1).

RESEARCH ASSISTANT (with a good honours degree in physics or chemical engineering and a special interest in particle mechanics or fluid dynamics or rheology) IN THE MINING ENGINEERING DEPARTMENT, to work on particle fluid flow in model systems, with special reference to blood—The Registrar, The University, Nottingham (December 1).

EXPERIMENTAL OFFICER/SENIOR EXPERIMENTAL OFFICER (with experience in the application of modern analytical techniques and in the organization of routine analytical work, and preferably experience in the application of auto-analytical procedures) to take charge of a chemical and biochemical analytical laboratory—The Secretary, Hill Farming Research Organization, 29 Lauder Road, Edinburgh, 9 (December 2).

LECTURERS (2) (with experience in numerical analysis and/or systems programming) IN THE DEPARTMENT OF COMPUTER SCIENCE—The Registrar, The University, Manchester, 13 (December 5).

RESEARCH ASSISTANT (graduate interested in genetics, biochemistry or microbiology) IN THE DEPARTMENT OF BOTANY, to work on problems concerned with the genetics and physiology of yeast—The Registrar, Queen Mary College, Mile End Road, London, E.1 (December 10).

LECTURER IN PHYSIOLOGY—The Secretary, The Queen's University, Belfast, Northern Ireland (December 17).

LECTURER/SENIOR LECTURER (graduate in veterinary science, agricultural science or rural science, with extensive postgraduate experience and preferably a higher degree) IN ANIMAL HUSBANDRY at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, December 18).

READER IN COMPUTING at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Brisbane and London, December 18).

SENIOR LECTURERS, LECTURERS OR ASSISTANT LECTURERS IN MATHEMATICS—The Registrar, University of East Anglia, Earlham Hall, Norwich, NOR. 05G (December 18).

SENIOR LECTURERS OR ASSISTANT LECTURERS IN PHYSICS—The Registrar, University of East Anglia, Earlham Hall, Norwich, NOR. 05G (December 18).

CHAIR OF PHYSICAL METALLURGY—The Registrar, University College of Swansea, Singleton Park, Swansea (December 31).

CHAIR OF PHYSICS—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (December 31).

SENIOR LECTURERS OR LECTURERS IN PURE MATHEMATICS AND APPLIED MATHEMATICS at Monash University, Melbourne, Australia—The Registrar, Monash University, P.O. Box 92, Clayton, Victoria, Australia, or The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, December 31).

TEACHING FELLOW (with an appropriate honours degree or equivalent qualifications, and preferably a background of organic and/or experience in organo-analytical chemistry) IN THE SCHOOL OF CHEMISTRY, University of New South Wales—The Agent General for New South Wales, 56–57 Strand, London, W.C.2; and The Appointments Section, The University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia (December 31).

CHAIR OF SOCIOLOGY—The Registrar, The University of Essex, Colchester, Essex (January 5).

I.C.I. RESEARCH FELLOW IN CHEMISTRY, BIOLOGICAL CHEMISTRY, ENGINEERING, PHARMACOLOGY, PHYSICS, or in a related subject—The Registrar, The University, Senate House, Bristol, 2 (February 1).

SENIOR LECTURER IN THE DEPARTMENT OF PATHOLOGY, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, February 1).

ENTOMOLOGIST (with a degree in zoology, postgraduate experience in the ecology of mosquitoes and other blood-sucking flies, and administrative experience) in the Cayman Islands, to undertake research and control of nuisance mosquitoes, with responsibility for the laboratory, field and laboratory staff—The Appointments Officer, Ministry of Overseas Development, Room 404, Eland House, Stag Place, London, S.W.1, quoting Ref. RC/205/36/01.

GRADUATE RESEARCH ASSISTANT IN MEDICAL MYCOLOGY—The House Governor, Brompton Hospital, London, S.W.3, quoting Ref. R.A.I.

JUNIOR LECTURER OR LECTURER (medical graduate) IN THE BACTERIOLOGY DEPARTMENT—The Dean, Guy's Hospital Medical School, London Bridge, S.E.1.

LECTURER (graduate) IN ZOOLOGY—The Bursar, Harper Adams Agricultural College, Newport, Shropshire.

LECTURERS OR SENIOR LECTURERS (well qualified and preferably significant research and/or industrial experience) IN (a) INORGANIC CHEMISTRY; (b) PHYSICS; and (c) METALLURGY OR MATERIALS—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 25/G.

MASTER TO TEACH MATHEMATICS throughout the School including Sixth Form; and a MASTER TO TEACH BIOLOGY to ordinary level and BOTANY AND ZOOLOGY to advanced level—The Headmaster, King's College School, Wimbledon, London, S.W.19.

POST-DOCTORAL RESEARCH FELLOW IN THE DEPARTMENT OF CHEMISTRY for the study of the gas phase reactions of methylene and ethylidene—The Secretary and Registrar (Room 9), The University, Highfield, Southampton.

REGIONAL TRIALS OFFICER (graduate in horticulture or with equivalent qualifications) at Stockbridge House, Yorkshire, for variety trials of vegetable crops—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

SENIOR LECTURERS (with good academic qualifications in chemical engineering, or an allied discipline) IN CHEMICAL ENGINEERING—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 24/G.

SCIENCE AND TECHNOLOGY AND THE NEW LABOUR GOVERNMENT

AFTER his recent election as Prime Minister, the Right Hon. Harold Wilson lost no time in re-organizing the Government and appointing Ministers and other personnel to carry out the policies already announced or to be developed in due course.

This includes science and technology: the various science, technology and education Ministers have already been selected and their names announced, and even scientific advisers who are not members of either the House of Commons or the House of Lords have been, or are about to be, appointed. Consultation with non-partisan scientists by the Government of the day is not a new idea, either in Britain or elsewhere; but it is nevertheless very worth while, indeed essential, and it seems that the Prime Minister is determined to take full advantage of it.

These are early days, of course, so any form of criticism is best deferred; nevertheless, we must recognize that it is quite clear that the Prime Minister and his Government are determined to do the best they can, in their own way (after consultation with distinguished scientists both within and outside Parliament), for the advancement of science and technology and their application in industry and medicine and for other benefits to the community.

Whether the Government takes the right, and most advantageous, course remains to be seen, though even at this initial stage it is encouraging to know that men who have already proved themselves in the various branches of science, technology and education have been appointed to the highest political and advisory posts. (Incidentally, it is to be hoped that as a result of the Government's aims and objectives, at any rate in science and technology, set out for public approval, and the appointment of appropriate men to carry them out, we shall no longer read (mainly in the lay Press) such ugly terms as 'boffins' and 'backroom boys'.)

It is perhaps significant and indicative of the importance attached in the new Government to science that so early as during the debate on the Queen's Speech at the opening of the new Parliament on November 3, Mr. Robert Maxwell (Member for Buckingham), who is well known throughout the world of science and science journal and book publication, should have, in his maiden speech, made the organization of the Government for science and technology his main theme.

During his speech, Mr. Maxwell directed the attention of the House of Commons to the great benefits which industry and the country can obtain by making use of the results of research in science, engineering and medicine. After discussing various problems which need solving in his own constituency, graciously commenting on the good work done there by his Parliamentary predecessor, Sir Frank Markham, Mr. Maxwell said:

"I very much welcome the Government's proposals to help our industries to gain the full benefit of advances in scientific research and technology. At this point, I wish to refer to the strictures which the Leader of the Opposition seemed to think it right to cast on the creation of the Ministry of Technology. . . . The House may wonder what authority I have to deal with these matters. I was chairman of one of the working parties appointed by my right hon. Friend the Member for Coventry East (Mr. R. H. S. Crossman) in his previous capacity as Opposition Front Bench spokesman on science and education, and chaired the committee on science, Government and industry. Also, I am a publisher of scientific magazines and books and I am in the closest touch with scientists from all over the world. . . .

"I hope to be able to prove to the House that the new Ministry of Technology is certainly one of the answers that the Government needed in order to get British industry to apply the results of research faster and better than it has done in the past. It is now well understood that the growth of our economy, the welfare of our citizens, our national security and the aid that we can afford to give to under-developed countries all depend to a growing extent on the effective use that our industries make of new technology.

"In recent years the rate of increase in our gross national product per worker and *per capita* has slowed down and has been substantially less than the increase of almost all highly industrialized nations. It is apparently not fully realized that scientific discovery followed by technological research and development produces nothing, other than knowledge, for society. They must be followed by their applications through the combined use of capital, and equipment and human resources—labour and management—to produce an economic good.

"It is commonly accepted that management in British industry, both private and nationalized, by and large has failed badly to make use of science and technology as an aid to increased productivity and profitability. For example, of the first fifty ethical drugs prescribed by doctors under the National Health Service, in order of sales value used in this country, only three were discovered and developed in this country—ordinary penicillin and the new Beecham penicillins, 'Broxil' and 'Penbritin'.

"It is generally agreed that one of the major obstacles preventing the wider application and use of science and technology in British industry is that there does not seem to be, at present, an effective organization or method to convey to individual companies, their managements and foremen, the new technology in a form which points the way to its practical applications.

"The other major problem is the great gulf, and lack of communication, which exist between the pure scientists and the applied scientists, the universities, the technical colleges, the trade research associations, industry and Government, and, finally, the gap which exists between management and scientists in individual firms.

"The whole issue may, therefore, be summed up as being a problem in communication of information and the need to change attitudes of mind. I submit that the creation of the Ministry of Technology is a massive and positive step in bringing about the necessary alteration and to obtain the needed change of attitude.

"The Government should provide something which has been lacking in our country for a long time—a sharp and independent means for recognizing when the mission of a Government research and development establishment has lost its validity, and the practical means for re-directing the establishment into more productive channels either within or outside the Government Department that originally sponsored it. When the independent nuclear deterrent is abolished, the problem of what to do with the

Aldermaston Weapons Research Establishment is a good example of the kind of problem which I have in mind.

"The present system of awarding development contracts tempts private companies to talk their way into a development programme with promises of results which wise technical judgment would deem unattainable. . . . The present arrangement does not provide for adequate penalties for failure to achieve promised results, nor does it give sufficient incentives for a high level of technical performance. It offers incentives to contractors to make systems complex and expensive or to prolong the development work. All this is most wasteful of our vital scientific and engineering manpower as well as of the taxpayer's money.

"Finally, the present defence research contract arrangement with its built-in competitive incentives and inadequate penalties for poor technical performance leads to the proliferation of many research and development groups in private industry of sub-critical size or quality. This is another important example of where the new Government's changes in the organization of science and engineering may prove to be most helpful and valuable both in saving taxpayers' money and in making better use of our scarce national resources in science and engineering.

"The Government and our scientific and engineering community should make it one of their major joint tasks to employ our new-found ability to combine the great diversity of scientific and engineering skills and disciplines to make a massive assault on very large-scale national problems. The effectiveness of employing this new Government tool has been demonstrated during the Second World War and in the massive American and Russian space programmes. The social innovation of use in peace-time of this new Government tool is of even greater consequence in the long run than the scientific and technical innovations on which most of our attention is presently focused. This is the spill-over from defence of the greatest national and social consequence, and we as a country have so far failed to use this instrument in peace-time. There can be no doubt that the development of this new capability has endowed us as a nation with great new powers. I am sure that the new Government will use this social invention for peaceful purposes and not just confine it to the defence sector.

"The Government should show the way how to use research and development in the modern inter-disciplinary way through industry to improve and raise the quality and excellence of the environment in which we work and live. Familiar examples of the material waste and erosion of the æsthetic environment which are very complex and which can only be solved on a multidisciplinary basis are traffic congestion and air and water pollution.

"The strength of British science depends on the initiative, imagination and intelligence of individual working scientists and engineers. The best possible programme formulated at the top can be made entirely ineffective by the people who are carrying it out. The purposes of organization for science and engineering in the Government must be to ensure quicker identification and support of new ideas and maintain support for basic research and development to guarantee that the most important national technological jobs are tackled by the most able people. I am convinced that the Government's arrangements for the organization of science and technology will do that."

It is hoped to publish later in *Nature* Mr. Maxwell's description and views of the new Labour Government's organization for science and technology in Great Britain. It is hoped that he will also show how the new Government's organization for science and technology compares and differs from those now in existence in the other scientifically advanced major countries.

The opinions and ideas of Mr. Maxwell are what we have been awaiting for a considerable time. However, one cannot help but feel that much that is talked about development of scientific progress into industrial practice is so much political ammunition, and only the next few months will show if the present Government is successfully on the way to taking full advantage of scientific research.

THE SCIENTIFIC SPIRIT

The Scientific Intellectual

The Psychological and Sociological Origins of Modern Science. By Lewis S. Feuer. Pp. xii+441. (New York and London: Basic Books, Inc., Publishers, 1963.) 10.00 dollars.

HARDY, in *A Mathematician's Apology* (pp. 18–19, Cambridge University Press, 1948), once referred to the motives which, in his opinion, lead men to prosecute research of practically any kind, be it psychology, classics or mathematics; they were "intellectual curiosity", "professional pride", and finally, "ambition, desire for reputation . . . even the power or the money, which it brings". Prof. Feuer, in this weighty volume, attempts to dig more deeply, to peer beneath the surface of such conscious and mundane considerations, using some of the vernacular of psychoanalytical jargon in the process. His question is, what inspired—at least at the psychological level—the rise of the scientific attitude and of the revolution in science, particularly since the seventeenth century? His major conclusion is that the scientific movement and the scientific intellectual are born from the "hedonist-libertarian spirit". Some of the traits of the hedonist ethic are freedom from a sense of "primal guilt", "asocial" in character, if not downright "subversive". Since the seventeenth century beginnings, scientists find "joy and pleasure in scientific activity itself"; they are utilitarian and individualistic, and above all they seek a conception of the universe which is "less fear-ridden, less anxiety-surrounded" than its predecessors. They also seek to rid themselves of "dependence-relations", an expression of a strong authoritarian super-ego: priests, elders and confessors often seem to have retarded scientific progress, and the individualism of the Jewish and Protestant spirit may be expected to yield useful results for scientific progress.

Feuer takes to task particularly earlier explanations of the rise of science, such as R. K. Merton's view that Puritanism and ascetic Protestantism were strongly linked with the growing curiosity concerning the phenomena of Nature, a view itself traced back both to Marxist and Weberian notions. In particular, he rejects (though without argument) a contrary theory of a brother psychoanalyst, Norman O. Brown, that rather than hedonism, "the essence of the scientific spirit [is] to be mercilessly ascetic, to eliminate human enjoyment from our relation to nature, to eliminate the human senses" (compare p. 316, *Life against Death*, Vintage ed., 1961, p. 316), a passage which in turn reflects the views of the distinguished French writer on the psychoanalytical background of science, Gaston Bachelard, whom Feuer does not mention at all.

Feuer indeed does not spend much time on confuting alternative hypotheses, nor consider any individual counter examples. Instead, we get a vast array of a scholarly collected (or rather 'selected') multitude of facts and features which, though they may not 'prove' the author's thesis, are at least intended to illustrate it. This, as every good scientist knows, is an exceedingly dangerous under-

taking. Feuer's wholesale paraphrase of the complex social phenomenon called 'modern science' under one single aspect, and his illustrative method of backing his doctrine, to one reader at least smacks all too much of the ancient alchemists' apocryphal search for the universal solvent. There is no serious argument against alternative interpretations, no sustained breaking down of the complex idea of science; nor is the psychoanalytical approach employed with much more than popularizing terminology. Sometimes, simplification is taken to absurd extremes. To cite just one instance: Chapter 3 discusses the "nominalist recovery of the sense of reality". Here, the medieval doctrine of the "reality of universals" is contrasted with incipient nominalism, as exemplified in the philosophy of Occam. There is no mention here of further important alternatives, such as Aristotelian (rather than Platonist) realism, nor of conceptualism. We are told (p. 87) that the realm of universals "was the projective universe of the celibate scholastics", Duns Scotus being cited as an example. But Occam, though eventually expelled from the Franciscan order, was surely a celibate also! Besides, it is misleading to imply that realism died in the fourteenth century. Surely it has had important defenders to the present day; a glance at any text-book on the foundations of mathematics will show this. In any event, when the psychoanalytic writer tries to 'explain' philosophical and social phenomena by means of such questionable concepts as "the reality-principle" and "reality-thinking"—notions which, though they may have their origin in Freud, are dismissed by other psychoanalysts as naïve (compare Brown, *op. cit.*, p. 235), we may say that it will be well to sit back and wait until the psychoanalysts have put their own house in order before we can be sure that their putatively illuminating commentaries are more than *obiter dicta*, and constitute a serious approach towards the sociology of science.

This is not to say that a patient reader may not extract much that is of interest from this volume. It covers a very large field, and in the process it has dug up or collected from primary sources much that will be useful to the careful scholar, ranging as it does from Asia via the Jews to the scientific intellectual in the United States (Chapter 11). Moreover, it is useful to be confronted by a more sophisticated approach towards the phenomenon of 'the scientific spirit' than the more simple-minded and more usual notion of the 'patient collection of facts'.

GERD BUCHDAHL

POPULAR ASTRONOMY ILLUSTRATED

The Flammarion Book of Astronomy

Translated into English by Annabel and Bernard Pagel. Pp. 670. (London: George Allen and Unwin, Ltd., 1964.) 100*s*. net.

ASTRONOMIE Populaire, by Camille Flammarion, was first published in 1880. It was an immediate success, and did much to establish Flammarion's reputation as a writer on popular science. Many subsequent editions have appeared in French, suitably brought up to date, and in 1894 an English translation was produced by J. Ellard Gore.

The last French edition appeared in 1954, by which time there was very little of the original text left. The whole book had been overhauled and expanded, with new sections written by various eminent French astronomers. Only the general plan, as laid down by Flammarion, remained unaltered.

A new English translation has long been overdue, and its appearance is therefore particularly welcome. It has been based on the 1954 text, translated by Annabel and Bernard Pagel, and again revised; there are sections by various French astronomers, including A. Danjon, A. Dollfus and C. Fehrenbach, while some material has also been added by one of the translators, B. Pagel, of the Royal Greenwich Observatory. The presentation leaves nothing to be desired; in view of the lengthy text coupled with the lavish illustrations (some of which are in full colour), the price of £5 is by no means excessive.

The style is non-technical, and the whole text may therefore be followed by the beginner, but a great deal of information useful to the serious student is also given. The general impression is one of excellence, and the book will certainly find its way into most scientific libraries.

The first section deals with the Earth as an astronomical body, with special emphasis on its motion in space. This is followed by almost 70 pages devoted to the Moon, illustrated with many fine photographs taken at the Pic du Midi and other major observatories. Considerable space is given to problems of the lunar surface itself, to which French astronomers have always paid great attention; the Moon's movements are also described in detail, and there is a chapter on lunar eclipses.

The next hundred pages deal with the Sun in all its aspects. This means giving an outline of elementary spectroscopy, and the result is very satisfactory; the chapter headed "Inside the Sun" is, for example, a model of clarity. Following this, the planets of the Solar System are described one by one. Some observers, including myself, will consider that the colours on the planetary drawings are rather too definite, but this is a matter of opinion, and it is not easy to give any precise standards of reference.

Minor planets are included with the large bodies of the Solar System, but comets and meteors are treated in a separate section. There is then a long description of the stellar universe, which will be particularly useful to the serious student even though there is relatively little about cosmology. Book 7, "The Instruments of Astronomy", is relatively brief, since it covers less than twenty pages and could well have been expanded, though it is clear and concise. Artificial satellites and space vehicles are treated separately, and at the end of the book there are useful tables of astronomical data.

It is inevitable that there should be a few points of criticism, particularly as the book is so long and so comprehensive. First, it must be said that the translation, though satisfactory on the whole, is not flawless; lunar observers will look in vain for the "Mare Pluvium", while the Sinus Iridum is translated as "Gulf of Irises". There are also some cases of curious grammar, and a few sentences which should have been tidied up. There are, moreover, various minor misprints which will presumably be weeded out in the next edition.

The other defect in the book is one which can scarcely be avoided in a project of this magnitude. Progress in astronomy is now so rapid that it is difficult to keep up to date even in the case of a book which can be produced quickly, and in an elaborate publication there is no hope of avoiding a considerable time-lag between the final preparation of the text and the subsequent appearance of the book. This means that recent developments cannot be included, which is unfortunate but inevitable. It is a pity that some particularly important discoveries have had to be ignored; for example, there is nothing about quasi-stellar objects or about the close-up lunar photographs obtained by the U.S. vehicle *Ranger VII*.

On the other hand, it seems that too little attention has been directed to making the book as up-to-date as was possible in the circumstances. Some of the sections give the impression of having been written years ago and left unaltered, though in a few cases footnotes have been added. A typical example occurs on p. 202, where there is a footnote stating that "at the time of writing news was received that on December 12, 1952, the solar spectrum was photographed from a height of 80 kilometres". Even the brief note about the pictures of the Moon's far side, obtained in 1959 by the Russian probe *Lunik III*, seems to have been tacked in as an afterthought. Further-

more, on p. 572 we read that "collisions between galaxies are very noisy in the radio wave band", though elsewhere (p. 547) it is correctly stated that the whole theory of colliding galaxies has now fallen out of favour. The whole of the section dealing with artificial satellites and interplanetary probes is out of date, and it would have been wiser to make it complete up to the latest possible date (presumably 1962 or 1963) and explain why subsequent developments could not be included.

However, these shortcomings are very minor when the book is considered as a whole, and it would be most unfair to place undue emphasis on them. On balance, this is certainly the best book of its type to have been produced in English during the past quarter of a century, and it will undoubtedly run to many editions. Revisions can be made from time to time, but the bulk of the text will need no drastic amendment for some years, except in the unlikely event of some spectacular discovery which overturns many theories which have become thoroughly established. All those who have been concerned in the production deserve the highest congratulations, and it is to be hoped that the book will have a wide circulation.

PATRICK MOORE

CRYOGENIC PROCESSES IN GEOLOGY

An Introduction to the Theory of the Formation of Frozen Rocks

By I. A. Tyutyunov. Translated from the Russian by J. O. H. Muhlhaus. (International Series of Monographs on Earth Sciences, Vol. 6.) Pp. xiv + 94. (Oxford, London, New York and Paris: Pergamon Press, 1964.) 50*s*.

THIS most welcome and fascinating book is the first to describe the physical and chemical changes that occur in regions of permafrost. Although active permafrost research is a restricted investigation, the contents of this book should arouse widespread interest in the more general fields of rock weathering, erosion, soil formation and clay mineralogy. The translation from the original Russian text has been ably carried out, although some passages appear to be rather unwieldy.

The main theme throughout the book is concerned with the energy that can be liberated by water during sequences of freezing and thawing and how, as a result, minerals covered by films of water are vigorously attacked. Permafrost investigations are covered by the field of cryogeny which is concerned with the complex physical, chemical and mineralogical changes in the upper strata of the lithosphere and hydrosphere at a negative geothermal level of heat exchange. The liberation of energy is described in terms of crystal fragmentation by water resulting in a tremendous increase in potential energy at the water surface layer. The rate and efficiency of conversion of energy in terms of mineral alteration in areas of permafrost are related to the degree of condensation of the potential surface energy and to the concentration of substances (cations, anions) in reactions at such locations. The site where energy changes occur at the water/mineral surface interface is referred to as the 'double surface layer'. The changes involved are dealt with in detail and the formation of cryogenic minerals is described, such as those formed by interaction of Na, K, Mg with Cl, SO_4. Through the process of freezing, water provides a significant agency for influencing the concentration and nature of solute present in terrestrial water.

The power of pellicular water in terms of potential energy and penetration is considered to parallel the forces of tectonic processes and is ranked as an outstanding geological factor that must be seriously considered in such environments. Changes concomitant with freezing are described as differentiation processes, and essentially result from dehydration and coagulation of colloids during freezing. The stronger the coagulation of suspended material in the soils the greater the result in the progressive increase in the segregation of ice, to such an extent that ice schlieren are formed—a cryogenic texture.

The book introduces various physical and chemical theories in simple terms and develops them to an advanced state. Although the salient points of permafrost investigations are outlined, geologists would perhaps welcome a more detailed account, particularly as this is the only book on the subject. Also a further chapter describing the practical effect of physical and chemical processes that occur in frozen rocks would be useful for mining and construction engineers.

Permafrost investigations are a rather specialized field of research; however, the approaches and conclusions discussed in this book will undoubtedly be welcomed by those interested in earth sciences.

E. I. HAMILTON

HANDBOOK OF ELECTROPLATING

Handbook of Industrial Electroplating

By E. A. Ollard and E. B. Smith. Third edition. Pp. x + 400. (London: Iliffe Books, Ltd.; New York: American Elsevier Publishing Company, Inc., 1964.) 65*s*.

IN their foreword Messrs. Ollard and Smith disclaim any attempt to produce a text-book, and the title happily defines their work as a *Handbook of Industrial Electroplating* and this it indisputably and most excellently is. No one, accustomed to the problems that arise daily in a modern plating shop and who has studied this book, can fail to believe that a copy of it is an essential item in the personal equipment of every plating shop manager.

Excellence in commercial electrodeposition, to a greater degree perhaps than in most crafts, depends on infinite capacity for taking care, and emphasis on this fact runs like a thread of gold through the whole book. It is certain that the reader who specializes in any section of the vast field covered by the authors will be stimulated to seek out and understand the theories which have contributed so much to the present rapid development of knowledge in this field. Such stimulation alone is rich reward for the possession and study of this book.

This constant need for care in the management of a modern electroplating shop is underlined by the fact that the authors have, with great insight, devoted more than one quarter of the actual reading matter to testing both depositing solutions and the deposits themselves. For some, these pages will themselves be of absorbing interest and for others an invaluable source of reference.

The growing body of regulation covering industrial effluent disposal fully justifies the attention the authors have devoted to this subject. None whose duty it may be to "design, erect or run" plating plants can afford to ignore the information on this aspect that is so readably set out in this book.

The references to, and information about, automatic and semi-automatic plants whet the appetite for more, and it is to be hoped that in later editions the authors will devote a full chapter to this aspect of plating-shop equipment. Much of the success or failure of operating platers depends on the human factor, and the advent of the completely automated plant must be the dream of many a plating-shop manager.

For many, the most valuable section is that devoted to costing and organization, especially the paragraph on estimating and the very valuable statistics on productivity. It is to be hoped that future editions will continuously bring these statistics up to date and will amplify them with some indication of the relationship between productivity and the percentage of installed vat time actually used in the period the statistics cover. Those interested in national productivity, and curious as to

where the shop, for which they may be responsible, stands in regard to the plants listed, will have food for thought in the fact that the largest shop, based on people employed, achieves barely half the turnover per employee achieved by the smallest shop, and little more than one-third of that achieved by the plant which is less than one-third its size. Of course, the comparative nature of the work, which the authors do not give, could, in part, explain these wide variations. Unfortunately, they accord too closely with Britain's general pattern, and it is to be hoped that in bringing these figures up to date in later editions the authors will give similar figures culled from the United States, to the benefit of their British and American readers alike.

The rapid advances in techniques for anodizing aluminium for exterior architectural work, that have been made over recent years, suggest that both revision and amplification of the authors' references to this subject would merit attention in future editions. Some comment, in the paragraphs on trichloroethylene degreasing, on the troubles experienced by some shops, which have used this process for cleaning aluminium intended for exterior architectural work, would also be welcomed in later editions. The short paragraph devoted to dyes for anodized coatings is too short to do the authors justice.

The attention to *BS.* 3382 in the chapter on plating threaded parts is surely inspired. It is becoming increasingly clear that the requirements of this specification are no more stringent than the minimum required to sustain and accelerate the growth of this market, which seems to have expanded more strongly since the publication of *BS.* 3382 than ever before.

The formulæ, so generously set out, cover much valuable information that, in the not distant past, would have been shrouded in commercial secrecy. Permission to publish such data displays confidence in the belief that what benefits the industry must benefit its members, and evokes the hope that later editions will include a glossary of troubles that platers must expect to meet and suggested methods to avoid or overcome them.

In conclusion, it must be said again that the authors have achieved in full their aim to produce "a handbook for those whose duty it is to design, erect, maintain, or run an electrodeposition plant" and, without doubt, this book should be on the shelves of all whose work is covered by the authors' description. J. Fox-Williams

BIOLOGICAL CLOCKS

The Physiology of Diurnal Rhythms

By Janet E. Harker. (Cambridge Monographs in Experimental Biology, No. 13.) Pp. vii + 114. (Cambridge: At the University Press, 1964.) 20*s.* net; 3.95 dollars.

PLANTS and animals show diurnal (or circadian) rhythms in their physiological processes and behaviour. In a natural environment, the timing of the phases of any rhythm is, within a pattern imposed by the genetical constitution of the organism (to use Dr. Harker's own words), primarily affected by light conditions, including both intensity and photofraction. But superimposed on the effects of light, variations may be induced by fluctuating temperature and humidity, amount of food present, age and sex of the organism, and the number of other animals of the same species present. However, once the phases of a circadian rhythm have been set, the rhythm will persist under constant conditions for many months or even throughout the life-time of an animal.

The phenomenon can be explained on alternative hypotheses. Either there is an endogenous mechanism, or there are external time signals which are perceptible to the organism, but not to the research worker. In a search for time-cues which would permit the latter hypothesis, F. A. Brown and his colleagues have invoked and investigated the roles of lunar and solar cycles and of changes in terrestrial magnetism and barometric pressure. According to Brown, for example, the diurnal pattern of oxygen consumption of organisms in a pressure-controlled chamber can be affected by the barometric pressure one to seven days ahead.

Dr. Harker's stated view is that neither theory can at present be proved. No evidence has been recorded to disprove the effects observed by Brown, even though his contention is not accepted by the majority of workers. Moreover, the adaptive significance of a short endogenous rhythm is not obvious; an immediate reaction to the prevailing environment would have many advantages. Nevertheless, the tenor of Dr. Harker's book supports the view that the ultimate controlling system of circadian rhythms is to be found within the organism, even though phasing factors are supplied by the environment. There seems to be little doubt, she says, that some clock-like cellular mechanism exists which is responsible for the observed physiological and biological rhythms. On another level she cites her own beautiful demonstration that a cockroach made arrhythmic in locomotor activity by keeping it for a long period in continuous light develops a diurnal rhythm when joined parabiotically with a rhythmically active cockroach which has been kept in alternating 12-hour periods of light and darkness. The source of the activity rhythm has been traced to a secretion of a group of neurosecretory cells lying on either side of the sub-œsophageal ganglion.

This attempt to summarize the major argument of Dr. Harker's monograph does not do full justice to its comprehensiveness or its logical presentation. The field of descriptive and experimental work on diurnal rhythms is explored and documented; their significance and the possible nature of biological clocks is fully discussed. The book should initiate a sphere of readers into an important branch of biology which has only developed within the past two or three decades. F. J. Ebling

RESEARCH ON WATER POLLUTION

Advances in Water Pollution Research

(Proceedings of the International Conference held in London, September 1962.) Edited by B. A. Southgate, Prof. W. W. Eckenfelder and Prof. E. A. Pearson. Vol. 1: Pp. xliii + 437. Vol. 2: Pp. vi + 578. Vol. 3: Pp. vi + 437. (London and New York: Pergamon Press, 1964.) 300*s.* net per set.

THE first International Conference on Water Pollution was convened with a view to disseminating information on recent advances in knowledge resulting from research in relevant fields, and was a logical outcome of the steady growth in the effort being devoted in an increasing number of countries to pollution prevention and control. The Conference was organized into three sections, the proceedings of each of which—comprising the sixteen papers presented and the accompanying discussion—form the main subject-matter of a separate volume. The first of these is concerned with the problem of pollution in streams and rivers, the second with the development of methods for treatment of effluents and of the solids derived from them, and the third with the disposal of effluents in estuaries and in the sea.

It is abundantly clear from these proceedings that water pollution research presents those concerned in it with a fascinating variety of problems covering a wide range of complex chemical, physical and biological phenomena. In the first volume the subjects covered include such diverse topics as the correlation of mass-transfer coefficients for the absorption of atmospheric oxygen in rivers with their hydraulic characteristics, the effects of liquid shear on invertebrates, the response of fish to temperature gradients, the occurrence of patho-

genic bacteria in rivers and the identification of trace organic chemicals. The second volume includes accounts of work on oxygen transfer, on the kinetics of aerobic and anaerobic treatment processes, on de-watering of sludges, on sedimentation and on methods of removal of nitrogen, phosphorus and biologically non-degradable organic compounds. The third volume deals largely with the development of rational procedures for the siting of outfalls for the dispersal of sewage, industrial, and radioactive effluents in the sea and with the prediction of the effects of polluting discharges and of natural phenomena on the distribution of dissolved oxygen and nitrogenous compounds in estuaries; the problem of pollution of the sea by oil is also examined.

In the case of each paper presented, at least one formal discussion contribution was prepared by a selected participant, and most of these rank as short papers in their own right; in addition, a good deal of pertinent discussion from the floor has been reported accurately in substance. In general these discussions form a most useful part of the *Proceedings* and in some cases even outweigh in value the paper under discussion or, by putting its contents into proper perspective, greatly enhance its value.

On the whole, these *Proceedings* are a chronicle of steady progress rather than revolutionary advance, interspersed, however, with the occasional exceptionally good paper such as one on the theory of the kinetics of gas absorption and one on the prediction of effects of pollution on the condition of water in an estuary.

There is no doubt that anyone concerned with the technical aspects of pollution problems would find a great deal that would be of interest in these volumes, and the research worker in the field should certainly have access to them.

A. L. Downing

PHYSIOLOGY OF MOLLUSCS

Physiology of Mollusca

Vol. 1. Edited by Karl M. Wilbur and C. M. Yonge. Pp. xiii+473. (New York and London: Academic Press, 1964.) 114*s*. 6*d*.

PHYSIOLOGISTS and zoologists alike look forward with interest to new volumes in the Academic Press series on physiology. The present volume, the first of two on the *Physiology of Mollusca*, is a welcome addition to the line and will be a useful work of reference for a long time. However, this volume illustrates the weakness of using a phylum or class as a frame of reference for a physiologist. Too often the reader feels that the most meaningful comparisons would be with members of other phyla rather than with other molluscs. Earlier volumes in the series, such as those on the fishes and the insects, had a unity, possibly derived in part from the adaptation of their particular group to one predominant environment. This unity is lacking in the present volume, and only occasionally, for example in the chapters on shell and muscle, are there signs of a peculiarly molluscan physiology emerging. This feeling of diffuseness is aggravated by our limited knowledge of molluscan physiology. Two volumes were devoted to each of the groups previously covered in this series and molluscs are also to receive two volumes. To fill them the subject matter has been widened to include ecology, embryology, comparative anatomy and systematics. Each of these chapters is admirable in its way and the authors have placed the emphasis on the physiological aspects of their topics, but when the two volumes together are so expensive as to be outside the pockets of many workers on the subject, a single more restricted volume might have been more valuable. The distribution of topics between the two volumes is rather arbitrary and makes it almost essential to buy them together. Muscles are dealt with in Volume 1, nervous physiology in Volume 2, ionic regulation in Volume 1, excretion in Volume 2, chromatophores in Volume 1, and pigment in Volume 2.

The book begins with a survey of molluscan structure and systematics. This is a fine essay in selection and compression by J. E. Morton and C. M. Yonge which readers not too familiar with the molluscs will find useful, yet few people interested in the molluscs will be without Morton's excellent little book which covers the same ground in a more expansive form. In the following chapters G. Newell surveys the ecology of intertidal molluscs and W. R. Hunter the ecology of nonmarine forms. Reproduction is a topic in which a peculiarly molluscan physiology may emerge, but V. Fretter and A. Graham's up-to-date survey shows that the subject is still largely in a descriptive phase. The wide variety of forms of hermaphroditism which occurs in the molluscs may surprise some mammalian physiologists. Embryonic development is described by C. P. Raven and this is followed by a largely technical account of the large-scale culture of marine bivalve larvæ by P. R. Walne.

The elegant geometry and convenient rigidity of the shell make the molluscs attractive material for the quantitative study of growth and ageing. Measurement and interpretation of growth are described by K. M. Wilbur and G. Owen, who also discuss the influence of metabolism, temperature and nutrition on growth rates. This is followed by an account of the specifically molluscan problem of shell formation by Wilbur, including the metabolism of shell formation, the organic matrix and the various forms in which calcium carbonate can crystallize. There is interesting evidence of a relationship between the nature of the organic matrix and the crystal type. This is a topic which may well throw light on the whole subject of skeleton formation, but, as Wilbur points out, it is curious that detailed information on the composition of the extrapallial fluid from which the shell is deposited is often lacking.

Osmotic and ionic regulation in the molluscs is dealt with by J. D. Robertson. One of the determining features of molluscan physiology here is the high permeability of the body wall which affects both the marine and freshwater forms. Robertson also discusses ionic and osmotic regulation in the tissues, a subject neglected until recently.

The wide variety of muscle conveniently available in the molluscs has made the group of unique importance to muscle physiologists. G. Hoyle provides an excellent critical survey of a complicated and disputed field and his article will be of value to all physiologists. Fine structure and biochemical studies are beginning to elucidate the structure of even the slowest molluscan muscles but, in contrast, knowledge of the details of the nervous control of the muscles is still sadly deficient. Two chapters by Morton describe a variety of minor topics such as bioluminescence and pigment cells, and locomotion. The mobility of the molluscan body has led to a remarkable range of methods of locomotion including both jet propulsion and a less-well-known screw locomotion in some pelagic gastropods. Pelagic molluscs have also developed two methods for obtaining neutral buoyancy. One depends on their powers of ionic regulation to produce a solution less dense but isosmotic with sea water, the other on the use of osmotic pressure to abstract water from a rigid shell to produce what is essentially a vacuum. These two phenomena are described by E. J. Denton, who was largely responsible for their discovery.

The volume is well produced and indexed and few errors were observed, although G. S. Carter did not state that hæmocyanin increased the oxygen carrying capacity of the blood by 3 per cent (p. 69) but to 3 volumes per cent. The description of the innervation of the anterior byssus retractor muscle (p. 331) would be clearer if the visceral connective, mentioned in the text, were labelled in the diagram and if the cerebropedal connective, also referred to in the text, were labelled as such and not as the cerebral connective.

W. T. W. Potts

ORIGIN OF THE CANYON DIABLO NO. 2 AND NO. 3 METEORITES

By Dr. DIETER HEYMANN
Enrico Fermi Institute for Nuclear Studies, University of Chicago

OF the thousands of irons which have been recovered from the Arizona Meteor Crater the vast majority are coarse octahedrites. However, careful searches by Nininger have turned up a small number of anomalous individuals designated as Canyon Diablo No. 2 and No. 3 (refs. 1 and 2). Both are medium octahedrites; they have a higher nickel content than Canyon Diablo No. 1 and often show a distorted and granulated structure.

There is no doubt that Canyon Diablo 2 and 3 are truly distinct from Canyon Diablo 1. The kamacite bands of Canyon Diablo 1 vary in width, ranging up to as much as 4–5 mm; whereas the kamacite bands in Canyon Diablo 2 average 1·4 mm in width. The nickel content of Canyon Diablo 1 is 7·11 per cent as against 8·09 per cent in Canyon Diablo 2, and the palladium concentrations are 3·98 p.p.m. and 5·30 p.p.m. respectively[3]. Nininger explained these chemical and structural differences in two ways. He suggested that Canyon Diablo 2 was a swarm of small iron meteorites, captured by the main mass while the latter was in orbit round the Sun. He also offered the alternative explanation that Canyon Diablo 2 and 3 were distinct falls but thought this possibility less likely. The capture hypothesis was not widely accepted because of the obvious unlikelihood of such an event. Goldberg *et al.* pointed out that the terrain round Meteor Crater is possibly the most extensively searched area for meteoritic material. This area is about 65 km² or $1{\cdot}3 \times 10^{-7}$ times the Earth's surface. A fall frequency on the Earth of about 35 iron meteorites a year[4] means that this area of 65 km² was hit on the average once in 230,000 years and twice in 460,000 years. (I have assumed that 6·7 per cent of all fallen meteorites are irons.) From other investigations[5] it appears possible that iron meteorites can survive on the surface of the earth for a million years or longer. The hypothesis of a distinct fall is, therefore, not altogether unlikely.

The evidence for distinct origins of Canyon Diablo 1, 2 and 3 is not very convincing, however, despite the chemical and structural differences. Canyon Diablo is one of the largest iron meteorites known. Pieces of the parent mass may have been spalled off during passage through the atmosphere and fallen near Meteor Crater. There is considerable disagreement as to the size of the projectile which produced the crater. Öpik[6] estimates a mass of 2·6 million tons, Shoemaker[7] gives 63,000 tons and Bjork[8] places the mass between 30,000 and 194,000 tons, depending on impact velocity. The lowest estimate corresponds to a diameter of 19·5 m. Thus it appears almost certain that the diameter of the projectile was at least 10 m. The three Canyon Diablo varieties might have been broken out from diametrically opposed locations, and, since nothing is really known about chemical and structural variations of iron meteorites on such a scale, a third hypothesis deserves consideration in my opinion, namely the one originally rejected: that Canyon Diablo 1, 2 and 3 did all come from the same object.

An essential difference among these hypotheses is that the first two assume the anomalous Canyon Diablo to have existed in space as small individual entities, whereas the third one assumes them to have resided in a single, large parent mass. These two possibilities can be distinguished experimentally inasmuch as they should result in markedly different concentrations of cosmogenic rare gases. Signer and Nier[9] have calculated the distribution of the cosmogenic nuclides helium-3, neon-21 and argon-38 in spherical meteoroids of different diameters, and their results are shown in Fig. 1.

This plot is based on measurements on the Grant meteorite which has a cosmic-ray exposure age of 640 ± 100 million years[10]. Between the break-up of its parent body, 640 m.y. ago, and its capture by the Earth, the

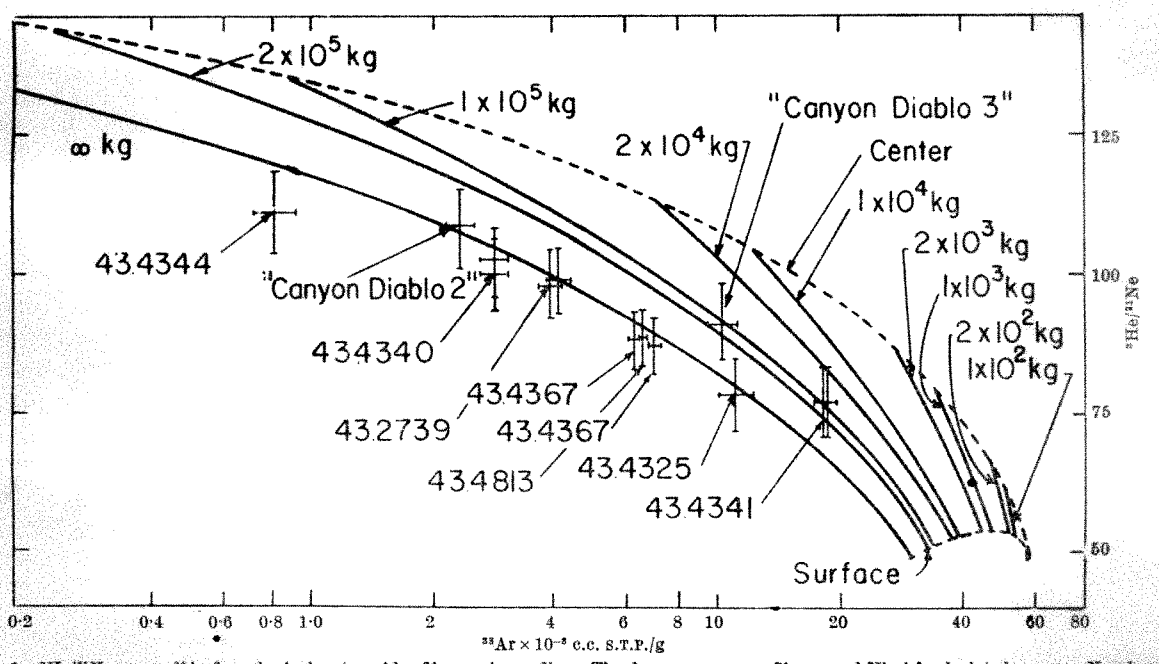

Fig. 1. $^3He/^{21}Ne$ versus ^{38}Ar for spherical meteoroids of increasing radius. The drawn curves are Signer and Nier's[9] calculated curves. Numbered points are measurements on Canyon Diablo 1

meteorite accumulated cosmogenic nuclides which were produced by high-energy nuclear reactions between cosmic-ray particles and the atomic nuclei of the meteorite. The concentration of any stable nuclide in a sample depends, of course, on the duration of the irradiation and the location of the sample below the surface of the meteorite before the latter entered the Earth's atmosphere. While this location cannot be derived from the observed location in the recovered object, due to considerable ablation losses in the atmosphere, the $^3He/^{21}Ne$ ratio in the Signer–Nier plot is a sensitive indicator of the depth of a sample; the higher this ratio the greater was the depth.

A measurement of helium-3, neon-21 and argon-38 in any meteorite which has the same exposure age as Grant should give a point on this plot corresponding to the pre-atmospheric mass of the meteorite and the location of the sample inside the object. A difference in cosmic-ray exposure age alone would merely result in a proportionate difference in argon-38 concentration and the point would be located on a curve which can be obtained from Fig. 1 by a simple horizontal displacement of the Signer–Nier curves. Unfortunately, the pre-atmospheric mass of a meteorite and hence the location of a sample in the object are usually unknown, but in special cases like Canyon Diablo it is clear that points must lie close to a Signer–Nier curve of infinite mass. Note that each sphere of given mass (masses range from 100 kg to infinity, that is, $\geqslant 2 \times 10^5$ kg) has a maximum $^3He/^{21}Ne$ ratio which occurs at the centre of the sphere.

In Fig. 1, I have also plotted my experimental results on seven different Canyon Diablo 1 specimens. A detailed discussion of the experimental procedure will appear elsewhere[11]. Evidently the results agree quite well with a Signer–Nier curve for a meteoroid of very large mass. The only specimen which is definitely outside the correlation is 43.4341. From the mean displacement of the Canyon Diablo 1 points to the left of the Signer–Nier curve for infinite mass, I conclude that the normal Canyon Diablo has a lower exposure age than Grant, namely 540 ± 100 million years, which is not in disagreement with a recently measured exposure age of 665 ± 65 million years by the ^{40}K–^{41}K method[12]. Shown also in Fig. 1 are results obtained on samples of Canyon Diablo 2 and 3. The results of individual measurements are given in Table 1.

Table 1. Cosmogenic Rare Gases in Canyon Diablo No. 2 and No. 3 Meteorites

Weight of sample (g)	Concentration, 10^{-8}			c.c. S.T.P./g		Ratios		
	^3He	^4He	^{21}Ne	^{36}Ar	^{38}Ar	$^3He/^{21}Ne$	$^3He/^4He$	$^3He/^{36}Ar$
1. Canyon Diablo No. 2, specimen No. 371.2								
0·3921	37·9	157	0·35	1·5	2·3	108	0·241	16·5
0·2834	34·7	151	0·33	1·4	2·3	105	0·219	15·1
0·2832	37·7	151	0·34	1·1	Lost	110	0·249	
Average	36·8	151	0·34	1·3	2·3	108	0·240	16·0
2. Canyon Diablo No. 3, specimen No. 586.1								
0·9183	180	664	1·96	6·57	10·3	92	0·271	17·5
0·6559	170	664	1·87	6·48	10·2	91	0·256	16·7
Average	175	664	1·92	6·53	10·3	92	0·264	17·0

The recovered mass of Canyon Diablo 2 is a few kilograms. I take this to mean that the meteorite was small, less than 500 kg if it was a 'satellite' or a distinct fall, unless most of its mass disappeared through weathering. The helium-3 content of Canyon Diablo 2, specimen 371.2, is about eight times lower than the highest helium-3 concentration measured in a Canyon Diablo iron: 301×10^{-8} c.c. S.T.P./g (43.4341). This result, taken alone, does not necessarily place Canyon Diablo 2 inside the main mass, since it is conceivable that this meteorite is a distinct fall and has a cosmic-ray exposure age of only 64 ± 12 million years. But this is unlikely. For one thing, all exposure ages of medium octahedrites measured so far are uniformly higher than 300 million years[13]. Moreover, the $^3He/^{21}Ne$ ratio of this specimen, 108 ± 7, is much higher than what one would expect to find inside a meteorite of a few hundred kilograms. The highest ratio observed in Grant (recovered mass 480 kg) is 82 ± 4 (ref. 10). Thus the $^3He/^{21}Ne$ ratio makes it extremely likely that specimen 371.2 was once inside a large mass: 10^4 kg or larger. Finally, the Canyon Diablo 2 point lies remarkably close to the curve defined by Canyon Diablo 1. In view of these facts, I conclude that the simplest explanation for the observed cosmogenic rare gas abundances is that Canyon Diablo 2 was once part of Canyon Diablo 1; was located approximately 50 cm below its pre-atmospheric surface; and was exposed to cosmic-ray irradiation for the same length of time as the main mass.

In the case of Canyon Diablo 3, the conclusion cannot be as definite. This iron has the third highest cosmogenic rare gas abundance of 47 Canyon Diablo individuals which I have examined. Moreover, its $^3He/^{21}Ne$ ratio does not fit well with the curve defined by Canyon Diablo 1, as can be seen from Fig. 1. The $^3He/^{21}Ne$ ratio of 92 is higher than what one would expect for this specimen: 82. Yet one detail in Fig. 1 leads me to the tentative conclusion that Canyon Diablo 3 also belonged to the main mass. Specimen 43.4341 seems to be displaced to the right of the Canyon Diablo 1 curve, yet it appears to belong to the normal variety. This could be explained in two ways. Either Canyon Diablo was broken out from its parent body 1 æon ago and suffered a second collision 540 million years ago * or specimen 43.4341 was located in a protrusion on the surface of the main mass. It can be easily shown that in the latter case the production ratios of cosmogenic nuclides are determined by the size of the protrusion, not so much by the radius of the main mass. In the present case the protrusion apparently had a mass of about 10^5 kg and a radius of 1·4 m.

Is it a coincidence that the cosmogenic rare gases in Canyon Diablo 3, specimen 586.1, can be explained with the same set of assumptions? It, too, could have come from a location in the main mass which was exposed for one æon and survived the collision 540 million years ago. Or it could likewise have come from a protrusion of about 10^5 kg which was exposed during 540 million years.

If all the varieties of the Canyon Diablo meteorite indeed come from a single parent mass, then it follows that substantial structural and compositional variations existed in the nickel-iron phase of the parent body of Canyon Diablo over distances of 10–100 m. This adds a new element of flexibility to all theories on the origin of iron meteorites.

I thank Prof. E. Anders for suggesting this experiment and for his advice. I also thank Prof. Carleton Moore, who made samples of Canyon Diablo Nos. 2 and 3 available. This work was supported in part by the U.S. Atomic Energy Commission contract *AT*(11–1) 382 and the National Aeronautics and Space Administration grant *NsG*–366 research.

* There is good evidence that iron meteorites suffer repeated collisions in space which produce new surfaces. Fragments from under such new surfaces have shorter exposure ages than the main mass (see: Vilcsek, E., and Wänke, H., *Proc. Symp. Radioactive Dating, Athens*, 1962, 381; IAEA, Vienna, 1963). I myself have measured four Canyon Diablo 1 specimens not shown in Fig. 1, which indicate another, still shorter exposure age for this meteorite of 150–200 million years.

COSMIC-RAY-INDUCED PARTICLE TRACKS IN A METEORITE

By M. MAURETTE
Laboratoire de Chimie Physique, Faculté des Sciences, Orsay
P. PELLAS
Laboratoire de Mineralogie du Museum, Paris
AND
Dr. R. M. WALKER
General Electric Research Laboratory, Schenectady, New York

THE existence of ancient or 'fossil' charged particle tracks in natural minerals was first established by Price and Walker in the examination of samples of terrestrial mica samples[1,2]. It was shown by these authors that particle tracks in terrestrial mica samples must be due predominantly to the spontaneous fission of uranium impurities. A new dating method based on the known spontaneous fission rate of uranium-238 was proposed[2] and has now been applied to a number of terrestrial systems[3–8].

Based both on calculation and direct experiment with high-energy proton beams[9,10], it has been realized for some time that samples such as meteorites which have been exposed to the primary cosmic radiation for long times should contain cosmic-ray-induced tracks which can be used to obtain information both about the cosmic radiation and the meteorite history. Indeed, the idea of finding fossil cosmic-ray-induced tracks was the original motivation for the search by Price and Walker for fossil-particle tracks in natural minerals. We wish to report here what we believe are the first observations of such cosmic-ray-induced tracks in samples of meteoritic material.

The observations to be described are preliminary in the sense that we cannot at this time definitely determine which of several possible cosmic-ray particles are responsible for the observed tracks. After presenting the experimental data we discuss the problem of theoretical interpretation and conclude that the majority of the observed tracks come either from spallation recoils or heavy primary ions. Additional experiments which should serve to solve completely the problem of track origin are indicated briefly.

Particle tracks in minerals can be revealed by a proper etching treatment which selectively attacks the trail of radiation-damaged material produced by the passage of a heavy charged particle; this initial damaged region is enlarged to a size where a hollow tube or track can be seen in an optical microscope. The etching treatment in olivine for good track revelation is somewhat more complicated than that which has been reported for mica[11] and other minerals[6]. It consists of a sequence of alternate etches of 4 min in a concentrated solution of hot potassium hydroxide (29 g KOH; 9 g H_2O at 160° C) and 30 sec in a 5 per cent hydrofluoric acid solution at room temperature. Different samples etch at somewhat different rates and the number of sequences for optimum revelation varies somewhat; typically, two sequences are required. Both the acid and base treatment are necessary since neither one alone will give narrow tracks. This treatment works well on polished 100 faces of olivine but not on other principal planes where somewhat different procedures must be used to obtain cylindrical tracks. Irrespective of the crystal orientation, however, a potassium hydroxide etching treatment will generally give some sort of etch pit if a track is present. Thus a base etching treatment can be used as a preliminary way of distinguishing interesting samples which contain a high density of tracks. The rather complicated etching behaviour of olivine is interesting in itself and will be reported in more detail elsewhere. Fig. 1 shows an example of etched particle tracks on a polished 100 surface of terrestrial olivine which has been irradiated with fission fragments from a californium spontaneous fission source.

Olivine is a common constituent of meteorites and in the pallasites it is possible to obtain large single crystals suitable for orientation and subsequent polishing. Experiments by Fleischer *et al.*[12] have shown that particle tracks are produced in olivine at the low temperatures expected in space and that, once formed, they should be retained for $T >> 10^{10}$ years even at high pressures. In a preliminary search for cosmic-ray-induced events in meteorites we obtained olivine crystals from the following pallasites: Pavlodar (Siberia), Brenham (Kansas), Molong (New South Wales), Brahin (U.S.S.R.), Krasnojarsk (U.S.S.R.), Admire (Kansas), Springwater (Canada) and Magnesia (Smyrna, Turkey). Parts of these samples were broken into small fragments which were etched for 15 min in the hot solution of potassium hydroxide and then examined for etch pits. In all the samples except those from

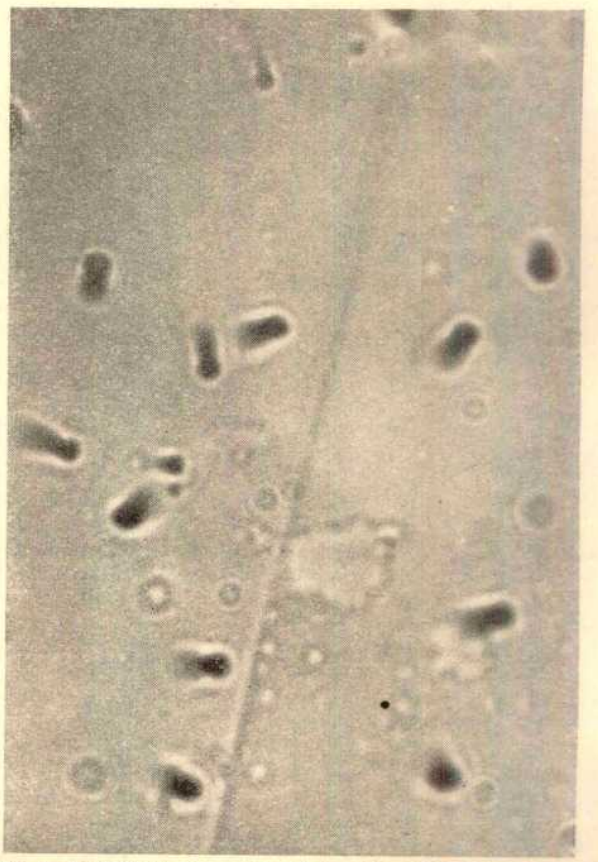

Fig. 1. Etched fission fragment tracks in olivine. This picture shows a 100 surface of a terrestrial olivine crystal which has been bombarded with fission fragments from a californium-252 spontaneous fission source and then etched as described in the text

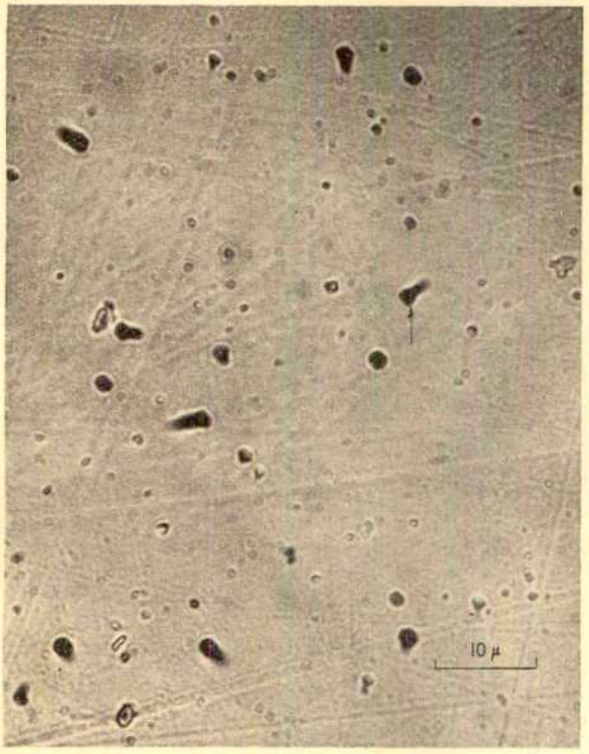

Fig. 2. Cosmic-ray-induced tracks in meteoritic olivine. This shows a polished 100 surface of an olivine crystal from the pallasite Pavlodar which has been etched as described in the text. The black lines similar to that indicated by the arrow are believed to be particle tracks produced by cosmic-ray interactions in the meteorite

Pavlodar[13] only an occasional etch pit was observed. In Pavlodar, however, we found an anomalously large density of etch pits indicating the possible presence of particle tracks. Crystals from this meteorite were then oriented by X-rays and cut and polished to give 100 faces which were afterwards etched as described above. The orienting and polishing of the remaining samples are now being carried out.

Before etching, the olivine crystals from Pavlodar show a very occasional short track-like inclusion; after etching, there is uniform concentration of short, cylindrical etch figures which we believe are due to fossil tracks produced by cosmic-ray interactions in the meteorite. Fig. 2 shows a representative portion of an etched 100 surface with a number of tracks visible. The tracks range in length from the minimum observable ($< 1\mu$) to approximately 10μ. The average length of definitely identifiable tracks is $\sim 3\mu$; but it is clear that there are many small etch pits which are present, probably of particle origin, which would lower this average value if they could be properly measured. The density of tracks which have a definite 'tail' and are readily identifiable is $\sim 5 \times 10^5/\text{cm}^2$. If the small etch figures are included the value is about three times greater. Although the tracks are distributed uniformly in density throughout the crystal, there is a marked angular anisotropy in the 100 plane. If an arbitrary line is drawn in the plane to distinguish 'up' and 'down' it is found that about 3–4 times as many tracks have their tails pointed up as down.

Dislocations can also give rise to cylindrical etch figures and could conceivably be responsible for the etch figures which we are ascribing to particle tracks. For the reasons discussed here we believe this explanation to be very improbable. First, the appearance of the meteoritic etch figures is quite different from the typical appearance of dislocation etch figures in olivine. These latter etch figures are usually very long ($> 100\mu$) and frequently show pronounced curvature. They almost always occur in localized areas and are usually accurately aligned one with the other in these zones. By contrast, the meteoritic etch figures are quite short and have a uniform density. Although they exhibit a general anisotropy they are by no means accurately aligned and all possible directions are represented.

Another strong argument for the particle-track origin is provided by annealing experiments performed on Pavlodar. When a sample was heated at 600° C for 20 min and afterwards re-etched, the density of short etch figures had dropped to zero. Occasional long dislocation etch figures, however, were still observed. Since it is known from the independent work of Fleischer *et al.*[12] that this heat treatment is sufficient to erase charged-particle tracks in olivine, the results lend support to the charged-particle origin of the etch figures in the unheated sample.

Finally, there are several sources of charged particles in the cosmic radiation which can easily account for the observed tracks. Fleischer *et al.*[14] have shown that the rate of loss of energy of a charged particle must exceed a certain critical value $(\text{d}E/\text{d}x)_c$, in order to form an etchable track. Although the value of $(\text{d}E/\text{d}x)_c$ has not yet been accurately determined for olivine, comparison of the length of fission fragment tracks in olivine with those in mica (where a value of $1{\cdot}5 \times 10^{10}$ eV/(g/cm²) has been previously measured) indicates that $(\text{d}E/\text{d}x)_c$ in olivine lies between the limits 2 and 3×10^{10} eV/(g/cm²). (All values of energy loss are referred to aluminium as a standard.) Theoretical calculation shows that there are at least six possible sources of particles whose rates of loss of energy could exceed the critical value necessary to produce tracks in meteoritic olivine: (1) spontaneous fission of uranium impurities; (2) cosmic-ray-induced fission of heavy elements; (3) cosmic-ray-induced spallation recoils of medium and heavy elements; (4) meson jets from very-high-energy cosmic-ray interactions[15]; (5) heavy ions in the primary cosmic-ray flux[16]; (6) magnetic monopoles[17] —particles first postulated by Dirac and not yet observed in Nature.

Tracks from these different sources would be expected to vary considerably in their appearance, their density, and their distribution within the meteorite. For example, cosmic-ray-induced fissions would give rise to '*v*-tracks' because the fission of the excited nucleus takes place in flight. Spallation recoils, on the other hand, would give very short, straight tracks. Slowed-down heavy ions would give different track-lengths depending on their masses, but would be quickly absorbed in the meteorite and thus would show a strong spatial variation of their density: very-high-energy protons producing meson jets would, on the contrary, show very little spatial variation. Spontaneous fission tracks should be distributed isotropically regardless of the position of the sample in the original meteorite; but all the other track sources could give rise to strong anisotropies if the test sample had originated from one edge of the meteorite.

The average length of the observed tracks and their angular distribution are clearly incompatible with a spontaneous fission origin and this source can definitely be ruled out as a contributor of the bulk of the observed tracks. The absence of any '*v*-tracks' similarly precludes the induced fission possibility. Further, the published figures on shower multiplicities and angular distributions for meson jets[15] indicate that the density of meteoritic tracks is much too high to be accounted for by this mechanism.

Calculated values of rates of energy loss for Dirac monopoles[18,19] show that doubly charged monopoles would probably register tracks though they would be close to the threshold for detection. The flux of such particles would have to be $\gtrsim 3 \times 10^{-11}/\text{cm}^2$ sec to account for the observed density. This value is slightly less than the upper limit measured by Malkus[20] in a terrestrial experiment, and on the basis of existing information we cannot completely rule out the monopole source though we regard this as an extremely unlikely explanation.

It can be shown that heavy cosmic-ray primaries which are known to be present in the cosmic radiation are capable of producing the observed density of tracks. Taking only iron nuclei into account and calculating the number of particles whose rate of loss of energy exceeds the critical value as a function of depth from the outside of the meteorite, we find that a typical space exposure of $\sim 10^8$ years[21] will give an unobservably high value of $> 10^7/cm^2$ near the surface. The calculated density drops off rapidly with depth because of nuclear absorption and reaches an unobservably low value at ~ 20 cm below the surface. Typical ablation distances which have inferred from other experiments range from 2 to 15 cm (ref. 22) and, in the absence of knowledge concerning the location of our sample with regard to the original surface of the meteorite, the heavy ion source remains a strong possibility for explaining the observed results. In this connexion it should be noted that Pavlodar was the smallest meteorite of the set which was examined. The total mass of Pavlodar was only 4·5 kg, while the others, with the exception of Magnesia, all had a total mass exceeding 50 kg. The observed track-lengths are somewhat shorter than we would expect for iron nuclei but could be accommodated within the present uncertainty in $(dE/dx)_c$ for olivine.

In our opinion, the most likely explanation for the bulk of the observed tracks is the production of spallation recoils by cosmic-ray interactions with medium atomic weight elements present in the olivine. The density, ρ, of visible recoils in a sample which has been exposed to the cosmic radiation for a period of time, T, is given by: $\rho = n\sigma d\varepsilon N_0 T$, where n is the flux of cosmic rays, σ is the average interaction cross-section, d is the average track-length, N_0 is the number of atoms/cm³, and ε is probability per interaction for the production of a visible track. Taking $n = 3$ p/cm² sec, $\sigma = 1$ barn, and $T = 10^8$ years, we find that $\rho = 1{\cdot}4 \times 10^{11}\varepsilon$. Thus the observed track density of $\sim 10^6$/cm² can be explained if only $\sim 10^{-5}$ of the total number of interactions give rise to visible tracks. Put another way, medium atomic weight impurities, which will almost always give heavy enough recoils to produce tracks, need only be present at a concentration of 10^{-5} to explain the observed results. Previous proton acceleration experiments in mica[9,10] have shown that visible spallation recoils are produced with a probability of $\sim 0{\cdot}05$. One sample of terrestrial olivine[10] gave $\varepsilon < 5 \times 10^{-5}$, but this is not particularly meaningful since it is clear that each sample must be calibrated independently with a proton beam because of the possible role of medium weight impurities.

It is expected that the following work should serve to settle completely the question of the track origin in Pavlodar: (*a*) determination of the response of individual crystals of Pavlodar to irradiation with high-energy protons and also thermal neutrons; (*b*) measurement of $(dE/dx)_c$ for olivine; (*c*) comparison of results obtained with other meteorites—particularly those the cosmic-ray exposure age of which has been measured and where it will be possible to measure the spatial variation of track densities within the meteorite. This work is now in progress.

Whatever the final explanation of the tracks in Pavlodar, it seems likely that fossil track investigations will be a fruitful source of information both about the meteorites and the cosmic radiation.

We thank Prof. J. Orcel, director of the Laboratory for Mineralogy and Crystallography of the Museum of Natural History in Paris, for his generous co-operation in providing the necessary samples. One of us (R. M. W.) held a U.S. National Science Foundation fellowship during the time this work was started, and he would like to thank both the National Science Foundation and the director of the Laboratory for Physical Chemistry at Orsay, Prof. Y. Cauchois, for their help. Finally, we would thank R. L. Fleischer and P. B. Price of the General Electric Research Laboratory for their advice.

CHANGES IN THE EARTH'S MOMENT OF INERTIA

By Prof. S. K. RUNCORN

Department of Physics, University of Newcastle upon Tyne, and Institute of Geophysics and Planetary Physics, University of California, La Jolla

VARIOUS theories of the Earth's evolution have suggested that its moment of inertia has gradually changed. Urey[1] inferred a cold origin of the Earth from chemical arguments. He supposed that initially the Earth was a uniform mixture of iron and silicate bodies, and that the iron has only slowly collected to form the core. I developed this idea as part of a theory of continental drift[2] and was able to obtain[3] an empirical law of the growth of the Earth's core, from which can be calculated the change with time of the Earth's moment of inertia[4,5]. Fig. 1 shows my result and the change in the length of the day which would have occurred in the absence of any external torque on the Earth. Lyttleton[6], in a theory of mountain building, has revived Ramsey's theory of the core–mantle boundary as a phase change. However, he argues that, in an initially cold Earth, there would have been no core but that as the temperature rose an increasing volume of silicate would go over into a dense phase. The resulting contraction of the Earth is held to account for mountains. Lyttleton finds that the Earth's moment of inertia has decreased by 30 per cent during the past 3×10^9 years. Thus both these theories predict that the Earth's moment of inertia was greater in the past than at present.

Other theories predict that the moment of inertia has increased with time. Egyed[7] has advocated a theory of an expanding Earth. He considers that an annual increase of the radius of between 0·5 mm and 1·0 mm is likely. Creer[8], on the basis of palæomagnetic reconstructions of the continents, suggests a similar rate of expansion.

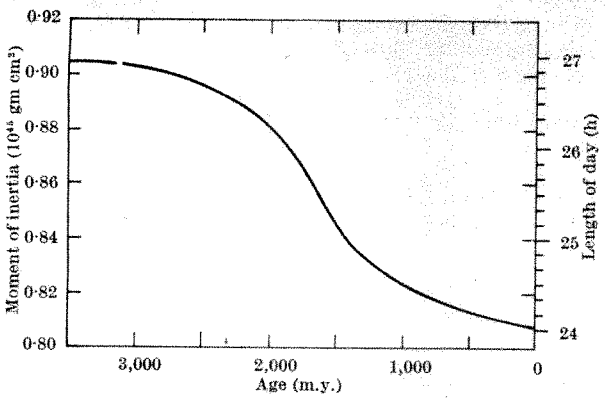

Fig. 1. Moment of inertia and length of day against time for growing-core hypothesis

Carey[9], from his interpretation of oroclines, has suggested a doubling of the Earth's surface area (and thus of its moment of inertia) since the Palæozoic. Heezen[10] has also postulated an expansion of the Earth of comparable magnitude to explain tensional features on the ocean floor.

My purpose is to point out that it is now likely that all these theories can be put to experimental test. A method of determining the rate of the Earth's rotation in the geological past has been suggested by Wells[11]. He shows that daily growth rings on the epitheca of corals can probably be recognized, and hence finds that the number of (presumably solar) days in the year in Devonian times was about 400. He states that counts on 12 corals lie between 385 and 410 and we may estimate the standard deviation as about ± 7 days. Wells[11] and Munk and Davies[5] regarded the result as reasonable in view of the known deceleration of the Earth due to lunar tidal friction.

However, Scrutton[12] has recently shown that it is also possible on certain Middle Devonian corals to recognize what appear to be monthly bands. He finds 30·59 days in the Devonian month. Counts on 10 corals give the standard deviation as ±0·13 day. If this is correct, the tides must be influencing the growth perhaps due to the change in sunlight with the height of the water. Thus the synodical month is determined by this method. To convert this to the number of days (s) in the sidereal month we divide by $1 + 30{\cdot}59/(w + 1)$, giving 28·4 days, where w is the number of sidereal days in the year (399). This is very important geophysically because it opens up the possibility of separating changes in the Earth's rotation due to changes in its moment of inertia from those due to lunar tidal friction, because the latter changes the length of the month as well as the day. Let t, Y and T be the lengths of the sidereal day, the year and sidereal month respectively for any geological period, and t_0, Y_0, and T_0 the present values. Then by Kepler's third law:

$$r^3/T^2 = G(M + m)/(2\pi)^2$$

where M and m are the masses of the Earth and Moon, and r is the mean Earth–Moon distance and G the gravitational constant. If L is the orbital angular momentum of the Moon at any geological period and L_0 the present value, then by Kepler's second law, neglecting orbit eccentricity:

$$L/2m = \pi r^2/T$$

Thus:

$$[G^2(M + m)^2 m^3].T = 2\pi L^3$$

Similarly, if $M_\odot$ is the mass of the Sun and N and N_0 the Earth's past and present orbital angular momenta:

$$G^2 M_\odot^2 M^3 . Y = 2\pi N^3 \qquad (1)$$

Thus:

$$\frac{m^3}{M_\odot^2 M}\left(1 + \frac{m}{M}\right)^2 \frac{T}{Y} = \frac{L^3}{N^3}$$

at any time in the past.

$$\beta(L_0 - L) = (N_0 - N)$$

where β is the ratio of the solar tidal retarding couple on the Earth to the lunar one. Theory gives the present value[13] as 1/5·1 if the equations of motion are linear and as 1/3·4 if the friction is proportional to the square of velocity. Because $N_0/L_0 \simeq 10^6$, N/N_0 is closely equal to 1:

$$\therefore \frac{T_0}{Y_0} \cdot \frac{w}{s} = \left(\frac{L_0}{L}\right)^3$$

thus:

$$L_0/L = 1{\cdot}016 \pm 0{\cdot}003$$

and is independent of G.

Lunar tidal friction results in angular momentum being transferred from the Earth's rotation about its axis to the Moon's orbit. Hence from the above value of L_0/L we may find that the average lunar tidal decelerating torque on the Earth over 370 m.y. is $3{\cdot}9 \times 10^{23}$ dyne cm (since the Devonian). This agrees with that given from measurements[14] of the longitudes of the Sun and Moon over the past 2–3 centuries ($3{\cdot}9 \times 10^{23}$ dyne cm). It has long been known that the value obtained from ancient eclipse data is twice as great[14,15]. This strongly suggests that the latter reductions are unreliable, as Munk and MacDonald[16] thought.

Now:

$$(1 + \beta)(L_0 - L) = 2\pi I/t - 2\pi I_0/t_0$$

where I and I_0 are the Earth's past and present moments of inertia respectively. Using the ratio (4·83) of the Moon's orbital angular momentum to the Earth's spin angular momentum:

$$1 - L/L_0 = [-1 + (I/I_0)(w/365{\cdot}25)(Y_0/Y)]/4{\cdot}83(1 + \beta) \qquad (2)$$

If:

$$Y = Y_0$$

then:

$$I = I_0(0{\cdot}999 \pm 0{\cdot}003) \text{ for mean } \beta = 1/3{\cdot}7$$

and:

$$I = I_0(0{\cdot}994 \pm 0{\cdot}003) \text{ for mean } \beta = 1/5{\cdot}5 \qquad (3)$$

The values of the errors may not be very realistic in view of the uncertainties of this new field and the restricted nature of the sampling of corals so far made.

These results dispose convincingly of Carey's and Heezen's extreme hypotheses. This is in agreement with the palæomagnetic evidence, which has been used by Ward[17] to determine the radius of the Earth in the Permian by relating within one continent the angles of magnetic inclination and the distances between the sites at which they were determined.

However, Dirac's[18] suggestion that G varies inversely as the time since the origin of the universe must be taken into account as some proponents[19] of the expansion theory have taken it to be the cause.

From equation (1):

$$Y/Y_0 = G_0^2/G^2$$

Then from equation (2):

$$I > I_0(0{\cdot}85 \pm 0{\cdot}003) \text{ for } \beta = 1/3{\cdot}7$$
$$I > I_0(0{\cdot}84 \pm 0{\cdot}003) \text{ for } \beta = 1/5{\cdot}5$$

for the age of the universe cannot be less than that of the solar system $4{\cdot}5 \times 10^9$ years, $Y/Y_0 > 0{\cdot}84$. However, as Fowler and Hoyle[20] have shown that the galaxy is 1×10^{10}–$1{\cdot}5 \times 10^{10}$ years old, Y/Y_0 lies between 0·93 and 0·98, thus the results of equation (3) become:

$$I_0(0{\cdot}98 \pm 0{\cdot}003) > I > I_0(0{\cdot}93 \pm 0{\cdot}003) \text{ for } \beta = 1/3{\cdot}7$$
$$I_0(0{\cdot}97 \pm 0{\cdot}003) > I > I_0(0{\cdot}92 \pm 0{\cdot}003) \text{ for } \beta = 1/5{\cdot}5$$

The results should be compared with the values in Table 1.

Table 1

Theory	Change in radius	I/I_0
Lyttleton	−0·01 mm/yr	1·030
Urey-Runcorn		1·005
Carey-Heezen		0·5
Egyed	0·5–1 mm/yr	0·89–0·94
Dicke	0·05 mm/yr	0·994
Creer	0·5–1·2 mm/yr	0·87–0·94

The observations need to be greatly extended, but they do not favour the expansion theories of Egyed and Creer unless G varies. There is evidence[21] from radioactivity against the latter. Lyttleton's figure would only be too high if it were assumed that the rate of change of the Earth's moment of inertia was uniform with time, which is not necessary. The discussion would be on much firmer ground, though, if it could be demonstrated, by determining w and s for other geological periods, that I/I_0 varies smoothly with time, and L/L_0 in accord with theory.

A preliminary account of this work was given at a conference on the Earth–Moon system at the Goddard Institute for Space Studies, Columbia University, New York. I thank Mr. C. T. Scrutton and Dr. G. Backus for their advice.

NEW U.S. RESEARCH STATION IN THE ANTARCTIC PENINSULA

By Prof. T. O. JONES
Office of Antarctic Programs, National Science Foundation, Washington, D.C.

THROUGH the combined efforts of the twelve nations signatory to the Antarctic Treaty and with advice from the Scientific Committee on Antarctic Research, scientists from these countries are delving deeply into the mysteries of the Antarctic Continent. These efforts comprise a major investigation of an environment which should enable us to understand better its relation to the rest of the world. The United States programme, to explore the Continent adequately and to take full advantage of the natural laboratory offered, is being constantly evaluated, and suggested projects of research are supported wherever possible. It is therefore reasonable, as research in certain regions passes the point of greatest scientific return, to establish sites in new areas which offer more fertile research possibilities. In this way the facilities of "Laboratory Antarctica" and the efforts of scientists can be used most effectively.

With the onset of the International Geophysical Year and the development of plans for that remarkable co-ordinated international research programme, the United States opened up a total of seven stations: Byrd, Ellsworth, Hallett, Little America, McMurdo, Pole and Wilkes. At the end of the International Geophysical Year, Little America was closed, the custody of Ellsworth Station was transferred to Argentina, and the custody of Wilkes Station was turned over to Australia. For some years a few American scientists continued to work at these stations in close co-operation with the scientists of these two countries. Ellsworth Station has now been closed, and its custody returned again to the United States, and Wilkes Station is now entirely manned by Australians.

For four years the American programme was carried on at the four remaining stations. In 1963, the United States installed a new station called Eights Station (after James Eights, the first American scientist to work in Antarctica) at the base of the Antarctic Peninsula at 78° W. and 78° 18′ S. for the purpose of investigating conjugate point and other upper atmospheric phenomena, and meteorology.

It became apparent some years ago that the vast ocean areas surrounding Antarctica and extending for some 1,000–1,500 miles north offered great potentials in modern research. For this reason, the American programme added to its efforts a sea-going research station, the U.S.N.S. *Eltanin*, which began her programme of research in and around the Scotia Arch, the Drake Passage, and the South Pacific.

University biologists in the United States who have been involved in programmes on the Continent and on the *Eltanin* have repeatedly expressed their interest in obtaining facilities for a sophisticated biological research programme in the peninsula area to complement and supplement the work being done on the *Eltanin*. For this reason, the establishment of a new American scientific station in the peninsula area has been under consideration for some time. The U.S. National Science Foundation, which bears the responsibility for planning, managing, and financing American scientific programmes, and the U.S. Navy, which is responsible for the logistics for the American programme, prepared a prospectus of potential locations for a station in the area. A wide reconnaissance of these sites was conducted during January–February 1963 aboard the Navy ice-breaker U.S.S. *Staten Island*. Even on this trip the biologists who accompanied the ship collected nearly 30,000 specimens. The group which made the reconnaissance of the sites recommended the Arthur Harbor vicinity on Anvers Island as the most promising location for the station, scientifically and logistically. Following this recommendation, early in 1964, a group of U.S. Navy construction experts surveyed the chosen location for a suitable site to construct the station.

The Falkland Islands Dependency Survey had chosen the Arthur Harbor area for a base which was built in 1955 and occupied until 1958. At that time, work was carried on by the British group in geology and topographic surveying, and observations were made in natural history. Many specimens were collected, and recently Dr. M. W. Holdgate[1] published observations of birds and seals made during the 1955–57 period. Dr. P. R. Hooper[2] has also written about the geological investigations made during that period. The availability of information from the countries which have carried out research in the area makes it possible to avoid duplication of efforts and confine the investigations to more specialized problems.

The British authorities have very graciously made the present hut at Arthur Harbor available for the initial phase of the American programme in the area. Along with the hut, which will be used to accommodate the laboratories, will be an additional building for living purposes. The new station will be called Palmer Station.

It is to be assembled by a small detachment of U.S. Navy Seabees who, along with the group which will stay over the winter, will be living aboard the ice-breaker U.S.S. *Edisto*. Once the station is complete, the five scientific and four Navy support personnel will move in for the winter, and the ship will proceed to other tasks.

In order to enlarge the effective working area of the station, a 125-f. wooden vessel designed for special service in and around the ice is being planned. Such a vessel would make possible biological, geological, and other investigations in the coastal areas of the peninsula and the off-lying islands.

The potentials for biological field investigations in the Antarctic Peninsula will, it is believed, attract research workers interested in problems of cold adaptation and physiology and, generally, in terrestrial and marine environmental phenomena. The biological laboratory planned for the Palmer Station will be equipped with standard apparatus and general supplies to meet the requirements for investigations of this type.

The peninsula area has been of interest to American geologists for many years, partly because of the strong likelihood that it may be the southern end of a land tie between South America and Antarctica. Although geological investigations both north and south of the Drake Passage have been carried out, much additional work on the history and structure of the peninsula remains to be done.

Palmer Station will be a most useful addition to the programme of the upper atmospheric scientist. It will provide a site for conjugate point studies which make possible the determination of some of the magnetospheric properties many earth radii out in space. The type of investigations which will be conducted may be the study of very-low-frequency whistler phenomena, the study of the absorption of particles which have been evaporated off the Sun, the study of the electro-jet which is a transitory current in the upper atmosphere, or a combination of these.

During the coming year, the Bernice P. Bishop Museum, Honolulu, Hawaii, will carry out ecological studies of Antarctic soil arthropods throughout the year to gather data on cold tolerances, temperature, humidity, food and hibernation requirements. In addition, continuous air plankton samplings will be maintained for recording the dispersal of land arthropods or other organisms by air currents. Complete soil and water analyses are planned for the ecological and climatological studies. Carefully controlled experiments will be initiated to analyse seasonal stresses on land arthropods. Collections will also be made of all arthropods, and particularly bird and seal parasites for faunal and systematic studies.

Glaciology and meteorology research will be carried out by scientists from Ohio State University's Institute of Polar Studies. Here they will investigate the balance of the ice cover and search for evidence of recent glacier fluctuations. Raised beaches will be sought also for evidence of sea level changes and datable material. A meteorological programme will include surface observations of temperature, wind, pressure, and cloudiness.

In keeping with the spirit of co-operation in Antarctica scientists from other countries will be welcome to join in the work at this station.

NEWS and VIEWS

The Royal Society of London: Award of Royal Medals

Her Majesty The Queen has been graciously pleased to approve recommendations made by the Council of the Royal Society for the award of the two Royal Medals for the present year as follows: to Prof. M. J. Lighthill, Royal Society research professor at the Imperial College of Science and Technology in the University of London, for his distinguished contributions to knowledge of the flow of compressible gases, and the mathematical theory of distributions; to Prof. F. W. R. Brambell, Lloyd Roberts professor of zoology in the University of Wales at the University College of North Wales and honorary director of the Agricultural Research Council's Unit of Embryology, for his important contribution to our understanding of the passage of protein from maternal to fœtal circulations.

Marine Biological Laboratory at Plymouth: Dr. F. S. Russell, C.B.E., F.R.S.

As a centre for the prosecution of research into every aspect of marine biology, the Plymouth Laboratory is unexcelled in the world. This stature it has attained by virtue of the outstanding qualities of three directors, E. J. Allen, Stanley W. Kemp and F. S. Russell, who successively have guided its growth over a continuous period of just on seventy years. For more than half this long period, F. S. Russell, who retires on September 30, 1965, has been associated with the Laboratory. After notable service with the Royal Naval Air Service and the Royal Air Force in the First World War and a year as an assistant director of Fisheries Research to the Government of Egypt, he joined the Marine Biological Association as an assistant naturalist in 1924. Later he was a member of the Great Barrier Reef Expedition in 1928–29, and spent the years of the Second World War in London as wing commander on Air Staff Intelligence. He succeeded Stanley Kemp as director in 1945. A pioneer worker on zooplankton, he was among the first to investigate diurnal migrations and relate these to variations in light intensity, while his name will always be associated with the discovery of plankton indicators through his investigations into the distribution of species of *Sagitta*. Early interest in medusæ, stimulated by the late E. T. Browne, culminated in the publication in 1953 of *The Medusae of the British Seas*, a notable addition to the great series of monographs in which, over the past two centuries, naturalists have described the varied members of the British marine fauna. During Dr. Russell's years as director, the facilities both in the Laboratory and for collecting and observing at sea have greatly increased. While war damage necessitated complete reconstruction of what was the Director's House, major additions for research and teaching have been completed, while the Laboratory is now served by two vessels, R.V. *Sarsia* and R.V. *Sula*, 130 ft. and 61 ft. long, respectively, and by a motor launch. The present condition of the Laboratory is described in *The Journal of the Marine Biological Association* (43, 281; 1963). With the building up of these facilities has gone a steady increase in the scientific staff, which now numbers twenty, including three Follows of the Royal Society. Visitors from all parts of the world come to work in the Laboratory and the magnificent library or to study the facilities. All has been achieved by careful planning and an unusual capacity for lucid exposition. Few major laboratories can have been conducted with less fuss and bother, fewer still with such a disarming sense of quiet humour. Retirement will represent a welcome return to research for Dr. Russell but with the satisfaction, shared, one knows, by Mrs. Russell, who has helped so much to bring it about, of realizing that, probably as no one else could have done, he has carried the Plymouth Laboratory into this post-war scientific age with universally acclaimed success.

Prof. J. E. Smith, F.R.S.

THE Council of the Marine Biological Association has appointed Prof. J. E. Smith to be director of the Marine Biological Laboratory at Plymouth in succession to Dr. F. S. Russell. Prof. Smith holds the chair of zoology at Queen Mary College, London, and is vice-principal of the College. He is chairman of the National Committee for Biology, chairman of the Grants Committee (Biology) of the Department of Scientific and Industrial Research, and chairman of the Advisory Committee on the Dove Marine Laboratory to the Development Commission. He is a member of the British National Antarctic Survey Committee of the Royal Society, and the Biological Unit of this Committee is attached to his Department. He is a Trustee of the British Museum (Natural History). He has made outstanding contributions to our knowledge of the nervous system of echinoderms and other marine animals, and to the embryology of marine animals and the ecology of the marine fauna.

Industrial Metallurgy at the College of Advanced Technology, Birmingham: Prof. J. C. Wright

DR. JOHN C. WRIGHT has been appointed professor of industrial metallurgy at the College of Advanced Technology, Birmingham, as from October 19, 1964. Prof. Wright, who is 34 years of age, was educated at the Grammar School, Dudley. Joining the Development and Research Department of the Mond Nickel Co., Ltd., in Birmingham in 1948, he studied part-time at the College of Technology for the external B.Sc. degree of London University, and was awarded this with first-class honours in 1954. After graduating he joined Imperial Chemical Industries Metals Division in Birmingham as a technical officer to assist in the development of titanium-melting techniques and, in 1956, he was awarded a senior research fellowship at Wolverhampton and Staffordshire Technical College to work on problems associated with pulverized fuel-fired gas turbines and was awarded the Ph.D. degree of the University of London in 1958. In the same year he was appointed to the staff of the College of Advanced Technology, Birmingham, as a senior lecturer in metallurgy and, in 1959, he took up his present position at the college as reader in industrial metallurgy. In 1961, Dr. Wright was elected a member of the Council of the Institution of Metallurgists. His present research interests are associated with the applied physical metallurgy of the deformation of metals—particularly of the newer metals.

Enrico Fermi Professorship of Physics, Columbia University: Prof. Tsung-Dao Lee

DR. TSUNG-DAO LEE, Nobel laureate and professor of physics in Columbia University, has been appointed the first incumbent of the newly established post of Enrico Fermi professor of physics in the University. Dr. Lee shared the 1957 Nobel Prize in Physics with Dr. Chen Ning Yang, member of the Institute for Advanced Study, Princeton University, for their research disproving the conservation of parity principle. At that time, Dr. Lee was thirty years old, the youngest full professor in modern times at Columbia. Born in Shanghai on November 25, 1926, Tsung-Dao Lee graduated in 1943 from the Kiangsi Middle School in Kanchow. He then attended the National Chekiang University in Kweichow but, in 1945, fled from advancing Japanese invaders to Kunming, where he attended the National Southwest Associated University. For his work in physics he was awarded a Chinese Government fellowship in 1946, which enabled him to study at the University of Chicago, where he received his Ph.D. in 1950. Dr. Lee went to Columbia as an assistant professor from the Institute for Advanced Study in 1953, and became a full professor in 1956. During 1960–62 he served as professor of physics in the Institute for Advanced Study, and at the same time served as adjunct professor of physics at Columbia. He returned to Columbia as a full-time member of the teaching staff in 1962. During the past summer Dr. Lee taught in Varenna, Italy, and spent two and a half months carrying out research in Geneva, Switzerland.

Enrico Fermi, in honour of whom the new professorship was named, was also a Nobel laureate in physics and served as professor of physics in Columbia during 1939–45. He helped to build the first atomic pile at Columbia and went to the University of Chicago on leave from Columbia in 1942 when the Manhattan Project, which developed the atom bomb, was transferred to the Chicago institution. Dr. Fermi died in 1954.

Gold Medal of the Royal Astronomical Society of Great Britain: Dr. Maurice Ewing

DR. MAURICE EWING, director of Lamont Geological Observatory, Columbia University, has been awarded the Gold Medal of the Royal Astronomical Society of Great Britain for his contributions to marine geophysics. It is the first Gold Medal the Royal Astronomical Society has given specifically for geophysical work. From now on the society will award two Gold Medals, one for astronomical and one for geophysical work. The citation recalls that in 1949 Dr. Ewing was made director of the Lamont Geological Observatory, Palisades, N.Y., which is now "perhaps the most comprehensive geological and geophysical research unit in the world. Over the years the two aspects of Ewing's work, geophysical work at sea and the study of surface waves as a method of gaining more information concerning the crustal and mantle rocks of the earth, have gone from strength to strength, with new methods constantly being developed. The work at sea now requires two deep-sea research vessels, and there are no oceans where Lamont scientists have not been working. In marine research, Ewing's name will always be coupled with turbidity currents, abyssal plains, mid-ocean ridges, and crustal thicknesses, and in seismology with the dispersion of Love and Rayleigh waves and the application of this study to the understanding of the Earth's deep structure".

H. B. Bigelow Medal in Marine Science: Dr. B. C. Heezen

THE Bigelow Medal, established in 1960, is awarded by the Woods Hole Oceanographic Institution for "significant inquiries into the phenomena of the sea". Dr. Heezen, the third recipient, is assistant professor of geology at Columbia University, and his contribution to marine science lies in the field of marine geology, particularly the physiography of the Atlantic and Indian Oceans. His interpretation of the sedimentary and tectonic processes governing the physiography of the ocean floor has been developed in the light of energetic work both in the laboratory and in the field.

Science in Parliament: National Parks

THE debate in the House of Lords on November 10 and 11 on the Address to the Throne ranged widely. Following Lord Mitchison's statement that National Parks would fall within the responsibilities of the Minister of Land and Natural Resources, Lord Molson specifically urged the need for legislation to increase the powers of the National Parks Commission. The Standing Committee on National Parks of the Council for the Preservation of Rural England had written some months ago to the Prime Minister on the whole subject of the preservation of amenities, both within and without the National Parks. The Prime Minister had invited them to prepare a full memorandum and had stated that this would be taken into account when the Government formulated its land policy. Lord Molson said that the memorandum had just reached its final form and would shortly be sent to the new Government, but in replying for the Government

neither Lord Stonham nor the Lord Chancellor gave the assurance that it would receive favourable consideration for which Lord Molson hoped.

Desalination of Sea-water

Lord Molson also supported some observations made by Lord Weir on the desalination of sea-water and expressed the hope that the new Department, to which responsibility for water supply and conservation had been specifically transferred, would direct special attention to the need for increased economy in the use of water and give expert consideration to the Morecambe Bay barrage project. Lord Weir dealt with desalination in some detail, directing attention to the report published this year by the United Nations. Moreover, he stressed the significance of the multi-flush distillant developed independently and almost simultaneously in 1956 by two British engineers, Dr. R. S. Silver and Dr. A. Frankel, giving 11 lb. of distillate from 1 lb. of steam instead of the previous 4 lb., and halving the capital costs. Between 1959 and 1964 the two British firms involved had secured orders for forty installations, or some 70 per cent of the available market. While welcoming the grant made by the Department of Scientific and Industrial Research to the Water Research Association to investigate the true incremental costs of additions to conventional water supply, he hoped that besides attention being directed to the invisible factors, the possibilities of distillation of sea-water, utilizing nuclear reactors as a source of heat, would not be overlooked. He also welcomed the establishment by the Department of Scientific and Industrial Research of an advisory committee and its financing of research into desalination economics. Lord Bessborough, speaking on the following day, supported Lord Weir, and added that the Americans greatly valued Britain's co-operation in this field and wished to see it extended.

Inland Waterways

On November 11, Viscount St. Davids pressed the claims of the waterways to be considered in a co-ordinated transport system. Their working loss had already been reduced from more than £1 million to just more than £500,000. Including capital and interest the working loss had been reduced by 26 per cent. With a further measure now being prepared by the British Waterways Board, he thought that the waterways would pay their way, but he also stressed the importance of the use of the waterways for purposes other than transport. Britain was in great need of major waterways which could carry cargoes of substantial size where speed was not of the first importance. Lord Lindgren, Parliamentary Secretary to the Ministry of Transport, assured Lord St. Davids of his interest in the waterways and that he had taken careful note of what he had said. He hoped that the Board's further review would enable the Government to decide on its policy and to start preparing the necessary legislation. On transport generally, the Government's policy was towards an integrated system covering road, rail, inland waterways, air and coastal shipping, using the most suitable vehicle for the journey to be made and the traffic to be carried, and geared to meet the economic and social needs of Britain.

Iron and Steel Industry

During his speech in the debate on the iron and steel industry in the House of Commons on November 9, the Minister of Power, Mr. F. Lee, said that since the industry's research effort had been criticized in a special report from the Iron and Steel Board in 1963 (see *Nature*, 201, 853; 1964) research expenditure seemed to have increased appreciably in the industry as a whole. Four major companies were planning substantial additional facilities for laboratory research, and the British Iron and Steel Research Association was to construct a new iron-making laboratory. The Government, however, knew of no plans for increasing the resources devoted to long-range research or for providing adequate facilities for large-scale plant work within the industry. On this point Mr. J. H. Osborn said, later in the debate, that the expenditure of £9·3 million on research in 1963 almost reached the figure recommended by the Board, and that the manpower devoted to research increased by 25 per cent last year.

Industrial and Technological Manpower

In his Budget statement in the House of Commons on November 11, the Chancellor of the Exchequer, Mr. J. Callaghan, said that large and important parts of Britain's industrial and technological manpower and capacity were locked up in production and research for the Government. It would be an urgent task to see how far this pattern could be modified in the national interest to release resources for more productive purposes and for expanding exports. Of the £2,000 millions spent on defence, more than £350 million was spent overseas, and it was the Government's intention to relate commitments to resources and ensure that the Armed Forces could discharge their tasks with greater effectiveness and economy. Government expenditure in the civil field would also be examined and it was intended to ask a task group of senior officials, including scientific and economic advisers, to sort out their projects and appraise their economic priority. The Chief Secretary to the Treasury would review the remaining fields of civil expenditure, and would consider whether the established priorities were right or whether men and plant could be released for other work. The basic objective would be to reveal any areas where expenditure was not yielding full value in social and economic terms. However, it was also recognized that there were fields in which increased Government expenditure could assist modernization and accelerate technical progress.

British House Journals Competition

House journals (alias staff magazines, works newspapers, etc.) are valuable vehicles of two-way communication between people in the board room and the shop floor or counter. They range from the office-duplicated bulletin to the glossy magazine that vies with the best on the bookstalls. One of the principal objects of the British Association of Industrial Editors, the professional body for house journal editors, is improvement in the standard of industry's private press. To this end, an annual national open competition is held, which is judged by a panel of experts nominated by the Institute of Journalists, the National Union of Journalists, the British Federation of Master Printers and the Society of Industrial Artists. Among the awards are four major trophies: (1) the best journal distributed to employees, presented by the Monotype Corporation, Ltd.; (2) the best journal for external readership, presented by the Kings Town Engraving Co.; (3) the best-designed house journal, presented by the De La Rue Co., Ltd.; (4) the best newspaper, presented by Lord Crook. In addition, the Shell-Mex and B.P. Trophy is awarded for the best house story of the year. The next competition closes on January 15, 1965. Entry forms can be obtained from the competition secretary, Mr. John Eve, c/o Standard Telephones and Cables, Ltd., Therese House, Glasshouse Yard, Aldersgate Street, London, E.C.1.

The Grassland Research Institute

Much of the work of the Grassland Research Institute, Hurley, is concerned with the interactions of soil, pastures and grazing animals in relation to other parts of the environment (*Experiments in Progress*, No. 16: Annual Report for 1962–63. Pp. 100+4 plates. Hurley, near Maidenhead: The Grassland Research Institute, 1964. 10*s*.). The research programme is planned to maintain

close contact between the eight departments of the Institute. An important aspect of the work is testing grass and clover strains from other latitudes both as pure stands and mixed with indigenous species. A new approach to reseeding is provided by destroying swards chemically. There are indications that different species react differently to particular chemicals and selective killing of species may be possible in the future. The growth characters of species and varieties are being studied in field and pot experiments as well as in a controlled environment. It has been shown that light breaks given to extend day-length in spring hastens ear formation in Timothy with increase in seed yield. It is now well established that increase in soil nitrogen under ley has a dominant influence on crop production. The physical condition of the soil is also improved by leys, and experiments are in progress to see how far this affects the availability of potash and phosphate. Extra-mural experiments in progress on private farms give information about grass management under a range of soil and environmental conditions. Among research projects in animal nutrition are *in vitro* digestibility studies on a wide range of herbages gathered at different stages of growth and the use of enzymes for digesting specific tissues such as fibre. The interaction of animal and pasture within intensive systems of husbandry is being investigated in a series of experiments. Animal agronomy is concerned, in broad aspect, with animal production in response to type of sward, and management and methods of determining the quality and amount of herbage eaten by the grazing animal are being investigated.

The Wildfowl Trust, Slimbridge

S. T. JOHNSTONE comments in the fifteenth annual report of the Wildfowl Trust that the long spell of severe weather in 1963 brought about the deaths of some 9 per cent of the total collection at Slimbridge (Pp. 150+45 photographs. Edited by Hugh Boyd and illustrated by Peter Scott. Slimbridge: The Wildfowl Trust, 1964. 17*s*. 6*d*.). The limited heating accommodation available soon became crowded with the more delicate waterfowl. Those that were taken in at the start of the cold spell survived well, but those that were caught up as the Arctic conditions continued suffered heavy losses. Cuban, fulvous and red-billed whistling duck were casualties. On the other hand, Javan, spotted and white-faced whistling duck, which were given priority, came through without loss. A species which had heavy losses was the North American ruddy duck, and while there had been twelve pairs in the Rushy Pen and some odd males in the autumn, when the spring arrived these had been reduced to five females and eight males. The extreme cold delayed nesting, and the first eggs were three weeks late. Once the weather broke the breeding season reached its peak very quickly. There was a record number of birds raised —more than 1,300 at Slimbridge and 300 at Peakirk. 104 kinds nested and 96 kinds were reared. Andean geese were reared for the first time, bringing the number of forms of waterfowl reared at Slimbridge to 123. The collection now contains some 2,250 birds of 160 kinds and races. Unfortunately, the blackheaded duck (*Heteronetta atricapilla*) is no longer represented. The male, the only one in Europe, that had been at Slimbridge for five years, died during the cold weather. Interesting arrivals have been additions to the greater, Cuban and Chilean flamingos, and a male bronze-winged duck for a tame female—it is hoped that having laid eggs for the past four years, she will do so again this year and that the eggs will be fertile. One of the two female buffleheads has been exchanged for a male.

World Directory of Crystallographers

A THIRD edition of the *World Directory of Crystallographers* is being prepared. The editor of this edition is Dr. D. W. Smits, of Groningen, Netherlands, and biographical information is being collected for each country by a sub-editor. It is intended to include in the *Directory* all practising crystallographers, including graduate students. Readers in the United Kingdom who consider their names should be included in the *Directory*, but who have not received a questionnaire by November 30, are requested to write to Dr. P. T. Davies, Shell Research, Ltd., Thornton Research Centre, P.O. Box 1, Chester.

Soils in North-west Ghana

TECHNICAL Report No. 62 of the Agricultural Research Institute (Ghana Academy of Sciences) is on "Soils of the Seilo-Tuni Land Planning Area, Wala District, Near Wa, Upper Region" and is by H. B. Obeng. (Pp. 196+4 maps. Agricultural Research Institute, Kumasi, 1963.) The area in question comprises 420 square miles in the north-west of Ghana. It has a long dry season (October–April) when the water problem is acute; the average annual rainfall is 44 in., the humidity varies between wide limits, the mean annual maximum and minimum temperatures are 98° F and 69° F. Most of the area lies on Cape Coast and Dixcove granites, but Lower and Upper Birrimian rocks underlie a considerable part and there are smaller areas of mixed parent material and of Black Volta alluvium derived from the above-mentioned rocks. It is probable that much of the area has been raised and degraded several times because there are ironpan-capped remnants of peneplains and river terraces at various heights above the present flood plains. The topography is gently undulating with broad valleys, and the vegetation is mainly short grass savannah with scattered shrubs and trees. There is a large variety of soils; sheet erosion is very common and between the upland concretionary soils and the valley bottom soils there are wide areas of colluvial drifts, falling within the group of Savannah Ochrosols, providing the best soils for crops such as yams, guinea-corn, maize, beans and groundnuts. About 25 per cent of the area is considered suitable for mechanized cultivation and 40 per cent for grazing; the remainder should be reserved for woodland and water-shed protection. The bulk of the report comprises a description of the soil associations and detailed recommendations for the improvement of agricultural practices. The four maps of geology, soils and Land Capability are on a scale of approximately 1 in. to 1 mile.

Priorities in the Physiology of Reproduction

THE fifth International Congress on Animal Reproduction and Artificial Insemination was held in Trento, Italy, during September 6–13. It was attended by about 1,200 scientists from more than 60 countries, and at the closing session the Congress approved a memorandum setting out the problems in this field which, in the light of present knowledge, appear to call for most urgent attention, or to offer most promising investigation. Research in mammalian reproduction has two major objectives, the increase of food production on one hand and the control of population expansion on the other. Divergent as these interests are at the applied level, both are served by basic research, much of which is also related to other aspects of physiology. Furthermore, although the control of human reproduction commands so much attention, it must not be forgotten that human infertility and fœtal mortality, menstrual disorders and other gynæcological problems still call for investigation. Indeed, recent progress in these important fields has been far from spectacular, and the 'conclusions' of the congress were obviously right in displaying no complacency in this regard. Among the more general themes suggested for future work, immunological aspects of reproduction, especially the antigenicity of gametes and fœtal–maternal incompatibility have prior place. They constitute a rewarding field of study. Environmental influences on reproduction are still felt to be in need of elucidation, particularly in relation to the interaction of environmental and hereditary factors. Another field of funda-

mental research of immense importance, both economically and in medical terms, is that of neuro-endocrinology. At a more 'practical' level, the congress agreed that "It is important that research be continued on the factors affecting sex determination because of its economic importance", and went on to define means of expressing farm animal fertility in uniform terms so as to facilitate comparison of records, and to make recommendations concerning hygiene and legislation in animal health.

Research in Immunology

Research in Immunology (WHO Technical Report Series No. 286) should interest everyone who is concerned with this field of investigation, which is nowadays advancing so rapidly and extending its influence in many directions. The Report deals with immunological problems under the following headings: I, immunoprophylaxis and immunotherapy; II, immunopathology; III, tissue antigens and transplantation; IV, immunochemistry; V, research programme in immunology. Each section comprises the report of a scientific group convened by the Director-General of the World Health Organization. Two annexes summarize the recommendations made for research and give an outline of current problems in immunology. The Report is obtainable in the United Kingdom from H.M. Stationery Office, the price being 8*s.* 6*d.*, and it is also published in French and Spanish.

CIBA Fellowships

Several fellowships will be awarded for tenure during the academic year 1965–66 at continental universities or institutions for full-time research in chemistry, physics or some other allied scientific subject. They will be awarded to graduates of universities situated in the United Kingdom of Great Britain or Northern Ireland or in the Republic of Ireland, or to members of those universities graduating in 1964. It is anticipated that some fellowships will be awarded to recent graduates and other fellowships to candidates who have already taken their Ph.D. degree, or who have already spent some time in industry. The basic award for Fellows who have already undergone training in research and wish to continue post-doctorate studies will be £1,000 per annum. For candidates who have obtained a first degree in science and wish to undergo training in research, the basic award will be £700 per annum. Awards may be increased by appropriate additional allowances depending on place of study and marital status, etc. The total value of each fellowship will be determined by the Advisory Panel. The amount awarded will be sufficient to cover the Fellow's full living and other expenses (including all fees and cost of travel) during the tenure of his fellowship, which will be for one year, renewable for a further one or two years. Twelve CIBA Fellows are at present working at Aarhus, Brussels, Copenhagen, Geneva, Genoa, Heidelberg, Munich, Stockholm, Strasbourg and Zurich.

University News:

Birmingham

The following appointments have been announced: *Lecturer*, Dr. N. Baggett (chemistry); Mrs. Christine A. McCauley (computing in the Department of Mathematical Physics). *Research Fellows*, C. Ashley (Imperial Chemical Industries Research Fellow in the Department of Mechanical Engineering); Dr. I. L. Dillamore (Imperial Chemical Industries Research Fellow in the Department of Physical Metallurgy); Dr. Teh-Hsing Wei (statistics in the Department of Pure Mathematics).

Bristol

The following have been elected to professorships: Dr. A. D. Buckingham (theoretical chemistry); G. F. C. Rogers (engineering thermodynamics); Prof. A. R. Battersby (organic chemistry). Announced also are the following appointments to lectureships: Dr. K. H. G. Ashbee (metallurgy and ceramics, within the Department of Physics); M. Chisholm (geography); Dr. K. B. Linton (medical bacteriology); Dr. S. Moran (pure mathematics); N. F. Richards (civil engineering); Dr. R. A. Sawyer (aeronautical engineering).

Edinburgh

The following appointments have been announced: *Senior Lecturers*, Dr. D. W. Moss (clinical chemistry); Dr. D. C. Simpson (medical physics); Dr. J. M. Last (public health and social medicine). *Lecturers*, Dr. E. M. Dixon (astronomy); Dr. J. S. McKinley McKee (biochemistry); Dr. Winifred L. Stafford (biochemistry); Dr. J. F. Collins (biophysics); P. Edmond (clinical surgery); H. Whitfield (computer unit); E. W. Powell (dermatology); A. M. Nicolson (electrical engineering); Dr. D. C. S. Hutchison (medicine); Dr. N. M. B. Doan (public health and social medicine); G. K. Crompton (respiratory diseases and tuberculosis); W. L. Ford (therapeutics).

Southampton

The following appointments have been made: Dr. R. L. Bell, reader in physical metallurgy in the University of London, to the chair of engineering materials in the Department of Mechanical Engineering from a date to be arranged. Dr. L. Brent of the National Institute for Medical Research, to the chair of zoology from April 20. Dr. W. A. Gambling, reader in electronics in the University, to the second chair of electronics. Dr. G. B. Trasler, lecturer in the Department of Sociology and Social Studies in the University, to the chair of psychology.

Synthesis of Organosilicon Monomers

It has been brought to the Editor's attention that a British edition of this book (reviewed in *Nature*, 204, 512, 1964) is published by Heywood Books (Temple Press Books, Ltd., London, W.C.1) to whom orders should be addressed by purchasers in the United Kingdom, the Commonwealth (excluding Canada) and Europe. The price is 130*s.*

Announcements

Mr. D. B. Collett, a director of Dunlop Rubber Co., Ltd., has accepted the invitation to deliver the twentieth Foundation Lecture of the Institution of the Rubber Industry. This will take place at the Midland Institute, Birmingham, on May 19, 1965.

A meeting on "Plant Waxes, Cutin and Associated Compounds", organized by the Phytochemical Group, will be held in London on January 7. Further information can be obtained from A. H. Williams, Research Station, Long Ashton, Bristol.

A symposium on "Energy Transfer in Radiation Processes", arranged by the Association for Radiation Research, will be held in University College, Cardiff, during January 7–9. Further information can be obtained from Dr. G. O. Phillips, Department of Chemistry, University College, Cardiff.

The 1965 Gordon Research Conferences on "Electrochemistry: Electrode Processes", "Polymers" and "Basic Chemistry of Aging" will be held in Santa Barbara, California, during January 25–February 5. Further information can be obtained from the director of the conferences, Dr. W. George Parks, University of Rhode Island, Kingston, R.I.

A joint meeting of the North of England Section and the Special Techniques Group of the Society for Analytical Chemistry will be held in Leeds on December 11. A paper on "Some Aspects of Polarography" will be presented by M. L. Richardson. Further information can be obtained from the Society for Analytical Chemistry, 14 Belgrave Square, London, S.W.1.

MATERIALS SCIENCE AND TECHNOLOGY

A CALL FOR ACADEMIC AND INDUSTRIAL COLLABORATION

A CONFERENCE on "Materials Science" was held at the Whateley Hall Hotel, Banbury, during October 2–4; this was the second of its kind to be held in Britain. The first[1], held in May 1963, was arranged by the Institution of Chemical Engineers. Since then, the Materials Science Club has been formed, and this year's conference was held under the auspices of this new organization, with Prof. E. W. J. Mitchell (University of Reading) co-ordinating the arrangements.

The Club itself is independent of the existing professional institutions, and its purpose is to hold meetings at which research and education in materials science and technology can be discussed in an informal atmosphere. While being independent and informal, it does, however, hope to exert an influence on developments in education and on Government research.

The conference's tone of informality was set by a stimulating lecture, "Toughness", delivered after the opening dinner by Dr. F. J. P. Clarke (Atomic Energy Research Establishment, Harwell). A further lecture which, like Dr. Clarke's, was not intended to form part of the main business of the conference was given next day by Dr. A. C. Rose-Innes on the subject "New Superconducting Materials and their Uses".

The conference consisted of three half-day sessions. The first of these was entitled "Collaboration in Teaching and Research between Universities and Industrial Laboratories" and consisted of six papers. Dr. K. Hoselitz (Mullard Research Laboratories) established what was later seen to be the general feeling of the meeting, that much more collaboration between universities and industry is necessary. He pointed out that, although some university staff already acted as consultants for industry and industrial firms place research contracts with universities, an extension of this practice is desirable. Universities could reciprocate by inviting consultants from industry to advise on both research and teaching, personnel might be exchanged for short periods and industrial scientists should act as part-time lecturers.

Dr. J. Hill (Atomic Energy Research Establishment, Harwell) described the great variety and extent of the collaboration which is practised between Harwell and teaching institutions. He outlined the system of research contracts, the interchange of staff, the work carried out at Harwell by university research students and the short-term research appointments. On the teaching side, courses for university lecturers are provided, demonstration equipment is lent to universities and many staff act as examiners for higher degrees. Dr. Hill's experiences appeared to contradict those of Dr. Hoselitz, and this marked difference between the collaboration which a university may expect from an industrial firm and a Government laboratory was emphasized by the next speaker, Prof. E. W. J. Mitchell, who enquired whether commercial security was the reason for industry's greater reluctance to invite university staff into their laboratories.

Prof. Mitchell showed how the universities were, at least to some degree, already collaborating with industry in most of the ways which the previous two speakers had mentioned, and pointed out that the structure of university government did not in itself prevent an extension of this kind of activity. He warned, however, of the dangers and futility of superficial collaboration. For effective collaboration, an industrial scientist lecturing to postgraduate students must be brought into the stream of university student life in some way, and a university lecturer acting as an industrial consultant should be invited to join research projects at the earliest planning stage and not used merely as an experimental supervisor.

The next speaker, Dr. H. M. Finniston (International Research and Development Co., Ltd., Newcastle), stressed the role which the universities could assume in educating industrial scientists, and asked them to consider whether they were using the most effective aids to this purpose. Lectures could be filmed and taped, for example, and made available to a wide public. Market research could be carried out by universities in order to discover which subjects were of most direct interest to industrial scientists at the present moment, and courses should be provided in these subjects. Dr. Finniston spoke also of the tendency of young scientists nowadays to choose a university career in preference to industry, and suggested that industry might use co-operation as one means, although an indirect one, of obtaining the services of these men.

Dr. L. Holliday (Shell Chemical Co., Ltd.) emphasized that the driving force in establishing this collaboration must come from the universities; industry itself is usually very willing to co-operate. A function which industry is well placed to perform is the carrying out of surveys of useful research programmes through trade associations. He spoke of the importance of proximity in fostering collaboration, and hoped that research associations would take this into consideration in choosing a site for a new laboratory, and that a university would perhaps consider seriously the possibility of having research associations on its campus.

The last speaker of this session, Dr. E. G. Stanford (Aluminium Laboratories, Ltd.), disagreed with earlier speakers in one respect, that he did not wish to see universities becoming too concerned with seeking industrial collaboration, but they should follow their own research interests. On the other hand, he wanted to see a considerable increase in liaison between industry and all institutions concerned with higher technological education. Too little liaison exists at present. He stressed a point that Dr. Holliday had made, that lecturers must go out into industry to find what is needed in research before deciding what subject to work on; the success of collaboration depends largely on the readiness of lecturers to go out and learn what problems industry is dealing with.

During the discussion which followed, it became apparent that, while everyone present agreed that a great increase in collaboration would be a healthy development, both for universities and industry, there were marked differences of opinion regarding the mechanism of collaboration which would be most effective and also regarding the influence which it could be expected to have on students.

Unanimity was, however, to be found among speakers with a common background. For example, Prof. J. G. Ball (Imperial College of Science and Technology), Prof. K. M. Entwhistle (Manchester College of Science and Technology) and Dr. N. Thompson (University of Bristol) spoke of the responsibility of a university to provide an integrated scientific education, both lecturing and research being directed to this purpose. With this in mind, industrial experience for undergraduates could be regarded as irrelevant, and industrial lecturers on undergraduate

courses are unnecessary. Postgraduate studies are another matter, and students at this stage should learn something of industry, but it is still important that by far the greater part of research for higher degrees, which must be regarded as an extension of the undergraduate work, should be carried out in the university itself.

A different point of view was expressed by Dr. C. P. Sandbank (Standard Telecommunication Laboratories, Ltd., Harlow), who is a consultant to the Electrical Engineering Department of the University of Edinburgh. In a subject in which the technology is changing rapidly and fundamentally, in which assemblies of electronic and electro-mechanical devices are being replaced by minute crystals, it is not sufficient to rely on information being fed to universities by staff with recent industrial experience. It is obviously better if some people working in industry have the formal responsibility of introducing up-to-date material to the students. There are difficulties in the way, such as commercial security and the lack of rapport between visiting lecturers and students, but the climate in industry is becoming more sympathetic, and the machinery which has enabled university staff to contribute to the success of industrial research can no doubt be extended to encourage the reciprocal process.

Dr. Holliday brought out again a point which Dr. Finniston mentioned in his address, the importance to industry of encouraging the best graduates from universities to take up industrial work and the difficulties encountered at present in doing this. To overcome these, he urged universities to allow research students to carry out a substantial part of their work in industrial laboratories. The value of doing this is already appreciated in applied sciences, but not in the pure sciences.

It was surprising to find that, in a discussion of the relevance of industrial experience to undergraduate studies, sandwich courses should come in for so little comment. It was left to Mr. K. M. Ginsburg (Battersea College of Advanced Technology) to raise the subject, and Dr. W. A. Holmes-Walker (Metal Box Co., Ltd.), who has experience of the industrial side of the scheme, spoke of the effectiveness of this type of training for undergraduates who intend to enter industry. Very few other speakers took up the subject.

The establishment of part-time chairs in universities for industrial scientists was discussed, and the system employed in Holland and other European countries was described by Prof. R. W. Cahn (University College of North Wales, Bangor). Several speakers described how a similar scheme, on a much smaller scale, operates in Britain. There is no difficulty in using funds from the University Grants Committee for this purpose, and many firms would encourage their senior men to take these positions. There was general agreement that, as an experiment at least, more part-time posts with senior rank in the universities should be created.

It is difficult to sum up briefly the results of the discussion, beyond that a general desire for collaboration exists, but it would be fair to comment that the desire appears to be more on the part of industry, rather than of the universities. All the university scientists who spoke were well aware of the debt which they already owe to industry for its help, particularly in the form of research grants, and several of them pointed out that university research is almost wholly financed from sources other than the University Grants Committee, but a deliberate break with tradition would be required to bring industry closer to the students than it is at present. The impression left by the discussion was one of industry trying to encourage universities to come out rather than of universities begging industry to come in.

The second session of the conference had the title "Materials Science in Universities", and the chairman was Dr. Holliday. The first speaker was Prof. K. M. Entwhistle (Manchester College of Science and Technology). He directed attention to the fact that, in thinking about a particular subject such as materials science, it is necessary not to lose sight of the general purpose of a university education. Undergraduates should be presented with a demanding and challenging course of study which could stimulate critical, logical and independent thinking; and, at the same time, the university, as part of society in general, should create in the student an attitude of mind which makes him eager to contribute to it. Materials science he defined simply as an integrated and scientific study of the relation between the structure and properties of matter. The *ad hoc* methods used in the past in the development of materials are still necessary in the solution of practical problems, but theoretical understanding of the behaviour of solids is rapidly improving, and materials science now is a study in which theory and practice interact. For this reason, there is much room for experiment in the way the subject is treated as an academic discipline. But there is a ribbon of continuity which runs through the theory of the behaviour of solids which makes the theory at present accepted sufficient to present a challenging and satisfying course. Prof. Entwhistle went on to consider whether materials science could most profitably be introduced at the undergraduate or the postgraduate stage. His suggestion was that a limited number of institutions should experiment with undergraduate courses, with existing courses in subjects such as metallurgy remaining in their present form, but at postgraduate level it is vital that an enormous extension of the general study of materials should take place.

The second speaker in this session was Prof. R. Edgeworth-Johnstone (University of Nottingham), who, as a chemical engineer, described himself as a consumer of materials science, in the respect that it is a subject provided for his students by other departments. The kind of problems he faces are: What kind of course should chemical engineers ask for? What proportion of time should be devoted to different materials? How is such a course to be related to industrial work? The answer to some of these would be provided if a survey could be undertaken of the relative importance in economic terms of the various classes of materials. Prof. Edgeworth-Johnstone considered that materials science within a university organization is unlikely to appear as a separate discipline, and the possibility is that existing departments may group themselves together. In this case, care should be exercised to ensure that a balanced view of materials as a whole can be taken by the unified group. The purpose of the group, however it is formed, should be to provide a course which will teach engineers to make a critical assessment of the materials they use. Finally, he described the organization of design study groups and emphasized the economic importance of including in these groups a materials specialist.

It was almost inevitable that the discussion which ensued should be concerned with existing or projected university courses in materials science. The undergraduate course at the University of Reading is already in its second year, a more technological course at Bradford Institute of Technology has just begun, and a similar course, but with a heavier bias towards metallurgy, is to begin next year at Battersea College of Advanced Technology. A postgraduate course being offered at Woolwich Polytechnic was described by Dr. D. J. Morantz, and the course which is now running for the second time at the Imperial College of Science and Technology was outlined by Dr. J. C. Anderson. This latter course was the subject of much discussion. Enrolment of suitable students had been difficult at first, but this is now improving. The greatest difficulty, however, and one to which no immediate solution is available, is that of obtaining maintenance grants for the postgraduate students. But for the generosity of one or two firms, such as International Research and Development Co., Ltd., grants would be almost unobtainable, and there seems to be no hope of an

extension of postgraduate teaching until this situation is altered.

The title of the final session of the conference was "The Appreciation of Materials Science and Technology in Schools", and the chairman was Prof. Mitchell. At first sight this would appear to be an unusual subject for a conference of this kind, but it was soon apparent, both in the talks and in the discussion, that the attitudes of schoolchildren and their teachers are of great concern to university teachers, particularly in the applied sciences.

Prof. J. G. Ball, the first speaker, spoke of the almost total lack of appreciation of the nature of applied sciences, including materials science, which, in his experience, exists among schoolboys. There is a barrier in their minds between pure sciences on one hand, and what they regard as second-rate technological subjects on the other. Physics and chemistry, the sciences with which they are familiar, seem to be unnecessarily remote from real materials and real life. He described his attempts to provoke interest in metallurgy in sixth-formers, and particularly his discovery that their ideas of the subject were only of the craft aspect of it, of forges and lathes, and they had no idea of the intellectual side. This intellectual challenge was, in his opinion, the approach which should be made in order to correct the erroneous ideas which boys have picked up. An interesting note of uncertainty came into Prof. Ball's address, as he confessed that he was not yet completely convinced that a course in pure science was not the best preparation for a career in applied science, for some students at least. He concluded his address with suggestions for ways in which an interest in materials science might be aroused in schools, all of which have been used in existing subjects to a small extent. Careers pamphlets issued by professional organizations, conferences with schoolmasters, displays and exhibitions provided by universities were some of the means suggested.

Mr. M. Deere (Reactor School, Atomic Energy Research Establishment) outlined the work being carried out by the Reactor School at Harwell to give schoolmasters and their pupils an opportunity to meet technologists and to learn from them the nature of their work. Teachers attend courses on which the lectures are given by senior scientists. Facilities are provided for science teachers to undertake research work at Harwell, and scientists visit schools to give lectures and to give advice on scientific projects carried out by pupils. Courses for mathematics teachers have also been held, and courses for careers masters are planned. Boys in the first year of sixth-form work will be invited to courses which will be designed to bring them into direct contact with the technical work carried out at Harwell by discussing with the scientists real problems which are being tackled there. The purpose of this is not recruitment, but is rather what Prof. Ball spoke of earlier, an attempt to give boys a realistic image of the work of an applied scientist and to reveal the intellectual challenge which the work provides.

Early in the discussion which followed, Mr. R. S. Barron (Dauntsey's School) described a scheme which is being used in his school to give sixth-form boys an opportunity to become acquainted with engineering. Each boy carries out, over a period of 12 months, a project of his own choosing, and a report of the work is assessed for the Advanced Level of the General Certificate of Education by the Cambridge Examination Board. Advice on the work and assistance with the provision of expensive equipment are sought from industry and from Government research establishments. It came as a surprise to many in the audience to find that the Advanced Level examination scheme is flexible enough to permit enterprise of this kind.

Mr. M. H. Devenport (Eton College) attributed the lack of interest in applied science among schoolboys partly to the subject's lack of glamour when compared with, say, physics and its association with the Nobel Prizes. He was of the opinion that a move towards a less academic type of science in schools could be brought about through the existing examination system, without radical changes, provided that engineers give a clear lead in suggesting lines of work which are interpretable at sixth-form level. Several technologists present were dismayed by Mr. Devenport's remarks about the way their subject failed to inspire boys, but had to admit the truth of them, and suggestions for making applied science more appealing carried little conviction. There was no doubt in anyone's mind that a great deal of work of the kind described by the various speakers would have to be done before a noticeable change in schoolboy attitudes could be expected.

It was left to Prof. Entwhistle to point out that there appeared to be no reason why schoolgirls should not be encouraged to study materials science. It was the first time in the conference that they had been mentioned.

R. STEADMAN

THE EUROPEAN ATOMIC ENERGY COMMUNITY

THE seventh annual report of the European Atomic Energy Community (E.A.E.C.)*, commonly known as Euratom, covers the period March 1963–February 1964 and consists of two distinct volumes, both in French. Volume 1 discusses in general terms the need for, and the economics of, the development of nuclear energy facilities in Europe; the co-operative programme of research undertaken by the six member states of Euratom; the relationship between Euratom and industry; the establishment of nuclear research centres and the dissemination of information about nuclear energy; health and safety precautions; and the links between Euratom and other nuclear energy organizations. The evidence, including the relevant technical facts and figures, for the statements and conclusions described in Volume 1 is given in the 37 articles which form the contents of Volume 2.

The illustrated report (*Eur* 1850*e*), though perhaps not so comprehensive as the annual report, is a much more readable and useful picture of the progress achieved by Euratom. It is in English and confines discussion in its 19 sections to a limited number of aspects of the technical and research work of the organization. Each section is written by one or more members of the group actively engaged in the particular aspect discussed. In the brief introduction to the report reference is made to the treaty signed in Rome on March 25, 1957, by the Governments of the member states (Germany, Belgium, The Netherlands, Italy, France and Luxembourg) establishing Euratom, and to the tasks and objectives of the Community. The aim is to foster progress in the peaceful uses of nuclear energy. Its main activities are carried out at, or directed from, the Joint Nuclear Research Centre, comprising the four establishments at Ispra (Italy), Petten (Netherlands), Geel (Belgium) and Karlsruhe (Germany). Ispra is the main establishment and has at its disposal large-scale digital and analogue computers essential for reactor studies, and there is a separate research programme on automatic translation and documentation. The European library of nuclear codes recently established by O.E.C.D. is to be housed at Ispra. The

* Communauté Européenne de l'Énergie Atomique, Euratom. Septième Rapport Général sur l'Activité de la Communauté, Mars 1963–Février 1964. Pp. 118. (Bruxelles: Euratom, 1964.) Documentation jointe au Septième Rapport Général sur l'Activité de la Communauté, Mars 1963–Février 1964. Pp. 213. (Bruxelles: Euratom 1964).

reactor physics, materials and engineering departments of the establishment are almost entirely concerned with the *Orgel* reactor project. The *Orgel* reactor is fuelled by natural uranium (in the form of ceramic compounds or alloys), heavy water moderated and cooled by high-boiling organic compounds. The structural materials consist of special preparations of light metals. Section 3 of the report by J. C. Leny and S. Orlowski describes in detail the *Orgel* project and the associated *Orgel* critical experiment and the *Essor* test reactor, which is now being constructed and which is expected to go critical at the end of 1966.

The Central Bureau of Nuclear Measurements, the establishment at Geel, is envisaged to become, in the nuclear field, a bureau of standards similar to the well-known national standards laboratories. The laboratories of the Central Bureau as planned in 1960 are now nearing completion; and by the end of 1964 the Bureau will have received all its heavy equipment. The pulsed 3-MeV Van de Graaff accelerator with a Mobley bunching system is in operation and the pulsed electron linear accelerator, of the travelling-wave type (*S* band, approx. 10-cm wave-length), is now being installed. The duties of the Bureau include not only the preparation and conservation of primary standards and their intercomparison with those of other laboratories, but also the improvement of standards, instruments and methods of measurement in addition to the accurate measurement of nuclear data. A full description of the Bureau together with its equipment for fissile and stable isotopes is given in Section 2 of the report.

Petten is a general-purpose establishment, the main function of which at present is to operate the test reactor (*HFR*) provided by the Dutch Government through the Reactor Centrum Nederland. The establishment is responsible also for the management of certain other important associations—*BR*2, Dragon, *THTR* and *Kema*—and a general programme of study related to them. The reactor *HFR* is virtually identical with the reactor *ORR* at Oak Ridge, and, consequently, close relations exist between the Petten and Oak Ridge establishments with regard to high-temperature reactors.

The specialized establishment, the Transuranium Institute at Karlsruhe, now in the course of construction on a site assigned to Euratom by the Gesellschaft für Kernforschung, is to be devoted to the non-military uses of plutonium in the nuclear energy industry. The laboratory will be brought gradually into use from about mid-1964 and is expected to be complete by 1966.

In addition to the sections dealing with the research establishments, there are sections dealing with thermonuclear research, radiobiology, radiation protection, industrial development of power reactors, marine reactors, the Euratom–United States joint programme, and the activities of the Eurisotop Bureau. The total personnel employed by Euratom on January 1, 1963, was 1,910, of which some 1,500 were members of the research establishments. The total is expected to rise to 3,200 by the end of the five-year programme in 1967.

NUFFIELD PROVINCIAL HOSPITALS TRUST

THE Nuffield Provincial Hospitals Trust has published its sixth report, recording the progress of schemes described in the previous report and announcing new projects during the past three years. A wide range of activities has been supported, and 150 projects are listed under 15 general headings*.

In welcoming the Ministry of Health's entry into the field of providing finance for service and operational research, the Trustees note that "this policy is to be applauded and the competition it introduces will be stimulating. Of course, it does not follow that there will henceforth be an abundance of money available for the kind of study which indicates how health services can be made more effective, or whereby resources can be deployed in a better way. Yet the implication is that Britain is entering a period of more intensive scientific enquiry into its health services—surely a wise investment from which excellent dividends may be expected in the future". The Trust's own contribution to this investment during the period under review amounted to £1,305,000. During the period covered by the report 13 books have been published on sponsored research, and several other projects have resulted in reports published under other imprints.

The most important single new subject appearing in the report is postgraduate medical education. The Trustees' decision to allocate a large sum of money (£308,750) to help promote schemes in the provinces has stimulated a great deal of activity. The aim of the Trustees, to stimulate the development of a comprehensive national policy for the continuing education of doctors, and so lead to the improvement of medical-care services, seems in a fair way to being realized.

The following selection gives an indication of the range of the Trust's interests: A grant of £20,000 over five years was allocated to the Oxford Regional Hospital Board for operational research studies of a number of aspects of hospital problems. £5,000 went to the United Birmingham Hospitals for a survey of health services for children in the City of Birmingham, and £1,000 to the University of Nottingham for a study on recruitment to, employment of, and demand for, certain of the professions supplementary to medicine; physiotherapy, occupational therapy, dietetics, orthoptics, and radiography. £2,400 over two years was made available for the secondment of a nurse to work in the Casualty Department of the General Infirmary at Leeds to investigate the cause and prevention of accidents in the home.

The North-Eastern Regional Hospital Board, Scotland, received a grant of £50,000 for the building of an in-patient and day hospital unit for child psychiatry in Aberdeen, and to cover the first year's running costs. The Aberdeen area, the report states, is particularly suitable for a project of this kind "in view of the basic demographic knowledge already available about the area, the close integration between the hospital service and the university department in mental health, the presence of an active research organization and the contacts already established with the local health and education authorities". £12,000 has been allocated for the provision of a parents' hostel at Smith's Hospital, Henley-on-Thames, which has facilities for some fifty psychotic or severely disturbed children. It has been found that little success attends efforts to treat these children unless the staff work very closely with the children's parents, particularly the mothers, since the corner-stone of treatment is the restoration or encouragement of this relationship. To an increasing extent the child is treated through the mother, because only rarely can anyone else give the necessary time and individual attention to bring about the return of the child to his or her normal position in the family.

A grant of £4,000 was allocated in order to make possible a study of community mental health services in Devonshire, the main purpose of which is to discover the problems and difficulties experienced by patients who have been

* The Nuffield Provincial Hospitals Trust. Sixth Report: A Record of the Progress of Schemes and Descriptions of New Projects 1961–1964. Pp. 152. (London: The Nuffield Provincial Hospitals Trust, 1964.)

mentally ill and received hospital treatment but who have now returned to live in the community. The Department of Psychological Medicine, University of Edinburgh, has been granted £15,725 over three years to develop a psychiatric treatment service for alcoholics, while £100,000 has been reserved for the development of a health centre at Witney, near Oxford: "All the general practitioners of the town will practise from surgeries in the centre, which will also provide accommodation for local health authority and dental clinics and consultant outpatient clinics, as well as X-ray and pathological facilities run by the Oxford Regional Hospital Board."

A further allocation of £92,250 has been made to the Hospital Engineering Unit at the University of Glasgow to undertake a programme of research work concerning problems met in heating, ventilating and air-conditioning of hospitals, including the means of attaining proper standards of performance. Much of the practical work will be carried out in an experimental ward unit which the Scottish Home and Health Department has built at Hairmyres Hospital, East Kilbride, Glasgow, but research will also be carried out at other hospitals. Another project concerning the physical problems of hospital design involves the allocation of £15,000 to the United Oxford Hospitals and the Oxford Regional Hospital Board jointly to enable a special unit to be built at the Churchill Hospital, Oxford, in which experiments can be conducted into the lay-out of wards and departments and where equipment and procedures can be tested.

£35,000 has been ear-marked for an experimental intensive-care unit which has now been opened at Broadgreen Hospital, Liverpool. The report comments that the successes claimed for progressive patient care in the United States have won adherents in Britain for the persuasive principles involved. However, there has been little practical experience of the system, or of any of its stages in Britain, although experiments and investigations in the care of acutely ill patients, and management of post-operative cases, have always been a feature of Britain's hospitals.

SMOKELESS AIR

THE autumn issue of the quarterly *Journal of the National Society for Clean Air* (35, No. 131; 1964, London) opens with some appropriate lines: "Ships, towers, domes, theatres and temples lie Open unto the fields, and to the sky; All bright and glittering in the smokeless air". This obviously epitomizes the aims of this organization, which have to-day become a matter of international concern.

Only a few decades ago the United Kingdom and the United States were the only countries actively organized to combat air pollution in big industrial cities, where the problem of contamination of the air breathed, in its progressively toxic aspects, had become a matter of both general and medical concern. "Today we find organization, investigation, research and legislation in many countries and in every continent . . . the natural result of the tide of industrialization flowing from the North Atlantic countries to almost every corner of the globe."

Progress of the movement since the early pioneer days is clearly revealed in the current number of the *Journal*, which contains a full first-hand report of the Council of Europe's Clean Air Conference at Strasbourg (June–July 1964). This has been described as the most comprehensive and longest event ever held on the problems of air pollution. Just previously, on the initiative of the Air Pollution Control Association of America, with the help of the U.S. Public Health Service, a meeting of six national air pollution organizations, including the United Kingdom, was convened and held at Washington, June 1964. The Strasbourg conference revealed not only what 14 member countries (including observers from the United States) had in common in air pollution problems, how different national situations determined procedure but, equally, despite the impracticable measure of uniformity in law and administration, the strong desire towards what is modestly described as 'harmonization' of mutual activities.

Fundamentally, at least in some parts of the United Kingdom, probably just as pertinent overseas, much depends on the availability and price of smokeless fuels, especially for domestic consumption; the position is not satisfactory at the present time, taking an overall survey, on either count. But air pollution is not only a question of utilization of smokeless solid fuel. As is well known, the Ministry of Transport in Britain has for some time been conducting a drive against smoke emitted by incorrectly maintained Diesel-engined vehicles using our public highways. The much-publicized national checks on some of the worst offenders have already had a disciplinary value, but, as another article in the *Journal* points out, the policy advocated by the Society is: ". . . that offenders should be required to put their vehicles in good order and that they should be prohibited from operating until this was done. This . . . is a better and more certain incentive to good practice than purely punitive measures".

Smokeless air, even better, pure air, as an environment in which both to live and to work, may be an ideal, perhaps unattainable in heavily built-up and industrialized areas, but at least the problem is a live one in most civilized countries to-day, and the organization responsible for this publication is doing great service in co-ordinating the efforts of everyone concerned in reaching the ultimate goal in Britain.

TRANSPLANTING MATURE DATE PALMS IN IRAQ

THERE is nothing very unusual nowadays in the transplanting of large trees for particular purposes. It is done in towns where the immediate effect of a large tree is required for amenity reasons and to save the wastage and delay in time brought about by the vandalism to which young trees are sometimes subjected in urban areas. So long as the special equipment is available, and the expense can be met, the operation has justified itself in the success it has had in temperate climates where advantage is taken of the dormant season of the trees, but it is a different matter in a hot climate where the rate of transpiration is one of the factors increasing the difficulty of the operation.

Mr. R. H. Nocton, an agronomist specializing in tropical agriculture, has recently prepared a paper describing the transplanting of 87 mature date palms in Iraq. The site was the New University of Baghdad and the trees ranged from 30 to 60 ft. in height. The operation was completely successful, and the following points are of particular interest.

The soil was alluvial to a depth of about 30 ft., fine textured and grading into sub-soil sand. This provided a good transplanting medium because water-holding capacity is better with fine-textured soils. From the nutrient point of view there were various difficulties such as the alkaline nature of the soil, *p*H 8–8·5, which tends to restrict the availability of certain nutrients to the trees and also the deficiency of important elements and the absence of nitrogen. Salinization of the lower root zone occurred, but this is known not to represent a serious factor where irrigation is practised. The climate made transplanting difficult because Iraq is tropical, with very hot summers, and always dry.

It is necessary to ensure the same orientation of the tree in the new site—especially the older the tree—and so a metal disk was nailed to the north side of the bole. Transpiration was arrested by pruning off the fronds to leave 6–8 per tree which were sprayed with water-dispersible plastic. Likewise, the root ends which were exposed on digging were sealed with plastic and the large bowl of earth, some 6 ft. in radius at the surface and about 7½ ft. deep, was covered with hessian during transportation. The tree with its bowl, a total of from 14 to 38 tons, was lifted by crane and moved to the new site in an upright position on a low loader. Planting took place 3–6 ft. deeper than normal to ensure stability and to promote the growth of roots. The hole was filled to within 2 ft. of the top and the space kept full of water for a month. Surface irrigation was undertaken and, although the Tigris is slightly saline, this did not matter because the major part of the irrigation occurred when the river was at its highest and the salt content was at its lowest level. In order to create a microclimate under the trees, a sprinkler irrigation system was used which not only increased the humidity from 18 to 80 per cent but also promoted root growth. New roots were produced on some trees two months after transplanting and a growth regulator was applied to any tree not showing new roots after three months.

The success of the experiment shows that physiological problems can be overcome. The economics largely depend on the availability of equipment, such as a suitable crane, low loader and excavator. The method is not only applicable to amenity planting but it is suggested by the author that it could be used to introduce 20–30-ft.-high date palms as shade trees in citrus plantations, thus saving some 15–20 years to the farmer. In this case the trees could be planted 3 ft. deeper than normal and the resulting formation of new roots would prolong their lives.

Copies of the paper can be obtained from Mr. R. H. Nocton, 591 Alwiya, Arasa, Iraq. C. J. Taylor

ISOLATION AND IDENTIFICATION OF THE INITIAL PEAK OF THE EARLY RECEPTOR POTENTIAL

By Dr. WILLIAM L. PAK* and Dr. RICHARD A. CONE†
Department of Biophysics, University of Chicago, Chicago, Illinois

RECENTLY, Brown and Murakami[1] observed a new receptor potential in the eye of the cynomolgus monkey using intra-retinal microelectrodes. They found that the new response is produced only with high-intensity stimulus flashes and is characterized by an extremely short latency (< 0·1 msec) and a strikingly high resistance to anoxia. The amplitude maximum of the response was found to occur at the ciliary connexion between the outer and inner segments of the receptors. Brown and Murakami have labelled this response the early *RP* (receptor potential). Afterwards Cone[2] has shown that a similar response occurs in the electroretinogram (ERG) of a variety of vertebrate eyes. He found that in the albino rat the early *RP* almost certainly depends on the rhodopsin in outer segments of rods because the early *RP* has the same spectral sensitivity as rhodopsin and the amplitude of the early *RP* is linearly proportional to the pigment bleached by a flash. His evidence, therefore, strongly supports Brown and Murakami's conclusion that the response originates in the receptors.

These authors further noted that in some vertebrate eyes the early *RP* has a biphasic wave-form[2,3], a small corneal positive phase (the positive peak) preceding the dominant, corneal negative phase (the negative peak). We have now observed a similar wave-form in the excised eye of the albino rat by lowering the temperature of the eye somewhat below the physiological temperature (Fig. 1 *B*). Apart from opposite polarity the most notable feature that distinguishes these two peaks appears to be their strikingly different temperature dependence. By lowering the temperature sufficiently it was possible to abolish the negative peak and isolate the positive peak (Fig. 1 *C*). Significantly, the positive peak persists well into sub-zero temperatures. This behaviour suggested to us that the two peaks are produced by separate processes. Although the corneal negative component of the early *RP* has been shown to be a receptor potential, the positive component has never been investigated as a separate process. We, therefore, sought to determine whether or not the positive peak also originates in the receptors. If the positive peak is a receptor potential, because of its shorter latency it is probably even more closely linked to the 'primary events' of visual excitation than the negative peak.

Using the apparatus previously described[2] we undertook to observe the early *RP* in the ERG of albino rats (Sprague-Dawley) at various temperatures. The stimulus flashes were produced by a 65-joule photographic strobe lamp (Honeywell Strobonar 65*C*) having less than a 0·7-msec flash duration. To minimize artefacts the strobe lamp was housed in a soft-steel box, and the electrodes were shielded from the flash as much as possible. With these precautions the artefacts were found to be negligible. The effects of temperature could be studied on excised eyes, because the early *RP* has such a high resistance to anoxia[1,2]. However, since visual pigment does not regenerate in the excised eye of the rat, each set of observations was performed on an eye freshly excised from a fully dark-adapted animal. The electrodes were placed against the cornea and the back of the excised eye. The eye and the electrodes were then mounted in a chamber partly submerged in a thermal bath. Wratten neutral density filters were used to vary the stimulus intensity. The wavelengths of the stimulus flash were varied by using a set of five Baird-Atomic interference filters transmitting at 420, 450, 500, 560 and 620 mμ. The band-widths of the filters at 10 per cent transmission were found to be about ± 6 mμ.

The signals obtained in the rat at 35°, 25° and 0° C are displayed in Fig. 1. At the physiological temperature the negative peak completely dominates the positive peak (Fig. 1 *A*). As the temperature is lowered, however, the amplitude of the negative peak decreases rapidly from

* On leave from the Department of Physics, Stevens Institute of Technology, Hoboken, New Jersey.

† Present address: Biological Laboratories of Harvard University, Cambridge, Mass.

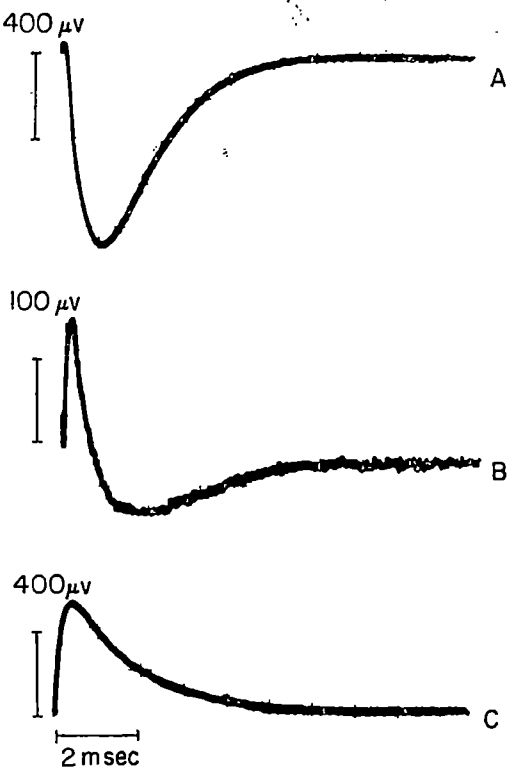

Fig. 1. Temperature dependence of the early *RP*. The positive and negative peaks of the early *RP* were elicited from the dark-adapted, excised eye of the albino rat by presenting a maximum energy, white flash at various temperatures: (*A*) 35° C, (*B*) 25° C, (*C*) 0° C

about 1 mV to about 100 μV in going from 35° to 25° C (Fig. 1 *B*). The negative peak is almost completely abolished at about 5° C. On the other hand, the positive peak becomes more and more prominent until it is essentially isolated below about 5° C (Fig. 1 *C*). Once the peak is isolated, its amplitude remains relatively stable at about 300–500 μV. The signal is still present at about −10° C. Qualitatively similar results have also been obtained with excised goldfish eyes. In this case, however, the biphasic response persists to much lower temperatures than in the case of the rat. In addition to these amplitude variations it may be seen in Fig. 1 that the responses, particularly the negative peak, slow down considerably as the temperature is lowered. Such changes in pulse speed with temperature should be valuable in excluding certain mechanisms which might be thought to generate these electrical responses.

As may be seen in Fig. 1, the positive peak always precedes the negative peak whenever both peaks are observed in the same record. This is consistent with the notion that the positive peak always has a shorter latency. Although the accuracy of the latency measurement is ultimately limited by the finite rise time of the stimulus flash, with the present equipment we can conservatively set an upper limit of 50 μsec for the latency of the positive peak at 0° C. At the physiological temperature the latency is probably much shorter.

The positive peak of the early *RP* has been observed in the cat, goldfish, frog[2] and cynomolgus monkey[3] at ordinary temperatures. Now, with the inclusion of the albino rat in this group, the positive peak has been obtained in every animal so far investigated. In the rat a suggestion of its presence can sometimes be detected even near the physiological temperature, provided the response is observed at sufficiently high sensitivity and sweep speeds. The effect of cooling seems to be mainly to suppress the negative peak without affecting the positive peak substantially. In both animals so far investigated the positive peak has been isolated by lowering the temperature.

The strikingly different temperature dependence exhibited by the two peaks strongly suggests that they are dependent on different processes. The positive peak could represent either: (1) an earlier, separate step in visual excitation, or (2) an event unrelated to visual processes. We sought to test the second possibility by identifying the pigment responsible for the positive peak. Since the positive peak has such a short latency, it cannot possibly be produced far from the absorbing pigment. Therefore, if the positive peak could be shown to be dependent on the visual pigment in the rod outer segments, it must follow that the positive peak, in all likelihood, is a receptor potential. Such an observation would exclude the second possibility. A series of experiments designed to identify the pigment were performed near 0° C on the excised eye of the albino rat. At this temperature the positive peak is almost completely isolated, and its amplitude is near its optimum value. The albino rat was used, because in the ERG of this animal only one visual pigment, rhodopsin, need be considered, and the eyes of the animal contain very few other pigments.

Since the negative peak has already been shown to be a receptor potential, it is pertinent to mention that, apart from the polarity and the temperature dependence, the properties displayed by the two peaks of the early *RP* are very similar. They both appear in the same high-intensity stimulus flashes; they both exhibit extremely short latencies; and they are both highly resistant to anoxia. In the series of experiments recorded here further similarities came to light. First, the amplitude of the positive peak was found to be reduced by successive flashes of high intensity in a manner consistent with the bleaching or excitation mechanism of visual pigments involving photoregeneration[4,5]. Furthermore, the amplitude of the positive peak, when plotted against the flash energy, produced a curve closely resembling that obtained by Cone[2] for the negative peak. Thus the amplitude of the positive peak appears to be linearly proportional to the amount of pigment bleached by the stimulus flash as in the case of the negative peak.

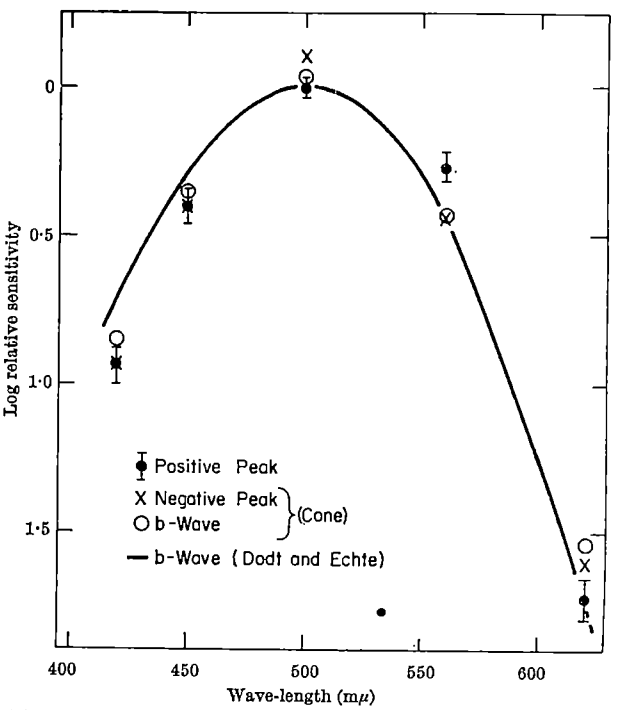

Fig. 2. Comparison of the spectral sensitivities of receptor potentials in the albino rat. The spectral sensitivity of the positive peak (•) has been superposed on the spectral sensitivities of the negative peak (×) and the *b*-wave (○) published in Fig. 2 of ref. 2. The solid line is the spectral sensitivity of the *b*-wave redrawn from Fig. 4 of ref. 6

Perhaps the most direct and convincing way of identifying a pigment is to measure a spectral sensitivity of the given response. The spectral sensitivity of the positive peak was obtained by finding the stimulus intensities needed to elicit equal responses at five different wavelengths. The results are presented in Fig. 2 along with the spectral sensitivities of the negative peak and the dark-adapted *b*-wave measured by Cone[3] and the spectral sensitivity of the dark-adapted *b*-wave obtained by Dodt and Echte[6]. The errors indicated on the positive peak spectrum do not include systematic errors arising from the optical arrangements, the calibration of the flash spectrum, etc. They represent statistical errors only. Since essentially the same experimental arrangement was used for the present measurement and Cone's earlier measurements, the systematic errors are expected to play only a minor part in the comparison of these results. We have remeasured the action spectra of the *b*-wave and the negative peak with our present arrangement to ascertain that no significant changes have taken place in experimental conditions since Cone's earlier measurements. As may be seen in Fig. 2, our positive peak spectrum is in good agreement with Cone's negative peak and *b*-wave spectra. There appears little doubt that all three responses are produced by the same pigment.

These results, particularly the action spectrum, almost conclusively point to rhodopsin as the pigment responsible for the positive peak. As possible sources of the rhodopsin, both the rod outer segments and the pigment epithelium need to be considered. Dowling[7] has shown, however, that no rhodopsin exists in the pigment epithelium of the albino rat. It therefore appears almost certain that the rhodopsin responsible for the positive peak resides in the rod outer segments. Since the latency is so short, the positive peak is probably generated very close to the rod outer segments. We therefore conclude that the positive peak is a receptor potential which manifests itself through a process earlier and distinct from that producing the negative peak.

Brown and Murakami[1] and Cone[2] have suggested that the early *RP* is probably closely connected with the initial photochemical events in visual excitation because of its short latency and its linearity with respect to the amount of rhodopsin bleached. Of the two peaks of the early *RP* the positive peak with its shorter latency is probably associated with an earlier step in the process of visual excitation. To the best of our knowledge it is the only electrical response recorded in the mammalian eye at subzero temperatures. Since a great deal of information regarding the initial events in the bleaching of rhodopsin has been obtained by investigating photolysis of the pigment at low temperatures[8], the positive peak of the early *RP* may provide a valuable means of linking the early physico-chemical events with the electrical responses of the eye.

This work was carried out under contract with the U.S. Atomic Energy Commission, and was supported by U.S. Public Health Service post-doctoral traineeships. We thank Prof. John R. Platt for his advice.

CRANIAL EPIPHYSES IN MAMMALS

By Prof. A. J. E. CAVE
Department of Anatomy, St. Bartholomew's Hospital Medical College, London, E.C.1

EPIPHYSES are anatomical mechanisms necessary to the post-natal development of most of the bones of the mammal skeleton, being found (principally as the pressure- and traction-epiphyses of Parsons'[1] classification) in association with the vertebræ and ribs, the limb girdles, and the long bones at least of the limbs. Despite their considerable functional importance in skeletal maturation such structures are apt to be ignored by the standard treatises on vertebrate morphology or else to be accorded but incidental mention in connexion with the ossification pattern of a long bone. It would thus appear that, as objects of study, epiphyses have been relatively neglected except by human morphologists. Knowledge concerning epiphysis development, structure and variation is more abundant for man than for any other mammal and it may be that the human pattern of epiphysis topography has become implicitly accepted as canonical for mammals generally. If this be so, it may explain the absence so far of any record of the occurrence of an epiphysis in connexion with any mammalian cranial bone. Certainly cranial epiphyses are unknown in man and his primate kin; but that such structures may—indeed do—occur in some mammals, at least, this article purports to show.

An undoubted epiphysis (ossiculum mastoideum) is present in relation to the temporal bone of the otariid pinnipedes and another epiphysis occurs in relation to the lacrimal bone of tapirs, elephants and rhinoceroses.

The ossiculum mastoideum is observable in the genera *Arctocephalus*, *Eumetopias*, *Otaria* and *Neophoca* (and is probably present also in *Callorhinus* and *Phocartos*). Its development and fate have been studied by Cave and King[2] in the extensive series of *Arctocephalus* specimens in the British Museum (Natural History), which include examples of all growth stages from birth to old age.

In the young *Arctocephalus* pup the squamo-mastoid suture occupies a sulcus bounded anteriorly and posteriorly by bony lips, to the posterior of which are attached the sternomastoid and other powerful neck muscles. Progressive growth of these lips converts the sulcus into an oval vallecula, the floor of which, like the posterior lip itself, manifests in older pups a typically epiphyseal configuration. Meanwhile, in the cartilage filling the vallecula, the mastoid ossiculum—a traction epiphysis on the mastoid process—makes its appearance as a thin, curved, osseous flake. It enlarges progressively to an average maximum size of some 16 mm × 10 mm in the adult male and some 8 mm × 5 mm in the adult female. As a discrete ossicle, synchondrosed to the mastoid process and separable therefrom by maceration, it persists until late adult life, when it effects complete synostosis with that process and leaves no trace whatever of its former independence.

The antorbital process of the lacrimal bone of tapirs manifests a half-moon-shaped, anteroposteriorly compressed epiphysis, which detaches readily prior to the commencement of its synostosis with the lacrimal. Its presence is indicated by such specimens as B.M.1912.4.22.1 (*Tapirus indicus*), B.M.1948.5.21.3 (*Tapirus terrestris*), B.M.1872.1.24.2 (*Tapirus roulini*) and C.58.3 (*Tapirus* sp.).

A hemispherical epiphysis is associated with the antorbital process of the lacrimal bone in the Asian and the African elephant. Obtrusive examples of its presence in *Elephas maximus* are provided by B.M. specimen 1879.11.21.693 and by the mounted skeleton in the Ghar Dalam Museum, Malta. In *Loxodonta africana* material it is present in B.M. specimens 10410, 1921.1.1.36 and 49.697; it is incompletely demarcated by an epiphyseal line in B.M. specimens 49.695 and 1937.5.20.2; in B.M. specimen 1928.11.13.1 a portion of one epiphysis remains *in situ* and is passively movable on the lacrimal bone.

A lacrimal epiphysis occurs in all rhinoceros genera. In *Rhinoceros unicornis* B.M. specimens 1951.11.30.2 and 3.2.13.1 this epiphysis remains *in situ*; from B.M. specimens 1952.4.1.1 and 70.3.10.18 it has been lost after death.

Fig. 1. *Arctocephalus tropicalis gazella.* Right mastoid epiphysis (*E*) *in situ*

Fig. 2. *Ceratotherium simum.* Left lacrimal bone showing lacrimal epiphysis (*E*) *in situ*

Fig. 3. *Ceratotherium simum.* Right lacrimal bridge showing bed (*EB*) of detached lacrimal epiphysis, between the superior and inferior lacrimal foramina

B.M. specimen 1902.12.18.1 displays the corresponding epiphysis of *Rhinoceros sondaicus*.

In *Didermocerus sumatrensis* (which agrees with the African form *Ceratotherium simum* in having the lacrimal fossa invariably bridged posteriorly by bone) a lacrimal antorbital epiphysis is present; it appears bilaterally in B.M. specimens 1948.1.14.1 and 1461*b*, and unilaterally in B.M. specimens 1949.2.1.1, 79.3.11.1, 86.12.20.18 and 1952.4.1.2.

The *Diceros bicornis* lacrimal epiphysis is observable *in situ* in specimens B.M.99.6.29.11 and C.58.11 (private collection).

In *Ceratotherium simum* material the epiphysis is present bilaterally in specimens C.58.7, 58.8 and 58.9; its former independence and extent are indicated by epiphyseal lines or scars in specimens C.58.5, C.58.18, B.M.1948.1.28.1 and B.M.1948.1.28.2.

The lacrimal epiphysis in *Rhinoceros*, *Didermocerus* and *Diceros* is a flattened hemispherical cap on the antorbital process. Exceptionally (for example, *Rhinoceros*, *Diceros*) it may develop from two centres of ossification or (for example, *Didermocerus*) may extend medialwards into the lacrimal fossa parietes. In *Ceratotherium* it is responsible for the ossification of the posterior arm, the apex and part of the anterior arm of the osseous bridge over the lacrimal fossa and for some portion of the lateral wall of that fossa.

All the forms manifesting a lacrimal epiphysis possess thick tarsal plates and a well-developed and active nictitating cartilage; the epiphysis is a traction epiphysis developed in response to the tension exerted on the antorbital process by the attached and powerful tendo oculi. The lacrimal antorbital process is itself essentially a 'muscular' process for the attachment of the medial canthic structures, the development and activity of which may (as in the elephants) render this process the dominant portion of the lacrimal bone.

It is not suggested that mastoid and lacrimal epiphyses are restricted to the genera mentioned above. The present observations are submitted to draw attention to the hitherto unnoticed association of traction epiphyses with certain bones of the mammalian cranium. A fuller account of these structures will be published elsewhere.

ARE PEPTIDE ANTIBIOTICS SMALL PROTEINS?

By DR. M. BODANSZKY and DR. D. PERLMAN

Squibb Institute for Medical Research, New Brunswick, New Jersey

IN the 35 years since Fleming's report[1] of the anti-Gram-positive bacterial effects of the peptide antibiotic, penicillin, nearly 65 other peptide antibiotics have been mentioned in the literature. These substances produced by a wide variety of micro-organisms contain one or more amino-acids or moieties derived from amino-acids. Some are effective in inhibiting the growth of various bacteria, Gram-positive and/or Gram-negative, others the growth of yeasts and fungi, and some have anti-neoplastic properties.

The recent interest in the genetic code and the biogenesis of proteins[2] has stimulated studies on the origins of the peptide antibiotics[3–6]. The findings that the 'small' physiologically active peptides, bradykinin[7] and angiotensin[8], arise from the specific enzymatic hydrolysis of larger proteins might be looked on as justification for the hypothesis that antibiotic peptides are also derived by similar mechanism, their biosynthesis being directed by 'special' genetic codes. The literature does not support the view that antibiotic peptides are formed from larger proteins, and we conclude that a different type of mechanism must be involved in the biosynthesis of antibiotic peptides from that concerned with formation of cellular proteins.

A summary of some of the biological and chemical properties of 42 of the better-characterized peptide antibiotics is presented in Table 1. Structures have been proposed for 21, and nine of these have been confirmed by chemical synthesis: benzylpenicillin, cephalosporin *N*, gramicidin *S*, enniatin *B*, actinomycin *C*, valinomycin, amidomycin, and polymyxin. In many cases, the micro-organisms producing these antibiotics synthesize a group of closely related substances rather than a single entity, and these have been grouped in this tabulation. Also the closely related antibiotics produced by different micro-organisms are mentioned as a group, for example, vernamycins *B*, ostreogrycins *B*, mikamycins *B* and staphylomycins *S*; streptothricin, streptolin, geomycin, racemomycin, myrothricin, and roseothricin. The members of these groups differ from each other usually only by a single amino-acid, the rest of the molecule being the same. Some peptide antibiotics are composed entirely of amino-acids, while others contain amino-sugars, fatty acids, pyrimidine derivatives and other moieties in addition to the peptide portion of the molecule. A list of the amino-acids found in hydrolysates of peptide antibiotics is presented in Table 2.

The peptide antibiotics appear to have several common features: (1) a wide variety of unusual constituents, including D-amino-acids, not found in proteins are found in antibiotic peptides; (2) the peptide antibiotics are cyclic peptides; (3) all are resistant to hydrolysis by peptidases and proteases of animal or plant origin.

A brief inspection of Table 2 is already convincing evidence against the concept that peptide antibiotics would be produced by the general mechanism which is operative in protein synthesis. The four bases of ribonucleic acids, if arranged in coding triplets, can provide information for 64 components[2]. Since several triplets correspond to (or 'code for') the same amino-acid[2], the number of components for which this coding system can provide sufficient information is considerably less than 64. This so-called 'degeneracy' of the code does not interfere with protein synthesis, because only about 20 amino-acids occur in proteins. The number of amino-acid components found in peptide antibiotics is already approaching 64, and, therefore, a degenerate three-letter code is certainly insufficient for the information which is necessary to put the components in a predetermined order, that is, in a well-defined sequence. If, in order to reconcile the number of building stones and the scope of coding, the degeneracy is disregarded, then the well-established universality of the genetic code has to be sacrificed too. But, even with this unattractive assumption that the code for peptide antibiotics is not degenerate and the genetic code is not universal, the number of possible components soon will be exhausted. Furthermore, the occurrence of 'antibiotic families' also indicates that the information provided for the synthesis of peptide antibiotics is less definitive than the coding system of protein synthesis. Therefore, the conclusion that peptide antibiotics are not produced by the same mechanism as proteins is not too hazardous.

Experimental evidence for differences in the biosynthetic procedures of peptide antibiotics and of proteins was found by Mach, Reich and Tatum[3], who examined the biosynthesis of tyrocidin by *B. brevis*. We cannot agree, however, with their conclusion that such a difference should exist also for other polypeptides of similar size. Since peptide hormones, some of which have molecular weights of the same order as peptide antibiotics, do not have unusual amino-acid components, the above considerations on coding are not valid for them. Moreover, since bradykinin and angiotensin are formed by enzymatic cleavage of proteins, this might well be the case with other peptide hormones. On the other hand, the studies of Zadrazil, Kroupa, Sormova and Sorm[6] on the biosynthesis of polymyxin and of Eikhom, Jonsen, Laland and Refsvik[5] on the biosynthesis of gramicidin *S* contribute to our contention that, from the point of view of biosynthesis, peptide antibiotics are not small proteins.

If the information needed for the sequential arrangement of building stones of antibiotics is different from the coding device of protein biosynthesis, there are still two possible mechanisms which can be postulated for such a purpose: (1) a yet undiscovered coding system involving nucleotides; (2) the amino-acid building stones are assembled on the surface of one or more enzymes. The assumption of an independent coding system for peptide antibiotics is rather unpalatable: it is easy to accept the existence of the genetic code because the products of protein synthesis, for example, the enzymes, are indispensable for life. Hence, evolution could, and probably had to, lead to such an intricate mechanism. Peptide antibiotics, however, with a few exceptions, are probably not absolutely essential for the survival of the micro-organisms which produce them. Some variants of antibiotic-producing cultures do not produce the antibiotic and apparently carry out all other metabolic functions found in the antibiotic producers. Thus it is possible that antibiotic peptides represent only products of metabolic pathways which were abandoned during evolution or that they are disposal mechanisms of undesirable metabolic by-products, for example, D-amino-acids. Therefore, the second possibility-that peptide antibiotics are assembled from specific pre, cursors without an independent coding system, but on a specific (enzyme ?) surface, seems to be the more reasonable

Table 1. Some Chemical and Biological Properties of Peptide Antibiotics

Name	Antibiotic-producing organisms	Antibiotic spectrum (organisms inhibited)	Est. mol. wt.	Amino-acids reported		Other components
				D-Amino-acids	L-Amino-acids	
Actinomycins (ref. 9)	*Streptomyces antibioticus*	Gram + bacteria antineoplastic	1,300	Alloisoleucine, valine	Sarcosine, *N*-methyl-valine, proline, threonine, *N*-methyl-isoleucine, *N*-methyl-alanine, hydroxyproline	Actinocinin
Alazopeptin (ref. 10)	*Streptomyces griesoplanus*	Antineoplastic	400	—	Alanine	6-diazo-5-oxo-hexanoic acid
Albomycin (ref. 11)	*Streptomyces subtropicus*	Gram + bacteria	1,140	—	Serine, *N*-hydroxy-ornithine	Iron
Amidomycin (ref. 12)	*Streptomyces* species	Yeast	1,000	Valine	—	D-α-hydroxyiso-valeric acid
Antibiotic I.C.I. 13,599 (ref. 13)	*Paecilomyces* species	Anti-trypanosome	—	—	α-aminobutyric, leucine, β-alanine, γ-methyl-proline, β-hydroxy-leucine	
Aspartocin (ref. 14)	*Streptomyces griseus* *Streptomyces violaceus*	Gram + bacteria	—	—	Aspartic, glycine, proline, valine, α,β-diamino-butyric, β-methyl-aspartic	D-α-pipecolic; (+)-12- and 13-methyl-3-tetra-decenoic acids
Bacillomycins (ref. 15)	*Bacillus subtilis*	Fungi and yeast	1,000	—	Aspartic, glutamic, tyrosine, leucine, valine, serine, proline	
Bacitracins (ref. 16)	*Bacillus subtilis*	Gram + bacteria	1,400	Ornithine, aspartic, glutamic	Lysine, histidine, cysteine, isoleucine, aspartic, valine, phenylalanine, leucine	
Bottromycins (ref. 17)	*Streptomyces bottropensis*	Gram + bacteria Acid-fast bacteria	750	—	Glycine, valine, β-(2-thiazole)-β-alanine, α-amino-β-phenyl-butyric acid	
Brevin (ref. 18)	*Bacillus brevis*	Gram + bacteria	—	—	Aspartic, glycine, tyrosine, serine	Unknown 'base'
Cephalosporin *C* (ref. 16)	*Cephalosporium acremonium*	Gram + bacteria Gram − bacteria	350	α-aminoadipic	—	
Cephalosporin *N* (ref. 16)	*Cephalosporium synnematum*	Gram + bacteria Gram − bacteria	350	α-aminoadipic Penicillamine	—	
Cinnamycin (ref. 19)	*Streptomyces cinnamoneus*	Gram + bacteria Acid-fast bacteria	—	—	Glutamic, lanthionine, aspartic, valine, proline, arginine, phenylalanine, β-methyllanthionine	
Circulin (ref. 20)	*Bacillus circulans*	Gram − bacteria	825	Leucine	α,γ-diaminobutyric, threonine, isoleucine	(+)-6-methyl-octanoic acid
Colistin (ref. 21) (polymycin)	*Bacillus colistinus*	Gram − bacteria	925	Leucine	α,γ-diaminobutyric, threonine, leucine	(+)-6-methyl-octanoic acid
Comirin (ref. 22)	*Pseudomonas antimycetica*	Fungi and yeasts	—	—	Serine, aspartic, glycine, α,γ-diaminobutyric, lysine, valine, threonine, leucine, arginine, glutamic, isoleucine, alanine	
Duramycin (ref. 23)	*Streptomyces cinnamoneus*	Gram + bacteria Fungi and yeasts	—	—	Lanthionine, β-methyl-lanthionine, aspartic, glutamic, glycine, valine, proline, phenyl-alanine, ornithine, hydroxyproline	
Enniatins (ref. 24)	*Fusarium* species	Acid-fast bacteria	840	—	*N*-methylvaline	D-α-hydroxy-isovaleric acid
Etamycin (ref. 25) (viridogrisein)	*Streptomyces lavendulae*	Gram + bacteria	800	Leucine, allo-hydroxyproline	α-phenylsarcosine, threonine, sarcosine, β-*N*-dimethylleucine, alanine	3-Hydroxypicolinic
Fungistatin (ref. 26)	*Bacillus subtilis*	Fungi and yeasts	2,400	—	Aspartic, lysine, serine, threonine, proline, alanine, isoleucine, valine, tryptophan, tyrosine	Unidentified acid
Gramicidins (ref. 27)	*Bacillus brevis*	Gram + bacteria	1,350–2,000	Leucine, valine, phenylalanine	Tryptophan, valine, alanine, leucine, glycine, tyrosine, isoleucine	Ethanolamine
Ilamycins (ref. 28)	*Streptomyces islandicus*	Acid-fast bacteria	1,170	—	Alanine, leucine, *N*-methylleucine, γ-formyl-methyl-norvaline, 3-nitro-4-hydroxy-phenylalanine, trypto-phan, 2-amino-4-hexenoic acid	
Licheniformins (ref. 29)	*Bacillus licheniformis*	Acid-fast bacteria	3,800–4,800	—	Aspartic, glycine, serine, proline, arginine, phenylalanine, valine, lysine	
Matamycin (ref. 30)	*Streptomyces matansis*	Gram + bacteria Gram − bacteria	—	—	Cysteine, glycine, serine, alanine, arginine (?)	
Micrococcin *P* (ref. 31)	*Bacillus pumilis*, *Micrococcus* species	Gram + bacteria	—	—	Threonine	Propionic acid, 2-propionylthiazole-4-carboxylic acid, 2(1-amino-2-methyl-propyl)thiazole-4-carboxylic acid
Mycobacillin (ref. 32)	*Bacillus subtilis*	Fungi and yeasts	1,525	—	Aspartic, proline, glutamic, tyrosine, serine, leucine, alanine	
Nisins (ref. 33)	*Streptococcus lactis*, *Streptococcus cremoris*	Gram + bacteria	7,000	—	Leucine, isoleucine, methionine, valine, proline, alanine, glycine, serine, aspartic, histi-dine, lysine, lanthionine, β-methyllanthionine	
Penicillins (ref. 34)	*Penicillium* species, *Aspergillus* species	Gram + bacteria	350	Penicillamine	—	Phenylacetic acid, valeric acid
Polymyxins (ref. 35)	*Bacillus polymyxa*	Gram − bacteria	1,225	Phenylalanine	Leucine, threonine, α,γ-diaminobutyric	(+)-6-methyl-octanoic acid

[*Continued overleaf*

Table 1.—*Continued*

Name	Antibiotic-producing organisms	Antibiotic spectrum (organisms inhibited)	Est. mol. wt.	Amino-acids reported		Other components
				D-Amino-acids	L-Amino-acids	
Polypeptin (ref. 36)	*Bacillus krzemieniewski*	Gram + bacteria Gram − bacteria Fungi and yeasts	1,150	Valine, phenylalanine	Threonine, leucine, isoleucine, α,γ-diaminobutyric	Unidentified acid
Quinoxaline, antibiotics (ref. 37) (echinomycin, quinomycins, triostins, actinoleukin, levomycin)	*Streptomyces echinatus*, *Streptomyces aureus*	Gram(+) bacteria Gram(−) bacteria Acid-fast bacteria Antineoplastic	850	Serine	Alanine, *N*,*N*′-dimethylcystine, *N*-methylvaline, *N*-methylisoleucine, *N*-dimethylleucine	Quinoxaline-2-carboxylic acid
Saramycetine (ref. 38)	*Streptomyces saraceticus*	Fungi and yeasts	14,000	—	Glycine, threonine, proline, cysteine, aspartic	
Sideromycine (ref. 39)	*Streptomyces griseoluteus*	Gram + bacteria	1,100	—	—	1-amino-5-hydroxylaminopentane
Streptothricins (ref. 40) (streptolin, geomycin, mycothricins, racemomycin, roseothricins)	*Streptomyces lavendulae*, *Streptomyces racemochromogenes*, *Streptomyces xanthophaeus*	Gram + bacteria Gram − bacteria Acid-fast bacteria Fungi	550	—	β-lysine	D-gulosamine, streptolidine
Stendomycins (ref. 41)	*Streptomyces* species	Yeast and fungi	1,850	—	Alanine, glycine, isoleucine, leucine, proline, serine, threonine, valine	
Subtilin (ref. 42)	*Bacillus subtilis*	Gram + bacteria	3,200	—	Glycine, alanine, valine, lysine, leucine, glutamic, proline, isoleucine, lanthionine, phenylalanine, tryptophan, β-methyllanthionine	
Telomycin (ref. 43)	*Streptomyces* species	Gram + bacteria	1,000	—	*cis*-3-hydroxyproline, *trans*-3-hydroxyproline, glycine, alanine, threonine, aspartic, β-hydroxyleucine, serine, allo-threonine, tryptophan, β-methyltryptophan	
Thiostreptons (ref. 44) (siomycin, bryamycin)	*Streptomyces azureus*, *Streptomyces hawaiiensis*	Gram + bacteria	1,650	Cysteine	Threonine, alanine, isoleucine	Thiostreptoic acid, thiostreptine
Tyrocidines (ref. 45)	*Bacillus brevis*	Gram + bacteria	1,200	Phenylalanine	Tyrosine, phenylalanine, tryptophan, aspartic, glutamic, ornithine, leucine, proline, valine	
Valinomycin (ref. 46)	*Streptomyces fulvissimus*	Acid-fast bacteria Fungi and yeasts	100	Valine	Valine	D-α-hydroxyiso-valeric acid, lactic acid
Vernamycins (ref. 47) (staphylomycins, mikamycins, ostreogrycins)	*Streptomyces loidensis*, *Streptomyces virginiae*, *Streptomyces ostreogryceus*, *Streptomyces mitakaensis*	Gram + bacteria	700	Aminobutyric	Proline, phenylalanine, threonine, phenylglycine, *N*-methylphenylalanine, *N*-methyl-*p*-dimethylaminophenylalanine	4-oxopipecolic
Viomycin (ref. 48)	*Streptomyces floridae*, *Streptomyces vinaceus*, *Streptomyces puniceus*	Gram + bacteria Gram − bacteria Acid-fast bacteria	475	—	Serine, β-lysine, α,β-diaminopropionic	Viomycidine

one. On the other hand, the size of such a specific surface limits the number of components which can be assembled. For large peptide antibiotics, the independent coding systems should be postulated.

Is there a need to make this unlikely visualization of a coding system? Do large-size peptide antibiotics exist? Apart from cellular proteins and toxins produced by micro-organisms containing the common amino-acids, there are two compounds reported which have large molecular weights and unusual amino-acids: nisin[33] and saramycetine[38]. Both contain 55 'amino-acid' components and have molecular weights of 6,300 and 14,000 respectively. As shown in Tables 3 and 4, alternative compositions and molecular weights can be proposed for these two antibiotics. If the new proposals are confirmed by experimental investigations, this would eliminate the need for the hypothetical and unlikely coding system for peptide antibiotics. The proposals in Table 3 seem justified on the basis that the presence of three rather than nine β-lanthionine residues allows an easier interpretation of Cheeseman and Berridge's[33] finding that from 20 peptide fragments, obtained during the partial hydrolysis of nisin, only two contained β-lanthionine. In saramycetine, a molecular weight of about 1,750, rather than 14,000, leads to a molar absorption coefficient of 48,000 at 275 mμ and 77,000 at 227·5 mμ instead of the very unusual values of 385,000 and 615,000 respectively.

Of course, caution should be used in such speculative interpretation of published experimental data. Molecular weight measurements by diffusion constant in the case of nisin and by diffusion and sedimentation constants in the case of saramycetine were used to support the high molecular weights proposed for these two antibiotics. On the other hand, the extremely pertinent warning from Battersby and Craig[49] should be kept in mind: "The problem of determination of molecular size approximately 1,000 or more has never been satisfactorily solved. Such approaches as freezing-point depression, diffusion and sedimentation in the ultracentrifuge have not given results in agreement. With these methods, the state of aggregation of the molecule probably is a confusing factor. In general, this type of substance shows a strong tendency to associate and tenaciously holds solvent of crystallization."

Less equivocal molecular weights can be calculated from the examination of partially substituted products. Partial dinitrophenylation of nisin and partial esterification or salt formation of saramycetine could provide the necessary compounds and data.

With the elimination of the exceptionally high molecular weight antibiotics, we cannot only re-state our contention that peptide antibiotics are not small proteins, but also conclude that the methods used for the elucidation of structure of these compounds should be different from the methods useful in the case of proteins.

In the chromatographic methods of amino-acid analysis, elution volumes or R_F values of the components of a mixture are compared with the known elution volume

Table 2. AMINO-ACIDS FOUND IN PEPTIDE ANTIBIOTICS

Amino-acids found in antibiotics and in 'normal proteins'*	Amino-acids found in antibiotics but not reported from 'normal proteins'
L-alanine	L-β-alanine; *N*-methyl-L-alanine
L-arginine	*N*-hydroxy-L-ornithine; D-ornithine; L-ornithine
L-aspartic acid	D-aspartic acid; L-β-methylaspartic acid; L-α-amino-butyric acid; L-α,γ-diaminobutyric acid; D-α,γ-diaminobutyric acid
L-cysteine	L-lanthionine; L-β-methyllanthionine; L-*N*-*N*′-dimethyl-cystine
L-glutamic acid	D-glutamic acid; D-α-aminoadipic acid
Glycine	Sarcosine
L-histidine	
L-hydroxyproline	Allo-D-hydroxyproline; *trans*-3-hydroxy-L-proline; *cis*-3-hydroxy-L-proline
L-isoleucine	Allo-D-isoleucine; *N*-methyl-L-isoleucine; L-β-dimethyl-leucine
L-leucine	D-leucine; *N*-methyl-L-leucine; L-β-hydroxyleucine; L-2-amino-4-hexenoic acid
L-lysine	L-β-lysine
L-methionine	
L-phenylalanine	D-phenylalanine; L-phenylglycine; L-α-phenylsarcosine *N*-methyl-L-phenylalanine; *N*-methyl-L-*p*-dimethyl-phenylalanine; L-3-nitro-4-hydroxyphenylalanine
L-proline	L-γ-methylproline; β-methyl-L-proline
L-serine	D-serine
L-threonine	
L-tryptophan	
L-tyrosine	
L-valine	D-valine; *N*-methyl-L-valine; D-penicillamine; L-γ-formyl-methylnorvaline
——	L-β-(2-thiazole)-β-alanine; L-α-amino-β-phenylbutyric acid; L-α,β-diaminopropionic acid

* Amino-acids for which a genetic code triplet has been assigned (Ochoa, ref. 2).

Table 3. AMINO-ACID COMPOSITION OF NISIN

Amino-acid	Reported[33]	Proposed alternative
Isoleucine-leucine	9	3
Methionine	3	1
Valine	3	1

values or R_F values of the 20 amino-acids. This comparison is fully justified if unusual components can be excluded with reasonable certainty. This is the case in the analysis of amino-acid mixtures from hydrolysates of proteins or peptides of animal origin. It is certainly not the case in the analysis of hydrolysates from peptide antibiotics. In addition to the possibility of erroneous identifications, the quantitative analysis of amino-acid content of microbial products is beset also with the danger of miscalculation, especially if the calculation is based on the ninhydrin yield of a single component. If the latter is not a common amino-acid, but was identified by mistake with a common amino-acid, or if it is a common amino-acid formed as a secondary degradation product from an unusual component in less than theoretical amounts, then the whole calculation becomes erroneous. The only reliable way out of this dilemma is the isolation of the individual building stone from the hydrolysates in amounts which allow elemental analyses, measurement of specific rotation, and comparisons by infra-red and/or nuclear magnetic resonance spectra with authentic material. This approach was used in the studies on tyrocidin, bacitracin, and micrococcin *P*.

After completion of amino-acid analysis and sequence investigations, a structure can be proposed for a peptide antibiotic.

Independent evidence for the correctness of a proposed structure can be obtained by synthesis and subsequent bioassay of the peptide. Unfortunately, the synthesis of peptide antibiotics has been an arduous task and achieved in only a few cases. An alternative method of confirmation of proposed structures is the detailed examination of the nuclear magnetic resonance spectrum of the peptide antibiotic. Supporting evidence for the 'amino-acid' composition and to some extent for the structure of peptide antibiotics can be found in these spectra.

The nuclear magnetic resonance spectra of vernamycin $B\alpha$[47] and of thiostrepton[44] taken in deuterioacetic acid (CD_3COOD) gave very useful information. Not only is CD_3COOD a general solvent for polar compounds, but it is usually not destructive. Trifluoroacetic acid, the solvent which is commonly used in nuclear magnetic resonance spectroscopy of amino-acids, can lead to radical structural changes in antibiotic peptides[44]. Since very polar compounds such as amino-acids are also soluble in CD_3COOD, a direct comparison can be made between the spectra of an antibiotic and those of its components. The chemical shifts observed in CD_3COOD are very close to those found in $CDCl_3$ and permit a comparison with literature values. On the other hand, the chemical shifts obtained in CF_3COOH are quite different from those in $CDCl_3$. CD_3COOD is also desirable since all the exchangeable hydrogens are exchanged for deuterium and this leads to simplification and less complicated interpretation of the spectrum.

On the basis of the foregoing discussion, we conclude that antibiotic peptides are not small proteins. Their biogenesis should be investigated using conventional enzymatic techniques without complete reliance on the applicability of the genetic code to the formation of large and small peptides. The methods used for the elucidation of protein structures are not always applicable to the study of peptide antibiotics.

DISCHARGE PATTERNS OF ELEMENTS IN CAT CEREBELLAR CORTEX, AND THEIR RESPONSES TO IONTOPHORETICALLY APPLIED DRUGS

By I. McCANCE and Dr. J. W. PHILLIS
Department of Physiology, Monash University, Clayton, Victoria, Australia

IN an earlier paper[1] it was indicated that cells in the cerebellar cortex are excited by iontophoretically applied acetylcholine. Excitable neurones were found most often in the deeper areas of cortical folia and were identified as granule layer cells on the basis of their electrical activity. Other units, identified as superficially located Purkinje cells, could not be fired by iontophoretically applied acetylcholine. Purkinje cells located more deeply had not been defined in these earlier experiments. Further experiments to be described in this paper have led to a more accurate definition of the cell types concerned.

Purkinje cells can be identified by the antidromic invasion of an action potential following stimulation of their axons or axonic terminals in the cerebellar white matter or deep nuclei[2]. Cells which fired with a short, constant latency to antidromic volleys and followed 100/sec antidromic stimulation frequencies were included as Purkinje cells in this survey. Figs. 1*A* and *B* illustrate the extracellularly recorded action potentials of two Purkinje cells which were identified by antidromic invasion. Both cells were invaded by short-latency action potentials after stimulation of their axons with an electrode situated in the fastigial nucleus. Both would follow repetitive stimulation in the deep nucleus at 100/sec and both fired in response to the application of glutamic acid from one barrel of the multi-barrelled micropipette. However, they differed in their responses to iontophoretically applied acetylcholine, since the cell illustrated in Fig. 1*A* fired 15 sec after the onset of application of acetylcholine by a current of 80 n.amp, whereas the second cell failed to fire even after several applications of this drug. In a series of experiments, a number of neurones, which have been identified as Purkinje cells by their responses to stimulation in the deep nuclei or white matter, has been tested with acetylcholine and, of these, less than a quarter were considered to be excited by acetylcholine. The micropipettes routinely contained an anticholinesterase (prostigmine or tensilon) in one of their barrels and this was frequently applied before testing the cells with acetylcholine. The majority of acetylcholine-sensitive Purkinje cells initially required prolonged application of large amounts of acetylcholine before they commenced to discharge, a finding that has also been reported by Crawford *et al.*[3].

An understanding of the relationship of electrical activity to cerebellar topography has been gained with a technique for making lesions of 100–200μ diameter in the cerebellum[4]. These are formed by passing currents of 2–10 μamp for brief periods through a microelectrode barrel containing 0·1 N hydrochloric acid at sites where anatomical-electrophysiological correlations are required. The cerebellar area under investigation (tuber vermis in these experiments) is then serially sectioned and the position of the lesions ascertained. In these experiments cerebellar folia were traversed at right angles to accentuate the differences between regions.

Lesion placements have demonstrated that the following electrical recordings are characteristic of the different cortical regions. (The micropipettes used had a tip diameter of 8–12μ.) As the microelectrode proceeds through a molecular layer the record is dominated by positive deflexions of 100–300 μV amplitude and 1–3 msec duration. These tend to disappear if the electrode tip is left at a particular site and are probably the result of injury to the Purkinje cell dendrites. Similar potentials can also be evoked by the application of glutamic acid, and this is illustrated in Fig. 1*C*. Simultaneous recording of d.c. potential changes has shown that these positive deflexions are associated with the development of a local negativity with respect to an indifferent electrode on the neck muscles of the cat; this may be of the order of 10 mV. Unlike the characteristically rapid onset and cessation of glutamate action on neurone soma spikes, the positive deflexions and negative potential shift develop and recover slowly, with comparable time courses. It seems likely that the positive deflexions are the result of Purkinje cell soma discharges generated by the dendritic depolarization.

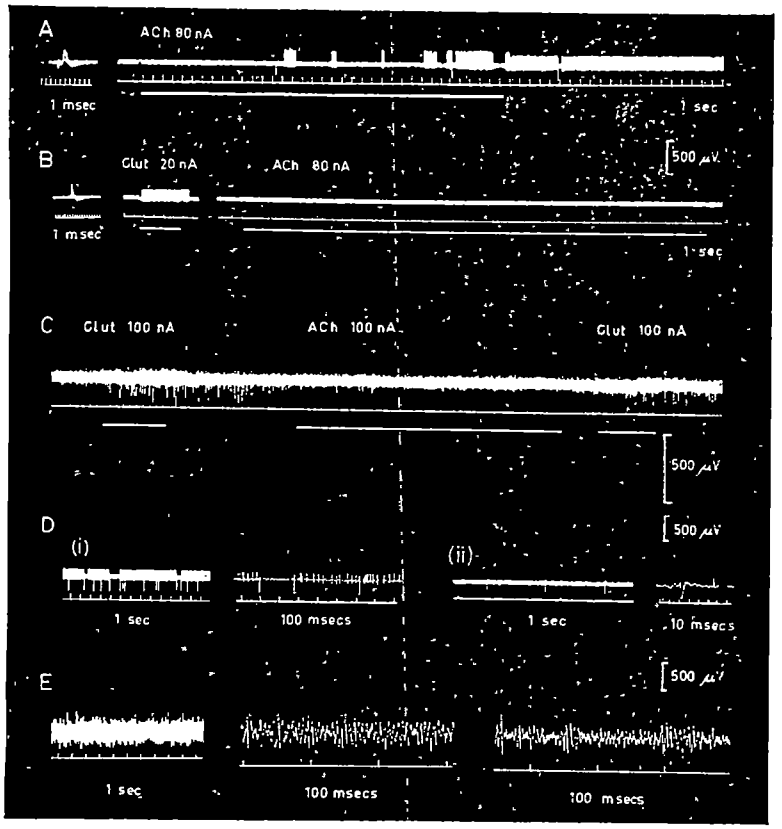

Fig. 1. Potentials (negative upwards −) recorded with a five-barrelled micropipette in cat cerebellar cortex. Solid bars indicate duration of application of drugs. *A*, Purkinje cells: successful antidromic invasion; excited by acetylcholine. *B*, Purkinje cell: successful antidromic invasion; excited by glutamate; no response to acetylcholine. *C*, Molecular layer: positive-going deflexions induced by glutamate, not by acetylcholine. *D*, Purkinje cells; positive-going potentials (i) associated with initiation and cessation of firing; (ii) regularity of firing; negative spike, superimposed on positive deflexion. *E*, Granule cell layer; firing pattern showing discharge at 160–170/sec and variations in amplitude

Neither of these phenomena could be elicited by acetylcholine.

Positive deflexions can be recorded through much of the molecular layer, but as the microelectrode tip approaches a Purkinje cell layer they frequently give way to small (about 100 μV) positive spikes which, in turn, reverse to become the characteristic negative Purkinje cell spikes (0·5–1 mV). Both positive and negative spikes are greatly accelerated by glutamic acid, the onset and cessation of action corresponding closely to the onset and cessation of application. A phenomenon characteristically recorded from this area of Purkinje cell bodies is a large (up to 1 mV) positive deflexion, which, if the cell is firing spontaneously, may frequently be associated with the initiation or cessation of firing (Fig. 1*D* (i)). Fig. 1*D* (ii), recorded from another cell, illustrates the regularity often associated with these discharges, which generally have one or more negative-going spikes superimposed on them.

A similar type of potential has been described by Granit and Phillips[2], who showed that it was associated with an intracellular depolarization. The potential can, therefore, be attributed to a relatively synchronous depolarization of the Purkinje cell dendrite tree by climbing fibres or parallel fibres. Thirty-seven of the 97 (38 per cent) Purkinje cells identified in this topographical survey were excited by acetylcholine; these were more frequently the cells that had been approached from the granule cell layer. Deeply located Purkinje cells showed a greater tendency to respond to acetylcholine. Excitation of Purkinje cells was often preceded by a discharge of adjacent units and these often fired when the Purkinje cell failed to discharge. These cells had small action potentials, and were probably situated in the granule cell layer.

Within the granule cell layer the microelectrode recorded activity that was principally the summed action potentials of groups of cells, though occasionally isolated spikes would predominate. Potentials ranged in magnitude from little more than the baseline noise-level to about 500 μV. There was a definite tendency for the amplitude of granule cell-layer activity to increase as the electrode approached a Purkinje cell layer that had not yet been penetrated.

Using the lesion technique, we have verified our earlier report that cells responding to acetylcholine occur throughout the granule cell layer; these were more frequently detected in the area of larger potentials described above. Fig. 1*E* illustrates, on slow and expanded records, the typical form of activity in these areas. The frequency of discharge in this record is 160–170/sec, and its amplitude underwent periodic modulation (7–8/sec). The activity evoked by acetylcholine on more susceptible groups of cells closely resembled the rapid discharge illustrated in Fig. 1*E*. However, there was a range of responses among sensitive cells, extending from a just demonstrable excitation to frantic activity.

The induced activity and some of the spontaneous firing could be inhibited by dihydro-β-erythroidine and hexamethonium. In areas where acetylcholine-sensitive cells were present, anticholinesterases had a powerful excitatory effect far exceeding that which might be expected of a direct action.

During these experiments it has been confirmed that acetylcholine sensitivity is more readily detectable in the depths of the cerebellar cortex. Fig. 2 shows the acetylcholine sensitivity of a population of 929 cells in the cerebellar cortex derived from experiments in which the micropipette entered the cerebellum in a series of parallel tracks commencing with one at right angles to the anterior portion of the tuber vermis. The tracks, therefore, will pass through one or more folia. The slope of the regression line is significant ($\chi_1^2 = 49 : P < 0{\cdot}01$).

Examination of the distribution of cholinesterase in the cerebellar cortex[5,6] has revealed that acetylcholinesterase is concentrated in the granule cell layer of cat cerebellum,

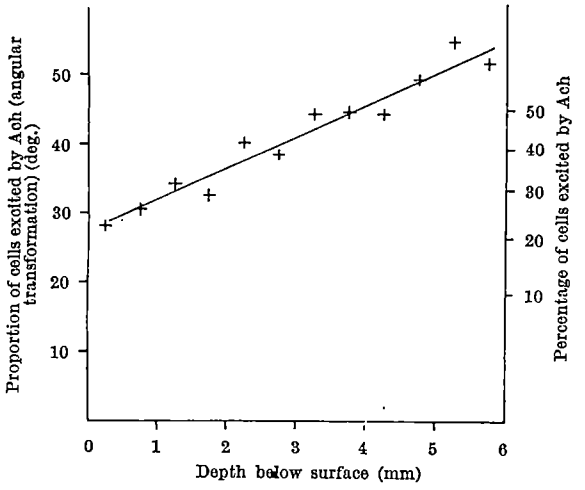

Fig. 2. Increase in proportion of cells excited by acetylcholine with increasing depth below the cerebellar surface. Depths recorded by micromanipulator; grouped into 0·5 mm classes

occurring on the surface of many granule cells and within the glomeruli. Experiments in which the middle and inferior peduncles were stained for acetylcholinesterase have shown that stained fibres were present in both peduncles, and it has been shown, using the technique of tract transection[7,8], that these fibres are running centripetally into the cerebellum. The cerebellar peduncles are known to contain choline acetylase[9,10], and, taken in conjunction with the distribution of cholinesterase, this indicates that some afferent fibres to the cerebellum are cholinergic.

The experiments described here have shown that some cells in the granule cell layer are excited by acetylcholine. This fact and the pattern of cholinesterase distribution make it likely that these may be granule cells and that a proportion of the mossy fibres terminals release acetylcholine. Since Golgi cells in the cat occur in a layer close to the Purkinje cell layer and have synaptic connexions with the mossy afferent fibres[11], it may be that these larger cells are responsible for both the greater amplitude of the discharges and the increased acetylcholine sensitivity that occurs in the area deep to the Purkinje cell layer.

Excitation of Purkinje cells with cholinergic substances has been reported previously[3], an action on dendritic receptors having been postulated. Evidence presented here suggests, rather, that Purkinje cells are being activated either as a result of stimulation of cells in the granule cell layer or by a direct action of acetylcholine on excitatory receptors on the Purkinje cell soma.

EFFECT ON TUMOUR GROWTH IN SYNGENEIC RECIPIENTS OF ANTIBODIES AGAINST TUMOUR-SPECIFIC ANTIGENS IN METHYLCHOLANTHRENE-INDUCED MOUSE SARCOMAS

By GÖRAN MÖLLER

Department of Tumour Biology, Karolinska Institutet Medical School, Stockholm 60, Sweden

SPECIFIC antigens characterizing tumour tissues and absent from normal cells have been demonstrated in tumours induced by various chemical carcinogens[1-5] and by different viruses[6-8], while analogous investigations with spontaneous mammary carcinomas and fibrosarcomas failed to reveal such antigens[2,3]. Transplantation of tumours containing tumour-specific antigens under conditions where their progressive growth is precluded (for example, by X-rays, sub-threshold isografting, etc.) may lead to immunization of syngeneic recipients. As a result, subsequent and otherwise lethal isografts of the same tumour may be inhibited to various degrees. The antigenic specificity of carcinogen-induced tumours is individually distinct and cross-reactivity between different neoplasms of the same ætiological group is rare or absent[8-10]. In contrast, tumour-specific antigens of virus-induced neoplasms appear to be identical in all tumours induced by a given virus[8]. The transplantation resistance induced by carcinogen-induced tumours in syngeneic recipients is immunological in nature, as indicated by its successful passive transfer to untreated syngeneic hosts by lymphoid cells taken from mice pre-treated with the tumour[4,9]. So far, the antigens in these neoplasms have only been demonstrated by transplantation methods, while serological techniques *in vitro* (for example, cytotoxicity) and *in vivo* (neutralization) have been negative[4,9].

Immunological enhancement has been successfully induced with leukæmias in non-*H*-2 systems[11] by passive transfer of antisera which were not cytotoxically active against otherwise sensitive target cells, such as lymphoid cells. Thus, enhancement appeared to be a sensitive test for demonstrating the presence of weak antibodies and it was attempted to apply it for the study of tumour-specific antigens in the present work.

Immune sera against tumour-specific antigens were prepared in syngeneic animals. In all experiments care was taken to avoid immune reactions against sex-determined antigens; tumours which originated in males were always transferred only into males, whereas tumours of female origin were inoculated into both sexes. Immunization was performed by inoculating trypsinized but otherwise untreated methylcholanthrene-induced tumour cells of recent origin (7th–20th transfer generation) subcutaneously into syngeneic recipients for three consecutive times. If progressively growing tumours appeared they were removed by operation. The animals were bled 10–30 days after the last inoculation.

In order to induce enhancement of the tumours, 0·1 ml. undiluted antiserum was injected intraperitoneally 30 min before the tumour inoculation and thereafter every third or fourth day until palpable tumours developed. Tumour cells were brought into suspension by exposure to 0·25 per cent trypsin for 1 h. A determined number of trypan-blue unstained cells was inoculated subcutaneously into the antiserum-treated recipients and into controls, which were untreated or treated as described with antiserum prepared in *C57BL*/10 mice against another, non-cross-reacting methylcholanthrene-induced sarcoma (*MBA*) of *C57BL*/10 origin.

The methylcholanthrene-induced sarcoma *MALA* of $(A \times C57L)F_1$ hybrid female origin, strongly antigenic according to transplantation tests[4], was inoculated subcutaneously (10^5 viable tumour cells from a trypsinized suspension) into two groups of four $(A \times C57L)F_1$ females. One control group was given 0·1 ml. immune serum directed against an unrelated methylcholanthrene-induced sarcoma (*MBA*), while the experimental group received 0·1 ml. $(A \times C57L)F_1$ anti-*MALA* serum. Both sera were injected 14 times during the first 44 days. It was found (Fig. 1) that all recipients treated with specific immune serum developed progressively-growing neoplasms, while two of four controls did not develop any palpable tumours at all. The other two controls developed progressively-growing sarcomas, which appeared later and grew slower, however. Thus, specific antiserum considerably facilitated growth in the strain of origin.

Attempts were also made to enhance the methylcholanthrene-induced sarcoma *MDAY* of $(A \times DBA/2)F_1$

Table 1. Growth of methylcholanthrene-induced sarcoma *MDAY* of $(A \times DBA/2)F_1$ origin in syngeneic recipients treated with $(A \times DBA/2)F_1$ anti-*MDAY* serum

Exp. No.	Tumour	Recipient	Treatment of recipients with:	Mean tumour diameter at the following days after transplantation: 10	14	18

origin by exposure to tumour-specific antiserum. Serum was taken from $(A \times DBA/2)F_1$ hybrids pre-treated as described. Two experiments were performed (Table 1). In the first, six injections of antiserum were given at intervals of 3–4 days and in the second nine injections at the same intervals. Controls were untreated in the first experiment and received nine injections of anti-*MBA* serum in the second: 10^5 trypsinized *MDAY* cells were inoculated subcutaneously into groups of three $(A \times DBA/2)F_1$ hybrids. In both experiments all antiserum-treated hosts developed progressively growing neoplasms, which had a shorter latency period and higher growth rate compared to the controls (Table 1).

Analogous experiments were performed with the methylcholanthrene-induced sarcoma *MC57G* of *C57BL* origin. Sera of immunized *C57BL* or $(A \times C57BL)F_1$ recipients were tested for their possible enhancing effect. Two groups of three $(A \times C57BL)F_1$ hosts received 10^5 trypsin-treated *MC57G* sarcoma cells subcutaneously. One group was treated with repeated injections of anti-*MC57G* serum while the other was untreated. In contrast to the results

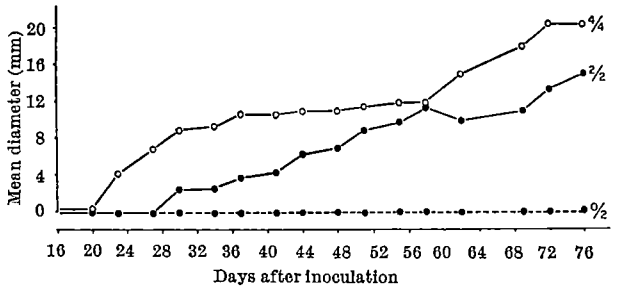

Fig. 1. Growth of 10^6 *MALA* cells of $(A \times C57L)F_1$ origin in $(A \times C57L)F_1$ hybrids repeatedly injected with $(A \times C57L)F_1$ anti-*MALA* serum (Group *A*) and in controls treated with *B*10 anti-*MBA* serum (Group *B*). The figures denote the number of mice killed by progressively growing tumours as related to the total number inoculated. Group *B* is represented by two curves: the solid line represents the mean tumour diameter in mice with palpable tumours, whereas the broken line represents mice which did not develop palpable tumours. This denotation will be followed also in the following figure. O—O, Group *A*; ●—● and ●- -●, Group *B*

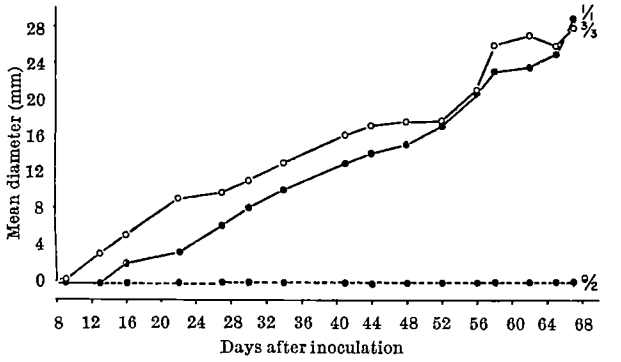

Fig. 2. Growth of 10^5 *MC57G* sarcoma cells of *C57BL* origin in $(A \times C57BL)F_1$ recipients repeatedly treated with *C57BL* anti-*MC57G* serum (Group *A*) and in untreated controls (Group *B*)

with the other sarcomas described above, the growth of this tumour was clearly inhibited in the antiserum-treated hosts as compared to untreated controls (Fig. 2) and only one of three antibody-treated recipients developed a progressively growing tumour, which showed a prolonged latency period in comparison with the three progressively growing control neoplasms.

A second attempt was made to enhance *MC57G* by using larger inoculum doses (3×10^6 cells per recipient). One group of three *C57BL* mice received eight injections of the same anti-*MC57G* serum with intervals of 3–4 days, while three others were untreated. In spite of the large inoculum dose the antibodies were clearly inhibitory as revealed by a delayed latency period, although the effect was less pronounced than with the lower cell dose.

The results presented suggest that humoral antibodies directed against tumour-specific antigens in methylcholanthrene-induced mouse sarcomas exist and can be demonstrated by their capacity to enhance or inhibit tumour growth in syngeneic recipients. Alternative explanations of the results, based on the presence of antibodies directed against isoantigens, because of residual heterozygosity of the mouse strains, or against the transplantation antigen characterizing male cells, are highly unlikely. The strains used in the experiments recorded here are all antigenically homozygous as revealed by uniform acceptance of intra-strain skingrafts and the incompatibility reactions against male antigens were excluded by the experimental design.

Attempts were made to demonstrate the presence of humoral antibodies against the tumour-specific antigens in the sera used for the above experiments by *in vitro* techniques. The cytotoxic test of Gorer and O'Gorman[12] was negative with all three sarcomas studied. The indirect fluorescent antibody technique performed on living tumour cells in suspension[13] gave positive staining reactions with *MALA* sarcoma cells treated with specific antiserum prepared in syngeneic hosts, whereas *MDAY* and *MC57G* cells gave negative reactions. The positive staining reaction with *MALA* cells was similar in nature to that seen with anti-*H2* sera: the membrane of living cells was clearly outlined by a fluorescent 'ring', whereas controls were unstained or stained with the homogenous reaction characterizing dead cells. It could be excluded that the 'ring' reaction with the *MALA* sarcoma cells was caused by antigens revealed by the trypsin treatment[8], since trypsinized sarcoma cells of another tumour (*S3A*) were entirely unstained with serum strongly efficient against *MALA* cells. The latter cells were not reacting with another immune serum prepared in syngeneic hosts against a methylcholanthrene-induced sarcoma of *C57BL*/10 origin (*MBA*). It would appear, therefore, that the positive staining reaction with *MALA* cells in the fluorescent antibody technique was caused by the presence of antibodies directed against tumour-specific antigens.

PANGLOBINOPENIA

By EMILE ZUCKERKANDL*

Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena

THE term 'panglobinopenia' designates a hypothetical hereditary inhibition of hæmoglobin synthesis distinct from thalassæmia. Whereas in α-thalassæmia the synthesis of hæmoglobin α-chains and in β-thalassæmia the synthesis of hæmoglobin β-chains are specifically inhibited, in panglobinopenia the inhibition is non-specific and involves simultaneously all hæmoglobin polypeptide chains.

Microspectrophotometric measurements of total hæmoglobin and of fœtal hæmoglobin were performed by G. Matioli on individual erythrocytes from a patient clinically characterized as a case of 'thalassæmia major'. The results of this work have been tentatively interpreted by Matioli and myself[1] as revealing a heterozygous panglobinopenia, superimposed on a heterozygous β-thalassæmia. Because of circumstances, this analysis could for the time being be based on only one single 'thalassæmic' individual. The notion of panglobinopenia had, however, been derived from an analysis of other results to be found in the literature. It is desirable to discuss these results, which furnish a background to the aforementioned publication.

While the existence of a panglobinopenia locus as distinct from the loci of α-thalassæmia and of β-thalassæmia is not demonstrated, the circumstantial evidence appears to justify the proposal of the concept. The results to be found in the literature and to be recalled here suffer from the considerable disadvantage (a disadvantage fully overcome for the first time by Matioli) that they offer only mean values relative to total cell populations. Even then conclusions of interest can be drawn, provided the data are expressed in the form of average content per cell of the different individual hæmoglobin chains, the α-, β-, γ- and δ-chains. This approach is adopted in the present article. The value for mean cellular hæmoglobin (MCH), based on the concentration of hæmoglobin in the blood and the red cell count, is used in conjunction with the percentage of the different hæmoglobin components that are present. The approximate percentage is usually established by the combined techniques of electrophoresis and alkali denaturation.

Thalassæmia or panglobinopenia ? The family, originally examined by Neel, Wells and Itano[2] and re-examined by Cohen, Zuelzer, Neel and Robinson[3] in 1959, presents a special problem. There are two normal offspring from a marriage between a normal person and a person doubly heterozygous for sickle-cell trait and what appeared to the authors to be thalassæmia trait. If the diagnosis of normality of the three offspring were genetically correct, if paternity were ensured, and if the thalassæmia were of the β-type, the findings would prove non-allelism between the β-thalassæmia gene and the β-chain gene, in opposition to the conclusion drawn from the great majority of available results[4].

The results of this family investigation, converted to mean absolute amounts of hæmoglobin chains per cell, are presented in Table 1. A third abnormal gene is present, that of hereditary spherocytosis, which appears, however, to have no influence on the amounts per cell of different hæmoglobin chains.

The siblings decisive for establishing independent segregation of the 'thalassæmia' and the β-chain genes are subjects II-5 and II-9. The presence of the sickle-cell gene allows one partly to clarify the situation. Table 2 reproduces the figures for the β^A- and β^S-chains relating to the individuals considered as thalassæmic (groups 2 and 4 of Table 1) and adds to it a column for the total β-chain. In the heterozygotes for HbS and the supposed thalassæmia (I-2 and II-3) the contribution of the β^A-chain gene is on the average 7·3 and 8·0 μμg of β^A-chain per cell. These would be good and, in the case of subject II-3, even high values for the synthetic activity of a single normal β^A-gene if it were associated with a normal allele. No known thalassæmic β-chain gene controls the production of polypeptide chain in such high amounts[5]. (The value for β-chain in the 'normal' group 1 of Table 1 is the result of the activity of the two allelic genes; it is here in general somewhat below the average normal value.)

If any β-chain gene were specifically inhibited, it would rather appear to be the β^S-gene. However, in the same family, the HbS heterozygotes without 'thalassæmia' (Table 1, group 3) produce normal amounts of β^S-chain, and the HbS-gene involved must be the same. A familial constancy of the synthetic activity of a given structural hæmoglobin chain gene is a reasonable assumption in view of the findings of Itano[6] and of the situation that prevails in thalassæmics[5]. The normal mean value for β^S-chain per cell in the peripheral circulation is 5·3 ± 1·1 μμg (ref. 5). With respect to this mean the inhibition of the β^S-chain production per cell in subjects I-2 and II-3 is seen to amount to roughly 50 per cent. Characteristically, the synthetic activity of the β^A-allele of the same subjects undergoes vicissitudes in this family quite like those observed for the β^S-gene.

When in association with the β^S-gene, the synthetic activity of this β^A-gene is normal. But when associated with another β^A-gene (subjects II-8 and III-1) its activity must be assumed to be depressed, because the total synthetic activity of the two β^A-alleles results in the average production of only about 10 μμg/cell, unless it were not the β^A-chain gene found in the 'thalassæmic' double heterozygotes, but its β^A-allele that were to be considered as 'thalassæmic' in subjects II-8 and III-1, a paradoxical assumption. Most likely both β^A-alleles display a reduced synthetic activity in subjects II-8 and III-1. The particular β^A-chain gene as well as the β^S-chain gene found in the supposedly thalassæmic individuals are, therefore, able to display a normal synthetic activity in some members of this family. Thus the presence in this family of a β-thalassæmia not only is in doubt because of the absence of an increase in Kunkel's HbA_2 component, as pointed out by Ingram and Stretton[7], but is ruled out by the behaviour of the critical β^A-chain gene itself on the defendable assumption that a given structural hæmoglobin chain gene that is thalassæmic in one individual will not be uninhibited in another[5].

The most significant observation on the present family, in the author's opinion, is the constancy of the mean total amount of β-chain in the four 'thalassæmic' individuals belonging to three generations, listed in Table 2. This total amount is the same, irrespective of whether it arises from the contributions of two β^A-chain genes or of one β^A- and one β^S-chain gene. Apparently only the limited mean total amount of β-chains that is found can be produced, and the control of this amount is distributed over whatever β-chain genes are present. In the competition for a compound that must be assumed to limit the total synthesis to the observed value, the product from the β^S-chain gene is, as usually, at an apparent disadvantage, and even more so than on the average. Yet there is a general depression of β-chain production in the individuals listed in Table 2. The amount of α-chain to be found in

Pedigree

the peripheral circulation is decreased correspondingly. It is reasonable to assume that this decrease in the amount of α-chain is a secondary effect[8]. We note, in any event, that in the cases under consideration, no non-α-chain gene appears to be inhibited specifically.

Table 2. Constancy of the Total Amount of β-chain per Cell in the 'Thalassæmic' Subjects listed in Table 1

Subject	βA-chain μμg/cell	βS-chain μμg/cell	Total β-chain μμg/cell
II-8	9·6	0	9·6
III-1	10·2	0	10·2
I-2	7·3	2·9	10·2
II-3	8·0	2·3	10·3

Can an α-chain gene be inhibited specifically? This is questioned by Ingram and Stretton[7], who consider the family re-analysed by Cohen *et al.*[3] as carrying a gene for α-thalassæmia. This interpretation cannot at present be ruled out with finality. It appears to me, however, to be of limited probability. It would seem reasonable to assume that in a heterozygote for α-thalassæmia the condition of which is not complicated by the presence of some other mutant gene, either the non-thalassæmic α-chain allele is able to make up for the thalassæmic allele to an extent sufficient for nearly all non-α-chains which are produced in normal amounts to combine with α-chains; that this can be the case is demonstrated by the α-thalassæmia—α^{I}-heterozygote investigated by Atwater *et al.*[9] (cf. Table 6, ref. 5)—or the synthetic powers of the α-chain gene fall short of this goal, and significant amounts of HbH and/or Hb 'Barts' (β_4 and/or γ_4) are produced. In the first case, and in the absence of a specifically inhibited β-chain gene, the total β-chain production would not be limited to a sub-normal level, as, in fact, it is. In the second case, HbH should have been observed by Cohen *et al.*[3]. In spite of the instability of HbH, which is liable to lead to under-estimates in quantitative assays, total mean amounts of β-chain per cell in HbH patients are occasionally found to be normal or sub-normal[5]. If α-thalassæmic, subjects I-2 and II-3 reported on by Cohen *et al.*[3] should either contain more HbA and notably more HbS per cell, or should contain in addition to what is found a mixture of HbH and Hb Augusta I (refs. 10, 11) ($= \beta_4^S$).

It seems likely, therefore, that the condition described by Cohen *et al.*[3] as a thalassæmia is neither a β- nor an α-thalassæmia. This family certainly cannot be quoted, as was done up to the time of its re-interpretation by Ingram and Stretton[7], as offering evidence in favour of independent segregation between a gene for thalassæmia and the structural hæmoglobin chain gene which shows the thalassæmic inhibition.

The family of Cohen *et al.*[3] appears not to be unique in kind. The case of Larry W., a HbC/HbA heterozygote described by Zuelzer and Kaplan[12], seems to be analogous to Cohen's *et al.* cases I-2 and II-3, except that the general inhibition of hæmoglobin chain synthesis in Larry is still more pronounced. Larry has, on the average, in μμg per cell, 7·0 α-chain, slightly less than 4·9 β^A-chain, 2·0 β^C-chain, and less than 0·14 γ-chain. The normal mean amount of β^C-chain per cell in β^C/β^A heterozygotes is 5·5 ± 2·0 μμg[5]. An α-thalassæmic individual with only 7 μμg of α-chain per cell will almost certainly possess significant amounts of HbH. The patient's blood was tested by Tiselius electrophoresis for abnormal hæmoglobins at *p*H 6·5 as well as by paper electrophoresis (*p*H unspecified), and was found to contain hæmoglobins A and C. If HbH had been present in significant amounts, it should have been detected, although in 1954 HbH would not yet have been identified as such. From the results we have good reason to believe that HbH was absent. Consequently, it appears unlikely that we are dealing with an α-thalassæmia; nor is the condition likely to be β-thalassæmia, since not only the β^A-chain gene, but also the β^C-chain gene are significantly inhibited in Larry. This implies that the β^A-chain gene is not inhibited specifically. Finally, the condition cannot be attributed to a simple deficiency anæmia, both because treatment failed and because of red-cell morphology. Let us emphasize the dual cell population noted by the authors, which includes a proportion of normal-appearing red cells—a fact of significance and in accord with the findings of Matioli[1]. (In the family investigated by Cohen *et al.*[3], discussed here, no similar phenomenon is noted. Perhaps spherocytosis, in that case, interferes with its expression.)

Expression of panglobinopenia and its relation to the synthesis of HbF and HbA$_2$. The analysis of the cases listed here, as well as of the one on which Matioli and I have reported, lead one to suspect the existence of a gene the action of which results in a general inhibition of hæmoglobin synthesis. The occurrence of such cases was predicted by Itano[6]. Whether the synthesis of all proteins is partly inhibited (as might occur in the case of a deficiency of ribosomes, in RNA-polymerase, or in other constituents) or only that of hæmoglobin polypeptide chains cannot be gathered from the available data, although the latter appears more probable in the case examined by Matioli. I therefore refer here provisionally to a panglobinopenia rather than to a panprotidopenia. Both conditions may actually exist.

The expression of the panglobinopenia gene and perhaps of the β-thalassæmia gene may be subject to variegation (cf. Lewis[13]). Matioli has indeed observed a mosaic condition of the degree of hæmoglobinization of the red cells in the case examined by him[1]. If this finding can be generalized, as the appearance of published photographs of red cell smears from 'thalassæmic' patients suggests, the clinical expression of the genomes may vary a great deal according to the proportion of affected red cells.

Homozygous panglobinopenia may be thought to be mostly a lethal condition since practically no hæmoglobin should be produced in the affected cells. The proportion (not the absolute amount per cell) of HbF should be very high because of the prevalent 'stress' condition[1,14], and the mean quantity per cell of HbA$_2$ should be below normal.

A heterozygous panglobinopenia would be characterized by a blood picture resembling that of thalassæmia, but

Table 3. Predicted Mean Amounts per Cell of HbF and HbA_2 in Thalassæmia, Panglobinopenia and Mixed Conditions

	Genetic constitution	HbF	HbA_2
1	$Th_\beta^N/Th_\beta^N.Pgl^N/Pgl^N$	Norm.	Norm.
2	$Th_\beta^T/Th_\beta^N.Pgl^N/Pgl^N$	Norm. or slightly incr.	Incr.
3	$Th_\beta^T/Th_\beta^T.Pgl^N/Pgl^N$	Strongly incr.	Incr.
4	$Th_\beta^N/Th_\beta^N.Pgl^P/Pgl^N$	Norm. or slightly incr.	Decr.
5	$Th_\beta^N/Th_\beta^N.Pgl^P/Pgl^P$	Absent or incr. Perhaps not observed	Decr. (mostly lethal *in utero*)
6	$Th_\beta^T/Th_\beta^N.Pgl^P/Pgl^N$	Incr.	Decr., norm. or incr.
7	$Th_\beta^T/Th_\beta^N.Pgl^P/Pgl^P$	Probably not observable (lethal *in utero*)	
8	$Th_\beta^T/Th_\beta^T.Pgl^P/Pgl^P$	Probably not observable (lethal *in utero*)	

Norm. = normal; incr. = increased; decr. = decreased; Th = β-thalassæmia locus; Pgl = panglobinopenia locus; superscript N = normal allele; superscript T = thalassæmia allele; superscript P = panglobinopenia allele.

HbA_2 would not be elevated. HbF, according to the degree of severity of the anæmia, would or would not be moderately elevated. Consequently this condition, on the basis of the criteria at present used, could easily be confused with an α-thalassæmia, except for the absence of HbH. This absence, however, does not rule out α-thalassæmia. Cases of heterozygous panglobinopenia may commonly be classified as 'thalassæmia minor'.

A pure heterozygous β-thalassæmia without panglobinopenia would mostly appear phenotypically normal or only slightly thalassæmic, but would in all cases be characterized by an increase in absolute amounts per cell of HbA_2. There would mostly be no increase or a moderate increase in the HbF component and the clinical picture would be most commonly that of 'thalassæmia minima'.

A pure homozygous β-thalassæmia would show significant increase not only in the HbA but also in the HbF component. True homozygous thalassæmia is expected to represent always a very severe, 'major' condition. The latter statement is made in view of the absence of any evidence for the existence of moderately inhibited thalassæmic β-chain genes (cf. ref. 5, Table 7).

A double heterozygote for β-thalassæmia and panglobinopenia would show elevated values for HbF because of the 'severity' of the condition, while the mean cellular amounts of HbA_2 would be variable, in part, according to the degree of variegation that may be observed at the level of the individual red cells. The clinical characteristics may be those of 'thalassæmia major'.

These predicted relationships are summarized in Table 3. Conditions 7 and 8 would be expected to occur only if the thalassæmia and panglobinopenia loci are not closely linked.

It is interesting that Table 3 predicts a decrease in absolute amounts per cell in the HbA_2 component in some cases which will be clinically characterized as thalassæmia major, namely in double heterozygotes for panglobinopenia and thalassæmia. The mean amount per cell of δ-chain is increased in heterozygous thalassæmia, but in a number of cases is less than doubled. If a heterozygosity for panglobinopenia is superimposed on such a situation, it is to be expected that the mean average amount of δ-chain per cell will be slightly below normal.

In conclusion, the multiplicity of the phenotypic manifestations in thalassæmia can, in part, be accounted for if the two following assumptions are justified:

(1) There are cases of pure thalassæmia, of pure panglobinopenia, and of mixed thalassæmia and panglobinopenia, each of these presenting a different picture.

(2) Within each of these categories, further variation is brought about by a variability in the mosaic condition (variegation) that seems to be observed, the mutant genes being expressed, within different individuals and/or different families, in different proportions of the cell population.

Although panglobinopenia should occur in conjunction with α-thalassæmia as well as with β-thalassæmia, the fragmentary topical data that are available do not warrant a discussion of this matter here.

FACILITATION OF HOST LYMPHOID TISSUE DEVELOPMENT IN NEONATALLY THYMECTOMIZED MICE BY INJECTION OF ALLOGENEIC DISPERSED THYMUS CELLS

By Dr. EDMOND J. YUNIS*, Prof. CARLOS MARTINEZ†, JUNE SMITH and Prof. ROBERT A. GOOD‡

Department of Physiology and the Pediatric Research Laboratories of the Variety Club Heart Hospital, University of Minnesota, Minneapolis

THE growth failure, early mortality and immunological deficiency of neonatally thymectomized mice may be prevented by several procedures: grafting of syngeneic or allogeneic thymus[1,2], injection of adult syngeneic spleen or lymph node cells[2–4], and intraperitoneal implantation of 'Millipore' chambers containing thymic tissue[5,6]. More recent investigations have established that thymus cells obtained from new-born or adult thymus can also provide immunological reconstitution of neonatally thymectomized mice[7,8]. Analysis of the immunological characteristics of the spleen and lymph node cells of the mice restored with allogeneic thymus cells has heretofore shown that these are of donor competence[7] and that the restoration is apparently not a function of the humoral factor capable of reconstituting host cell competence following intraperitoneal implantation of allogeneic thymus in 'Millipore' diffusion chambers.

The purpose of this article is to present evidence that administration of large numbers of fully dispersed neonatal thymus cells can facilitate, to some extent, the host cell development of the spleens of mice thymectomized in the new-born period.

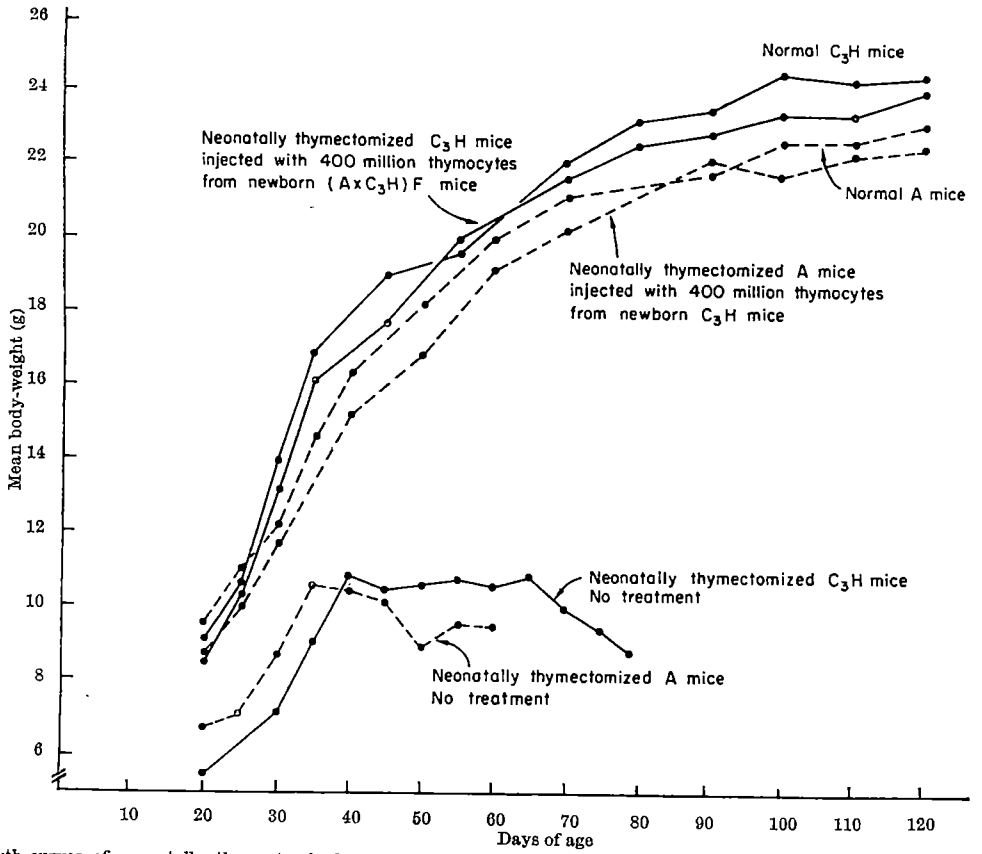

Fig. 1. Growth curves of neonatally thymectomized mice injected with allogeneic or hemi-allogeneic new born thymocytes, compared with intact and neonatally thymectomized animals of both strains. The points on the curves are mean values

Mice of the *C3H* and *A* strains of both sexes were thymectomized within 24 h after birth by the method routinely used in this laboratory[9]. Thymectomized *A* and *C3H* strain mice were given intraperitoneal injections of isolated thymic cells obtained from new-born mice of *C3H* or $(A/C3H)F_1$ strains. Two intraperitoneal injections of 50 million viable cells were given each week over a four-week period, beginning on the fifth day of life. Suspensions of viable, fully dispersed cells from thymus were prepared in Ringer's lactate saline solution, using a loose-fitting Potter–Elvehjem glass homogenizer. Further dissociation of the cells was completed by passing the suspension gently in and out of 24-, 27- and 30-gauge needles. Another group of neonatally thymectomized mice (*C3H*) were grafted with hemi-allogeneic new-born thymus $(A/C3H)F_1$ five days following thymectomy. The entire thymus from the new-born donors was introduced into the subcutaneous tissue of the dorsal region of the recipients.

Neonatally thymectomized mice were evaluated by the following parameters: changes in body-weight, survival to 120 days of age, capacity to reject skin homografts, and the capacity of spleen cells derived from the treated mice to produce splenomegaly after injection into appropriate F_1 hybrids. The immunogenetic characteristics of the spleen cells from thymectomized *A* strain mice given *C3H* thymus cell suspensions were examined by the discriminating spleen assay of Simonsen and Jensen[10]. In this assay 30 million spleen cells from 2–3-month-old animals of both the experimental and control groups were used.

In one group of experimental animals (*C3H* mice neonatally thymectomized and treated with thymus cells or thymus grafts from new-born $(A/C3H)F_1$ donors), the discriminating spleen assay of host component was used[10]. Ten million spleen cells from experimental and control groups were administered intraperitoneally to 8-day-old $(C3H/C57BL)F_1$ mice. Litters of 6–8 animals were injected, in groups of one or two, with spleen cells from: (*a*) 2-month-old intact *C3H* mice (positive control); (*b*) 2–3-month-old $(C3H/C57BL)F_1$ animals (negative control); (*c*) 2–3-month-old $(A/C3H)F_1$ mice (negative experimental control); (*d*) 2–3-month-old *C3H* neonatally thymectomized mice treated with either 400 million $(A/C3H)F_1$ thymus cells or $(A/C3H)F_1$ thymus grafts from new-born donors (experimental group). Eight days after cell administration the hybrids were killed, their spleen and body-weights determined, and relative spleen weights (mg/100 g body-wt.) calculated. Finally, spleen indices were calculated. The mean of the log of each relative spleen weight was determined and the differences between the experimental group and the positive and negative control groups evaluated by the '*t*' test. The experimental spleen index was calculated using the experimental control as the divisor, because these cells caused slightly greater splenomegaly in the $(C3H/C57BL)F_1$ hybrids than did syngeneic cells, perhaps a reflexion of host versus graft activity.

At two months of age, a group of *A* and *C3H* thymectomized mice treated with allogeneic or hemi-allogeneic thymus cells were grafted[11] with skin from mice of the same strain as the donor of the thymocytes and with skin of an unrelated strain (*BALB/c*). All reconstituted neonatally thymectomized mice were killed at 120 days of age. Extensive search was made in each thymectomized mouse with a stereoscopic microscope and sample serial

Table 1. Survival of Neonatally Thymectomized Mice treated with Allogeneic Dispersed Thymus Cells from New-born Donors

Thymectomized recipient strain	Treatment	No. of thymus cells	Survivors at 120 days
A	50×10^6 *C3H* thymus cells intraperitoneally at 5, 8, 12, 15, 18, 20, 22 and 24 days of age	400×10^6	9/10
	None	None	0/17*
C3H	50×10^6 $(A \times C3H)F_1$ thymus cells intraperitoneally at 5, 8, 12, 15, 18, 20, 22 and 24 days of age	400×10^6	12/12
	None	None	0/24†

* All mice died before 70 days of age. † All mice died before 89 days of age.

sections obtained to rule out thymic remnants. In none of the animals included here could remnants of thymus tissue be found.

The results of these experiments show, first of all, that neonatally thymectomized mice injected with thymus cells obtained from new-born hemi-allogeneic or allogeneic mice show steady increase of weight, do not develop wasting disease, and survive for prolonged periods (Fig. 1) (Table 1).

Assessment by discriminating spleen assay of the immunogenetic composition of the spleens of thymectomized *A* strain mice injected with thymus cells from new-born *C3H* mice showed that host *A* cells did not contribute significantly to the immunological reconstitution (Table 2). This result was similar to an earlier study of this same strain combination in which 300 million adult *C3H* thymocytes were used in the inoculum[7].

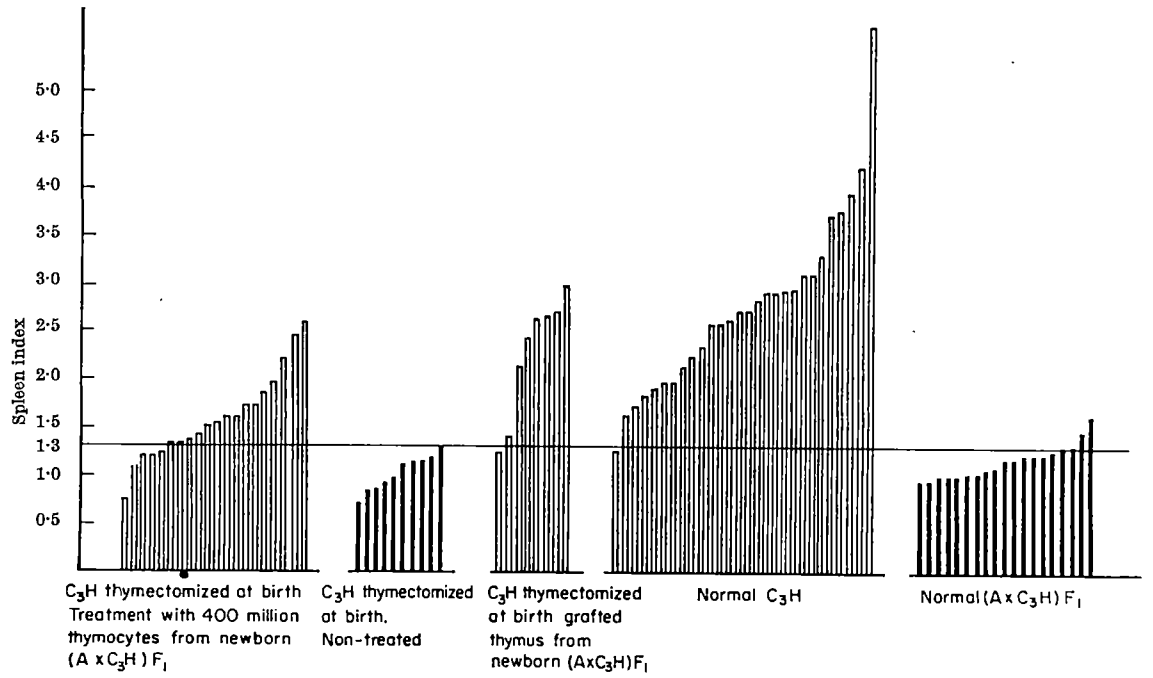

Fig. 2. Graft versus host assays of spleen cells from neonatally thymectomized *C3H* mice treated with either a thymus graft or thymocytes from new-born $(A \times C3H)F_1$ donors. The solid bars represent spleen indices calculated with the relative spleen weights of syngeneic cell-injected $(C3H \times C57BL/1)F_1$ animals as the divisor. The other indices were calculated with the relative spleen weights of $(A \times C3H)F_1$ cell-injected $(C3H \times C57BL/1)F_1$ mice as the divisor. They show the relative activity of the positive controls (normal *C3H*), of the neonatally thymectomized *C3H* animals grafted with neonatal $(A \times C3H)F_1$ thymus, and of the neonatally thymectomized *C3H* animals treated with new-born $(A \times C3H)F_1$ thymus cells. There was significant restoration of host reactivity in most of the thymus-grafted animals, and in about half the thymus cell injected mice

The discriminating spleen assay of host component in the spleens of neonatally thymectomized *C3H* mice grafted with $(A/C3H)F_1$ thymus showed a predominant host component (Table 3), consistent with the earlier observations of Dalmasso *et al.*[2]. This assay also showed significant host reactivity in the spleens of some *C3H* animals receiving new-born $(A/C3H)F_1$ thymus cells, as shown in Table 3. As indicated earlier, administration of spleen cells from adult $(A/C3H)F_1$ mice to the test $(C3H/C57BL)F_1$ hybrids resulted in a slight increase of the relative spleen weights; hence the mean relative spleen weights of the test hybrids receiving $(A/C3H)F_1$ cells were used as the divisor in calculating the spleen indexes shown in Table 3 and Fig. 2. Of the 10 experimental neonatally thymectomized animals injected with hemi-allogeneic $(A/C3H)F_1$ cells, five were capable of inducing significant splenomegaly in the $(C3H/C57BL)F_1$ hybrids. The levels of statistical significance varied from 0·01 to 0·005. The values of the positive controls were statistically significant at a level between 0·0001 and 0·01.

The restoration of immunological capacity of the neonatally thymectomized mice injected with new-born thymocytes was also revealed in the skin-grafting studies, summarized in Table 4. All the mice tested accepted skin from the same strain as the thymocyte donors, and rejected skin from a third strain.

These results demonstrate that mice thymectomized at birth can be immunologically reconstituted by injections of isolated thymus cells obtained from allogeneic new-born donors. The results with neonatally thymectomized *A* mice injected with new-born *C3H* cells corroborate our previous results which showed that reconstitution is entirely attributable to donor cells when the neonatally thymectomized *A* strain mice were treated with *C3H* thymus cells obtained from adult donors. The experiments on neonatally thymectomized *C3H* mice injected with large numbers of fully dispersed $(A/C3H)F_1$ thymus cells show that some of the animals develop immunologically competent cells of host characteristics in their spleens. The effect observed could, of course, be consequent to seeding of thymic stromal cells to other parts of the body where they can exercise their hormone-secreting function. Alternatives exist, however, and it seems entirely possible that a trephocytic function of the donor cells or other forms of cell–cell interaction could account for development of immunological capacity in host cells under the conditions of these experiments. Whatever the basis, it seems clear that permission for development of immunological capacity of host cells may be provided by fully dispersed allogeneic thymus cells in at least some strain combinations.

Table 4. SKIN HOMOGRAFT SURVIVAL IN NEONATALLY THYMECTOMIZED MICE INJECTED INTRAPERITONEALLY WITH THYMUS CELLS FROM NEW-BORN MICE

Group	Skin grafts*

SPECIFICITY OF THE INTERACTIONS BETWEEN HISTONES AND DEOXYRIBONUCLEIC ACID

By E. W. JOHNS and PROF. J. A. V. BUTLER, F.R.S.

Chester Beatty Research Institute, Institute of Cancer Research: Royal Cancer Hospital, Fulham Road, London, S.W.3

RECENT experiments have shown that DNA free from histone can act as a template for the synthesis of RNA, under the influence of the RNA polymerase demonstrated by Weiss[1] and Hurwitz *et al.*[2], while the native nucleoprot ein has been shown to have little ability in this direc tion[3]. Furthermore, the addition of histone to DNA in amounts approaching those present in the native complex markedly reduced the ability of DNA to promote RNA synthesis[4,5].

These observations support the view originally expressed by Stedman and Stedman[6] that histones control gene function; but they do not provide a mechanism whereby the DNA of active genes may be uncovered and that of inhibited genes covered by histones in differentiated cells. In fact, few differences have been found so far between histones from different tissues of the same or even of widely different animals, although little precise knowledge exists of the relative amounts of the various histone fractions[7].

The question whether there are specific interactions between the DNA of different genes or classes of genes and particular kinds of histone molecules is thus of considerable interest. A number of distinct histone fractions of well-defined composition (designated *F1*, *F2a*, *F2b*, *F3*) have been obtained in this laboratory. Although these are known to be capable of further resolution, their differences of composition and character are considerable[8], and they may be expected to be sufficiently distinctive to yield information about the specificity of DNA–histone interactions. The experiments described here were all carried out with DNA and histones obtained from calf thymus. The DNA was prepared by the method of Kay, Simmons and Dounce[9] and the methods of preparing the histone fractions have been recorded[8].

(1) *Precipitation of DNA from solution with increasing amounts of histone.* The concentration of histone at which the first precipitation occurs depends on the salt concentration, and at low ionic strengths higher proportions of histones have to be added to cause precipitation. However, in previously reported experiments[10] it was found that each histone fraction, in sufficient amount, is capable of precipitating almost the whole of the DNA in 0·9 per cent sodium chloride. The lysine-rich fraction, *F1*, precipitates the DNA at a lower concentration than

Fig. 1. Starch-gel electrophoresis patterns of histones present in nucleoproteins prepared by the successive addition of DNA to excess histone. *a*, Whole histone; *b*, first precipitate; *c*, second precipitate; *d*, third precipitate; *e*, fourth precipitate

the other fractions, which are similar in their precipitating power. Thus, almost complete precipitation of DNA is obtained with *F*1 when the ratio of histone to DNA (w/w) is about 0·8, but with the other fractions the ratios required for complete precipitation are about 1·5 or higher.

(2) *Addition of histone fractions to excess of DNA.* It was suggested by Huang, Bonner and Murray[11] that if an opportunity of equilibration is given by mixing DNA and histone in a strong salt solution (in which the complex is dissociated) and reducing the concentration of salt slowly by dialysis, the histones will find their positions of 'maximum stability' on the DNA. If this is true, when specific histone fractions are added to excess DNA in sufficient quantity to precipitate the major part of it, one might expect to find that the DNA remaining in solution has distinctive properties which might be demonstrated by a variation in the base ratios.

To test this, about 15 mg of histones *F*1 or *F*3 were added to 50 mg of DNA in 2 M sodium chloride. The solution was dialysed to 0·14 M sodium chloride and the precipitated nucleoprotein removed. Under these conditions, using a deficiency of histone, *F*1 gives a fibrous precipitate, while *F*3 forms a gel. The base ratios of the DNA remaining in solution (about 20 per cent in the case of *F*1 and 10 per cent in the case of *F*3) were determined. The results shown in Table 1 indicate that only slight fractionation of the DNA resulted, much less than can be produced by differential extraction of DNA from the denatured nucleoprotein by salt solutions[12].

(3) *Addition of DNA to excess of whole histone.* If different portions of DNA combine specifically with particular fractions of histone, the addition of DNA to an excess of the homologous whole histone should result in the precipitation of nucleoprotein containing histones in the proportions in which they are present in the native nucleoprotein.

Successive portions of DNA (50 mg in 10 per cent sodium chloride) were added to a quantity (400 mg) of whole histone from calf thymus dissolved in 10 per cent sodium chloride. The mixture was dialysed against water

Table 1. Base Ratios in DNA remaining after Precipitation with Histone Fractions *F*1 and *F*3

	G	*A*	*C*	*T*
Original DNA	23·8	28·0	21·8	26·6
DNA remaining after precipitation with *F*1	26·0	25·7	23·4	24·8
DNA remaining after precipitation with *F*3	24·0	27·2	23·5	25·4

The bases were determined by the method of Wyatt[13] and are expressed as a percentage of all bases recovered.

to 0·9 per cent salt concentration and the precipitate collected. After bringing the salt concentration up to 10 per cent again, a similar addition of DNA was made and the dialysis and collection of precipitate repeated. This was carried out twice more and the histones present in the precipitates were extracted with 0·25 N hydrochloric acid and examined by starch-gel electrophoresis at *p*H 2·3 as previously described[14] (Fig. 1). It can be seen that DNA does not combine with the histone fractions in their 'natural' proportions. The first two precipitates contain histones *F*2*a*, *F*2*b* and *F*3; the third precipitate contains *F*2*a*, *F*2*b*, *F*1 and a little *F*3 in proportions which cannot be exactly evaluated, and the fourth contains *F*1 only, which is also the only histone present in the solution after the whole series of additions. Table 2 gives information about the approximate amounts of histone and DNA in the different precipitates.

Table 2. Composition of Precipitates formed on Successive Addition of DNA to whole Histone

Successive additions of 50 mg DNA to solution containing 400 mg tota histone

Addition of DNA	Composition of precipitate (mg) DNA	Histone	Ratio *H*/*D* in precip.	Nature of histones in precipitate
1	47	107	2·3	*F*2*a*, *F*2*b*, *F*3
2	45	70	1·55	*F*2*a*, *F*2*b*, *F*3
3	40	40	1·0	*F*2*a*, *F*2*b*, *F*1 and trace *F*3
4	40	25	0·62	*F*1 only

(4) *Addition of excess of histone fractions to DNA.* It is of interest to determine the amounts of the histone fractions which can combine with DNA. An excess (180 mg) of each histone fraction in 10 per cent sodium chloride was added to 45 mg of DNA in the same medium. The mixtures were dialysed against water until the salt concentration was 0·9 per cent (0·14 M). The precipitates, which contained nearly all the DNA, as judged by the extinction of the supernatant at 260 mμ, were collected, washed twice with 80 per cent EtOH, three times with acetone and dried. The ratios of histone to DNA (*H*/*D*) in the precipitates were determined in two ways: (1) by the weights of the precipitates obtained knowing that all the DNA had been precipitated; (2) by nitrogen and phosphorus analyses. The results given in Table 3 are averages obtained by these two methods, which did not differ by more than 10 per cent. It can be seen that under these conditions much less of fraction *F*1 is required to precipitate the DNA than the other three fractions.

Table 3. Ratios of Histone to DNA in Precipitates of DNA with Different Histone Fractions

Histone fraction	*H*/*D*
*F*1	0·9
*F*2*a*	2·3
*F*2*b*	1·4
*F*3	1·5

These experiments do not provide any evidence for specific interactions between specific histones and parts of the DNA which are different in composition, even when, by slow dialysis from a concentrated salt solution, an opportunity is given for the histone molecules to find positions of maximum stability. While each of the histone fractions is capable of precipitating all the DNA, there are, however, marked differences in the modes of combination of the different histones. Much less of the lysine-rich fraction *F*1 than of the other fractions is required to precipitate a given quantity of DNA. This indicates that the mode of combination of *F*1 is different from that of the other fractions and this may explain the greater effectiveness of the fraction in inhibiting RNA synthesis[4,11]. The differences between *F*1 and the other histones are

too great to be accounted for in terms of its rather greater proportion of basic groups. On the other hand, *F*1 is less strongly bound in the natural nucleoprotein than the other fractions, as is shown by the fact that it is more easily extracted by dilute acids[15], and also, as shown previously, in a mixture of histones, *F*1 is the last to be precipitated by DNA. It is therefore unlikely that experiments with reconstituted nucleohistones can throw any light on the parts of the DNA covered by particular histones in the native state.

VIRUS SPECIFIC RIBONUCLEIC ACIDS IN BABY HAMSTER KIDNEY CELLS INFECTED WITH FOOT-AND-MOUTH DISEASE VIRUS

By Dr. F. BROWN and B. CARTWRIGHT

Animal Virus Research Institute, Pirbright, Woking

IT is now generally accepted that double-stranded DNA replicates by a progressive separation of the two strands and the formation on each of a complementary strand. The demonstration by Sinsheimer *et al.*[1] that the single-stranded DNA of bacteriophage φ × 174 becomes double-stranded during replication raised the question of whether double-stranded structures are also produced during the multiplication of the single-stranded RNA viruses. Montagnier and Sanders[2] have provided evidence that a double-stranded infective RNA is produced in Krebs II ascites cells infected with mouse encephalomyocarditis virus, and more recently Darnell *et al.*[3] have demonstrated a double-stranded RNA in HeLa cells infected with poliovirus, although in these experiments the RNA was not examined for infectivity. Double-stranded RNA molecules have also been found during the multiplication of the bacteriophages MS_2 (ref. 4) and R_{17} (ref. 5).

In the work described here it is shown that infection of cultured baby hamster kidney cells with foot-and-mouth disease (FMD) virus leads to the appearance in the cells of 3 distinct ribonucleic acids which can be separated by centrifugation in sucrose gradients. All 3 are infective but only one is destroyed by ribonuclease.

Monolayers of a cloned strain (*C* 13) of a baby hamster kidney cell line *BHK* 21 (ref. 6) were infected with FMD virus of type O (strain 1) which had been given 10–15 passages in *BHK* cells. After washing free from phosphate, the cells were incubated in a low-phosphate medium containing carrier-free phosphorus-32-labelled phosphate and 1 μg/ml. actinomycin *D*. The actinomycin was included in the medium to prevent the uptake of phosphorus-32 into ribosomal RNA. This concentration of the inhibitor has no effect on FMD multiplication in *BHK* cells[7]. After incubation for 6 h at 37° the cell sheets were washed in Eagle's medium to remove as much unincorporated phosphorus-32 as possible and then extracted with phenol at 2°. The aqueous layer containing the RNA was then extracted twice with ether and centrifuged immediately on a sucrose gradient. Fractions collected from the bottom of the tube were assayed for radioactivity and ultra-violet absorbancy at 260 mμ. The details of the fractionation and the results of a typical experiment are shown in Fig. 1. The distribution of radioactivity and ultra-violet absorbancy from the fractionation of the RNA from uninfected *BHK* cells incubated in phosphorus-32 and actinomycin *D* is shown for comparison. The results show the presence in the RNA from infected cells of 3 radioactive peaks which are not present in the RNA from uninfected cells.

As the RNA prepared in this way is contaminated with phosphorus-containing substances of low molecular weight, it was important to establish that the material in the radioactive peaks was acid-insoluble RNA. Aliquots of each fraction from the sucrose gradient from one experi-

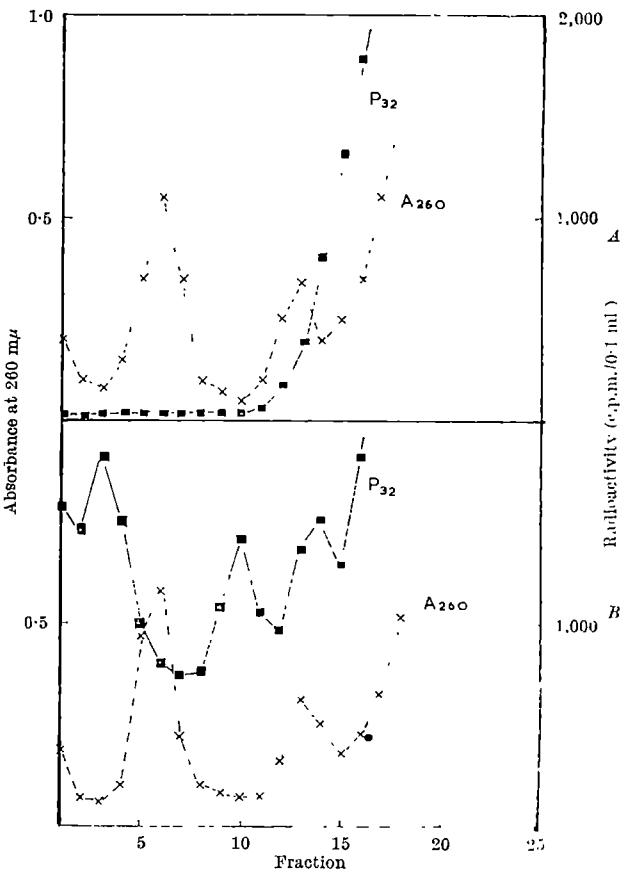

Fig. 1. Sedimentation in sucrose gradient (5–25 per cent) of RNA extracted from actinomycin-inhibited *BHK* cells (*A*) uninfected (*B*) 6 h after infection with FMD virus (16 h 24,000 r.p.m. *SW* 25 in *tris*-hydrochloric acid, 0·005 M, EDTA 0·02 M, *p*H 7·2)

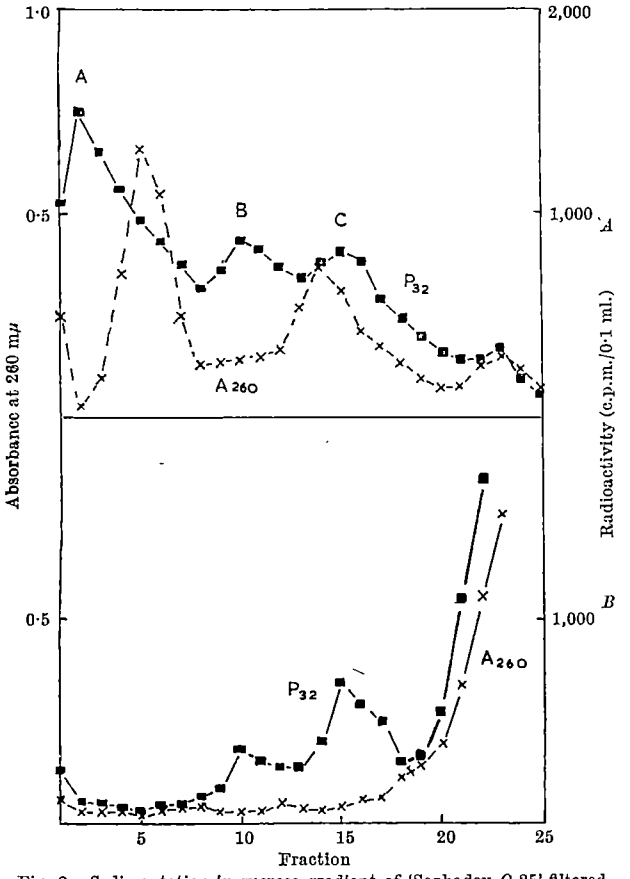

Fig. 2. Sedimentation in sucrose gradient of 'Sephadex G-25' filtered RNA from actinomycin-inhibited *BHK* cells 6 h after infection with FMD virus (*A*) untreated (*B*) after incubation with 0·01 μg RNase/ml.

ment were therefore mixed with cellular RNA and then precipitated with cold 5 per cent trichloroacetic acid (final concentration) and the radioactivity contained in the washed precipitate was measured. These experiments confirmed the presence of 3 additional radioactive peaks in the RNA prepared from infected cells. In further experiments the phenol extracts were filtered through a column of 'Sephadex *G*-25' (41 cm × 1·5 cm) before centrifugation on the sucrose gradient. Fig. 2*A* shows the distribution of radioactivity and ultra-violet absorbancy when RNA which had been purified in this way was centrifuged in a sucrose gradient under the same conditions as described for Fig. 1. The relative amounts of radioactivity in the 3 peaks *A*, *B* and *C* were usually as shown in Figs. 1 and 2, but in some experiments the radioactivity in peaks *B* and *C* exceeded that in peak *A*.

When the RNA from infected cells was incubated with 0·01 μg RNase/ml. for 10 min at 20° prior to centrifugation, all the ultra-violet absorbing material was then found at the top of the tube (Fig. 2*B*). In contrast, the radioactivity in peaks *B* and *C* still sedimented to approximately the same positions as previously, but peak *A* was lost and the radioactivity from this peak was then located at the top of the tube.

Preliminary experiments showed that the RNA extracted from *BHK* cells 6 h after infection was highly infective for *BHK* cells. For the purpose of this assay, which has recently been developed in this laboratory[8], monolayers of *BHK* cells were washed twice in phosphate-buffered saline, once in 1 M sodium chloride in 0·04 M phosphate, *p*H 7·6, and the RNA added in 2 M magnesium sulphate in 0·1 M *tris*, *p*H 7·6. After absorbing for 15 min at 20°, the sheets were washed with phosphate-buffered saline and then overlaid with nutrient agar. After 2 days at 37°, the plates were stained with neutral red to reveal the plaques. A small proportion of the RNA from infected cells resisted the action of RNase at a concentration of 0·01 μg/ml. Determination of the infectivity of the individual fractions from a sucrose gradient centrifugation of infected cell RNA showed that the bulk of the infectivity was present in peak *A* but small amounts were present in the region of peaks *B* and *C*. Treatment of the individual fractions from the gradient with 0·01 μg RNase/ml. destroyed the infectivity of peak *A*, but the fractions in peaks *B* and *C* were still infective, although the infectivity was lower than in the untreated fractions. The lower infectivity in the region of peaks *B* and *C* following RNase treatment may be due to destruction of the trailing edge of peak *A* which would be present in these fractions prior to enzyme hydrolysis.

These experiments show that, as with the multiplication of encephalomyocarditis[2] and polio[3] viruses, RNase-resistant RNA molecules are produced during FMD virus replication. The experiments described here for FMD virus replication differ from those with encephalomyocarditis and polio viruses in that a third RNA molecule, which is specific to virus infection, is observed by centrifugation in sucrose gradients. The question of whether the RNA molecules in peaks *B* and *C* are double-stranded awaits the results of accurate base ratio analyses. The role of these molecules in the replication of FMD virus is being investigated.

PLANT POPULATION AND CROP YIELD

By E. F. I. BAKER

Agricultural Research Division, Moor Plantation, Ibadan, Western Nigeria

UNDER the above title, Holliday[1] has described the relationship between population per unit area and crop yield. He defined two basic types of relationship and expressed them graphically. One form gave a curve which was approximately parabolic in shape and was typical of the yield response to population change when yield was a function of the fertilization process. The second relationship defined was asymptotic and was claimed to be typical of the yield response to population change when yield was a function of vegetative growth.

At Ibadan, Western Nigeria, population investigations have been carried out over a number of years with the white yam, *Dioscorea rotundata* Poir, the yield of which is a tuber and thus a function of the vegetative growth of the plant.

Yams are grown from tuber cuttings, termed setts, and in this note 'sett' will refer to the planting material used for an individual plant whereas 'seed rate' will refer to the total weight of setts used per unit area.

In much previous work on this subject seed rate was directly proportional to the population per unit area because sett weight was kept constant. Yam setts, however, may weigh anything from a few ounces to six pounds[2], and in the present investigation treatments were

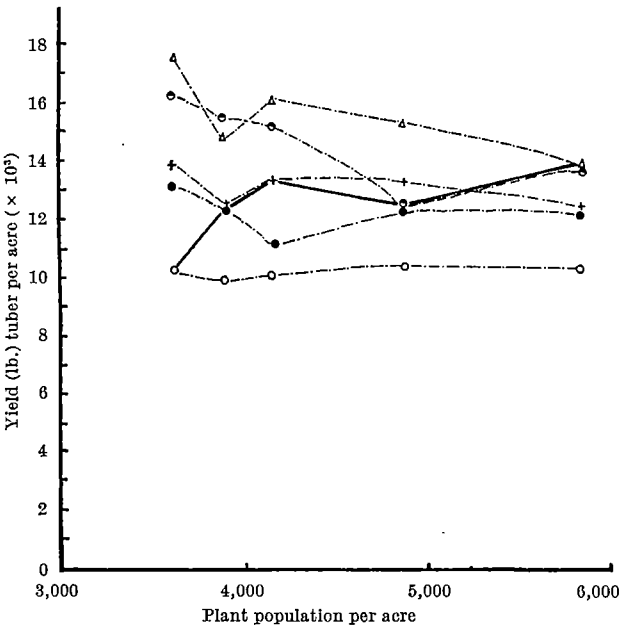

Fig. 1. Responses to population change at different seed rates per acre as yield per acre (lb. tuber). Seed rate per acre: ○, 1,815 lb.; ●, 1,936 lb.; +, 2,074 lb.; ◓, 2,420 lb.; △, 2,904 lb.; ○—●—◓—△, constant sett weight (8 oz.)

so designed that the effect of population on yield could be determined when sett weight was constant at eight ounces, and when sett weight varied but seed rate remained constant. The full range of treatments is given in Table 1 and the design and layout of the experiments is fully discussed by Freeman[3].

Thus the effects of population on yield when seed rates were constant could be obtained from treatments along the row in Table 1, while the effect of population on yield when sett weight was constant could be obtained from treatments along the leading diagonal (underlined in Table 1).

The results, shown graphically in Fig. 1, indicated that an asymptotic curve was only obtained when sett weight was constant and seed rate was proportional to population. When seed rate was maintained constant the yield response to population change was approximately linear and the slopes of the curves for the different seed rates were themselves in linear relationship to the seed rate per unit area. Regression coefficients for the five curves relating population to yield per acre at the different seed rates are given in Table 2.

Table 1. Experimental Treatments

Seed rate per acre	Sett weight in lb.				
2,904 lb.	0·500	0·600	0·700	0·750	0·800
2,420 lb.	0·417	0·500	0·583	0·625	0·667
2,074 lb.	0·357	0·428	0·500	0·536	0·571
1,936 lb.	0·333	0·400	0·467	0·500	0·533
1,815 lb.	0·312	0·375	0·437	0·469	0·500
Population (No. of plants per acre)	5,808	4,840	4,149	3,872	3,630

Table 2. Regression Coefficients for Population against Yield at Different Seed Rates per Acre

Seed rate (lb.)	b
1,815	+0·0631
1,936	−0·1498
2,074	−0·3359
2,420	−1·3783
2,904	−1·2038
b'	−0·001297

Although the individual regression coefficients, b, were not significantly different from zero, the linear by linear component of the interaction between population and seed rate was significant at the 5 per cent level in the analysis of variance. The significance of this interaction was fully supported by b', the regression coefficient of the values of b on seed rate. This regression coefficient was highly significant:

$$(b' = -0{\cdot}001297 = 0{\cdot}000405).$$

With the variety of *Dioscorea rotundata* used in these experiments, cultivar 'Olonko', only one shoot per sett was produced and large setts may be expected to produce more vigorous plants than small setts[4]. The change in the slope of the curves relating population to yield, reflected by b', was a measure of the increased intensity of competition experienced by the more vigorous plants produced from the larger setts at the higher seed rates.

Holliday[5] has stated that the relationship between yield and population, when yield is a function of vegetative growth, may be simply given in terms of the reciprocal of the yield per plant. Expressed in this form the relationship between yield and population is approximately linear and is written:

$$\frac{1}{Y_p} = a + bx \qquad (1)$$

where Y_p is the yield per plant and a and b are constants at population x per unit area.

Fig. 2 shows the curves obtained for the different seed rates per acre. There was no difference between the slopes of the curves, but the intercept at the y axis of each curve was related to seed rate. Thus the value of a in equation (1) was no longer constant but varied with seed rate. A further term must therefore be introduced into the equation to allow for the effect of seed rate, w, on yield. Thus:

$$\frac{1}{Y_p} = (a + cw) + bx \qquad (2)$$

where c is the regression of $\frac{1}{Y_p}$ on seed rate.

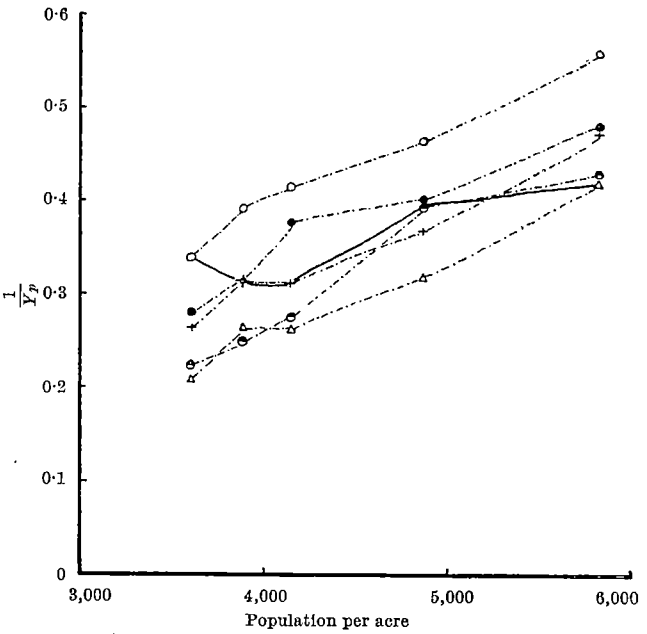

Fig. 2. $\frac{1}{Y_p}$ Response to population change for the different seed rates per acre. Seed rates per acre, same as Fig. 1

It is considered that equation (2) will be applicable in cases where the crop yield is influenced, as in the yam, by the size of the individual sett.

A more detailed account of the work carried out at Ibadan will be published elsewhere.

I thank Dr. C. A. Puddy, chief agricultural research officer, and Mr. G. E. Hodnett of the Department of Mathematics, University of Ibadan, for their assistance.

EFFECT OF CERTAIN CONDITIONS ON YIELD OF CROP PLANTS

By R. G. FAWCETT

The University of Sydney
North West Wheat Research Institute, Narrabri, New South Wales, Australia

Plant Density : Soil Water : Yield Relationships

THE results of recent wheat seeding trials carried out in southern New South Wales[1] have indicated that, under a relatively wide range of rainfall conditions during the growing season (11–29 in.), varying the seeding rate from 20 to 60 lb. per acre had negligible effect on grain yield.

Similar results have been obtained on chernozem-like soils of high natural fertility in the Narrabri district of New South Wales, provided the plants were not subjected to a period of water stress sufficiently severe to impair ear development prior to anthesis. However, where such water stress conditions had occurred, and where stem rust damage was negligible, grain yields were markedly reduced with plant densities above optimum. Some results of seeding-rate trials carried out in the 1961–62 seasons are presented to illustrate these effects.

Exp. 1. A 7 × 2 factorial combination of the following treatments was used: seeding rate, 5, 10, 15, 20, 30, 40 or 80 lb./acre; row spacing, 7 or 14 in.; replication, 3; plot size, 7 ft. × 70 ft; five sites were selected to give a range in the depth of wet soil at sowing (about 9–30 in.); variety, *Triticum aestivum* cv. 'Mengavi'. All sites were sown during June 19–29, 1961, and gathered during November 9–15, 1961. Rainfall during the growing season was similar at all sites and ranged from 4·4 in. to 5·3 in. No basal fertilizers were applied. At gathering, two quadrats (each 7 ft.^{2} in area) were taken from each plot using a method of sampling described by McIntyre[2].

As the row spacing treatments did not have any significant effect on grain yield, the results have been combined for each seeding rate treatment.

Exp. 2. A 2 × 5 × 4 factorial combination of the following treatments was used: variety, *Triticum aestivum* cv. 'Mengavi' or 'Spica'; seeding rate, 'Mengavi', 5, 10, 20, 40 or 80 lb./acre; 'Spica', 6, 12, 24, 48 or 96 lb./acre; sub-soil water at sowing, 4 levels; replication, 3; plot size, 7 ft. × 70 ft.; sown, July 31, 1962; gathered, December 6–10, 1962; basal fertilizer, superphosphate and ammonium sulphate, each at 100 lb./acre; rainfall during the growing season, 7 in. The seeding rates for 'Spica' were adjusted in order to obtain plant densities comparable to those for 'Mengavi'. The four levels of sub-soil water at sowing were effected by growing grain sorghum during the fallow period for 0 (bare fallow), 8, 11 or 13 weeks; the sorghum treatments are referred to as S_0, S_8, S_{11} and S_{13} respectively. For the S_0 treatment, the soil was wet to a depth of about 40 in. at sowing. In both experiments, the depth of wet soil refers to the depth where soil consistency changed from a plastic to a non-plastic state. At gathering, the plots were divided into four strata and one quadrat (7 ft.^{2}) taken at random from each stratum.

The relationships between grain yield and plant density are shown in Fig. 1. It should be noted that the 'Mengavi' in 1962 was affected by stem rust, damage (as indicated by 100 grain weights and bushel weight estimates) increasing with decreasing plant density.

The yield curves for the 'Spica' S_0 and S_8 treatments, as well as those for the 'Mengavi' S_{11} and S_{13} treatments (Exp. 2), are examples of the typical flat-topped parabolic type described by Hudson[3] and Holliday[4], in that increases in plant density from about 5 to 20 plants/ft.^{2} resulted in relatively small changes in yield. In contrast the yield curves for both 'Spica' S_{11} and S_{13} treatments, and at all sites in 1961, fell sharply with increasing plant densities above the optimum, the range of near-optimum densities being particularly restricted. The tendency for optimum plant densities to become less with reduced levels of sub-soil water is in agreement with previous findings[4].

Because of stem rust damage, the 'Mengavi' grain yields (Exp. 2) for the lower plant densities at all soil moisture

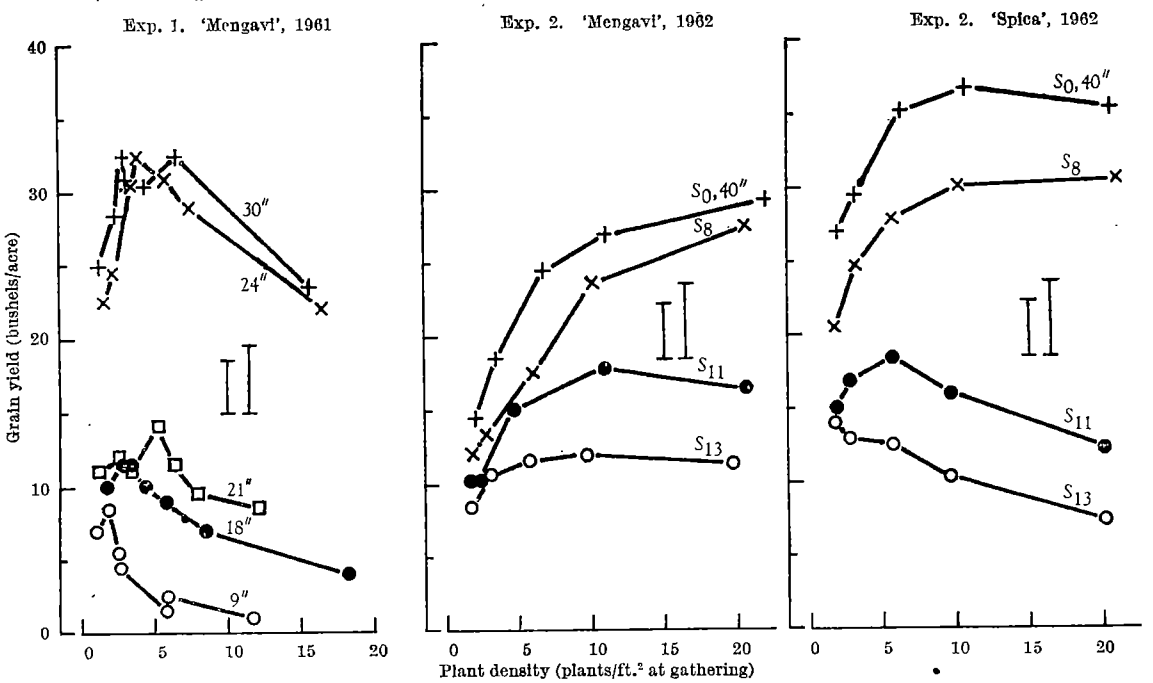

Fig. 1. Effect of plant density and sub-soil water at sowing on grain yield. The numbers refer to the depth of wet soil at sowing (in.), and the symbols S_0, S_8, S_{11} and S_{13} refer to the period (weeks) for which sorghum was grown during the fallow period prior to sowing. The short vertical lines indicate *L.S.D.* values at $P < 0{\cdot}05$ and $P < 0{\cdot}01$

* Values until November 15 and December 10, the last day of gathering for the respective years.

† Vapour pressure deficit; the values for 1962 are approximate, being estimated from thermohygrograph recordings.

levels were less than may have been expected and the yield–plant density relationships were modified accordingly.

The overall grain yields for each site or fallow water treatment generally decreased with decreasing levels of sub-soil water.

The pattern of climatic conditions during both growing seasons was generally similar (Table 1). In both seasons a relatively dry period, during which less than an inch of rain fell, lasted for 6–7 weeks prior to anthesis (early October 1961 and late October 1962). Air temperature and vapour pressure deficit values began to increase rapidly during these dry periods.

'Ear tipping', an effect where the development of the upper florets is impaired by a period of severe plant water stress prior to anthesis, was not evident on plants of the S_0 and S_8 treatments (Exp. 2). The incidence of ear tipping for the S_{11} and S_{13} treatments in 1962, and for all sites in 1961, while low at plant densities up to the optimum for maximum grain yield, increased markedly with further increases in density. At the driest sites in each year, most of the ears were affected at the highest plant density. The plants sown at densities below optimum were, therefore, subjected to less water stress prior to anthesis than those at the higher densities, presumably because of a greater reserve of available soil water. The incidence of ear tipping was a significant factor with regard to the reduction in grain yields where plant densities were greater than optimum.

Where stem rust damage was negligible, environmental conditions during the period of grain development were sufficiently favourable in both seasons for the formation of well-filled grain, irrespective of plant density.

It is concluded that the range of near-optimum plant densities for wheat with regard to the efficient utilization of soil water (as measured by grain yield) may under certain environmental conditions be particularly restricted. Evidence from the present trials has provided information on some aspects of these environmental conditions.

In recent years, there has been a trend among many wheat growers on fertile chernozem-like soils in north-west New South Wales to reduce seeding rates to within the range of 25–35 lb./acre. The present results suggest that where the depth of wet soil at sowing is less than 2 ft. even lower seeding rates could be advantageous.

Plant Arrangement : Yield Relationships

EVIDENCE so far indicates that grain yields of cereals and some other grain crops tend to be greater the closer the planting pattern is to a square grid[1,2]. Holliday concluded that, at constant seed rate, decreasing the row width less than 7–8 in. had, in most cases, given a small increase in the grain yield of cereals (5–7 per cent), whereas yields tended to decrease with row widths greater than standard.

The effect on grain yield of varying the spatial arrangement of wheat plants has been examined on fertile chernozem-like soils near Narrabri, New South Wales, in order to provide some information on the magnitude of these effects under local environmental conditions.

Exp. 1. A 4 × 5 factorial combination of the following treatments was used: seeding rate, 10, 20, 40 or 80 lb./acre; row spacing, 7, 14, 21, 28 or 35 in.; replication, 3; plot size, 7 ft. × 70 ft.; variety, *Triticum aestivum* cv. 'Mengavi'; basal fertilizer, superphosphate and ammonium sulphate each at 100 lb./acre; sown, June 11, 1962; gathered, November 20–22, 1962.

At gathering the plots were divided into four strata and one quadrat was taken at random from each stratum. It should be noted that the effective area sampled per quadrat was 7 ft.^{2} for the 7-, 14- and 21-in. row spacings but only 4·7 and 5·8 ft.^{2} for the 28- and 35-in. row spacings, respectively. The yield estimates are, therefore, less

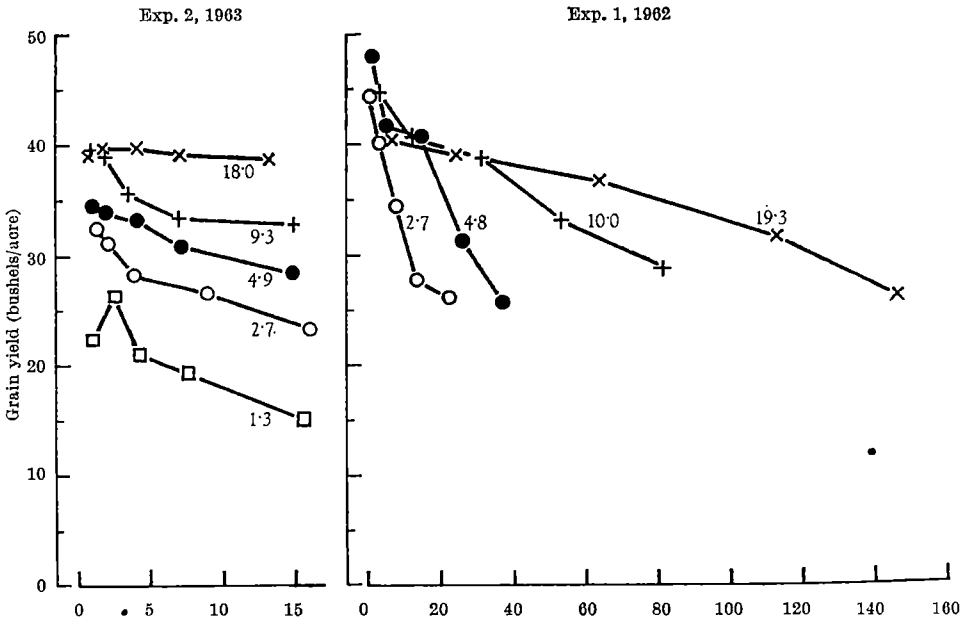

Fig. 2. Effect of plant arrangement on grain yield. The numbers refer to the mean plant density at gathering (plants per sq. ft.)

accurate for the latter spacings. Plant counts were made on each sample before threshing.

Exp. 2. Row spacings were adjusted to confine the values of r/p (ratio of the distance between the rows to the mean distance between the plants within the row at gathering) within the range of approximately 1–16 for each seeding rate treatment.

A 5 × 5 factorial combination of the following treatments was used: seeding rate, 5, 10, 20, 40 or 80 lb./acre; value of r/p (approx.), 1, 2, 4, 8 or 16. Details of row spacing in relation to seeding rate and values of r/p are given in Table 2. Replication, 4; plot size, 8 ft. × 9 ft.; variety, *Triticum aestivum* line No. 52, a line derived from the cross 'Mengavi' × 'Koda' × 'Spica' × 'Gabo'; basal fertilizer, superphosphate and ammonium sulphate each at 150 lb./acre; sown, July 25–26, 1963, into a dry seed bed; germination was delayed until late August when sufficient rain was received to wet thoroughly the seed bed; gathered during December 16–20, 1963.

Table 2

Row width (in.); Exp. 2

r/p (approx.)	Seeding rate (lb./acre) 5	10	20	40	80
1	11·0	7·5	5·5	4·0	2·5
2	15·0	11·0	7·5	5·5	4·0
4	21·5	15·0	11·0	7·5	5·5
8	30·0	21·5	15·0	11·0	7·5
16	43·0	30·0	21·5	15·0	11·0

At gathering two quadrats were taken from each plot and plant counts made on each sample before threshing. The effective area sampled per quadrat was approximately 7 ft.² for all row spacings except the 30-in. spacing (10 lb. seeding rate) for which the effective area was approximately 5 ft.². Growing conditions were relatively favourable in both seasons.

The overall results are in agreement with the conclusions of Donald and Holliday in that at constant seed rate the closer the planting pattern was to a square grid, that is, the closer values of r/p were to unity, the higher the grain yield per unit area (Fig. 2). This effect was more pronounced at the lower plant densities, and the use of row spacings greater than 7 in. also brought about substantial reductions in grain yield.

Although the 1963 results suggest that grain yields may be higher where the use of row spacings less than 7 in. give values of r/p closer to unity, the practical value of such row spacings has yet to be established.

EVIDENCE FOR THE PARTICIPATION OF CHLOROPHYLL *b* IN THE PRIMARY REACTION OF PHOTOSYNTHESIS

By B. RUMBERG

Max-Volmer-Institut, Physikalisch-Chemisches Institut, Technische Universität, Berlin

BY the method of sensitive flash photometry it has been possible to derive a reaction scheme for the electron-transport system in photosynthesis of green plants[1–15]. TPN is reduced by transfer of electrons originating from water through at least eight intermediates (Fig. 1). The electron transfer between Cyt-*f* and *Z* and between *Y* and *Q* (both endergonic in the dark, energy gaps ≈20 kcal) is made possible by excitation of Chl-a_I and Chl-a_{II} with $h\nu_I$- and $h\nu_{II}$-light. In earlier experiments[1–6] it was shown that the electron acceptor of Chl-a_{II} is an unknown substance *X* (absorption changes at 478 and 513 mμ). Later[7–13], evidence was given that *X* is very closely related to, or identical with, plastoquinone *Q* (absorption changes at 254 mμ):

(*a*) The absorption changes of *X* and *Q* have the same action spectrum (long wave-length limit at ≈700 mμ)[9,12,13].

(*b*) X/X^- and Q/Q^- have the same redox potential (≈0 V)[8].

(*c*) The absorption changes of both *X* and *Q* disappear after extraction of plastoquinone and reappear in full after recondensation of plastoquinone[8,12].

(*d*) The difference spectrum of both *X* and *Q* can be separated from that of the other intermediates (Chl-a_I and Cyt-*f*) by addition of DPIP and ferricyanide in excess. Ferricyanide oxidizes via DPIP Chl-a_I chemically and traps via DPIP the electrons from *Q*. In this way the further flow of electrons from *Q* to TPN is prevented[12].

(*e*) The magnitude as well as the time-course of the absorption changes of *Q* (at 254 mμ) and *X* (at 515 mμ) correspond to each other under different conditions. This is shown to be true by exciting photosynthesis with light flashes longer than 10^{-2} sec (ref. 12).

These similarities lead to the assumption that the reaction of *Q* (absorption changes at 254 mμ) influences physically the absorption of the surrounding pigments *X* which results in additional absorption changes at 478 and 513 mμ.

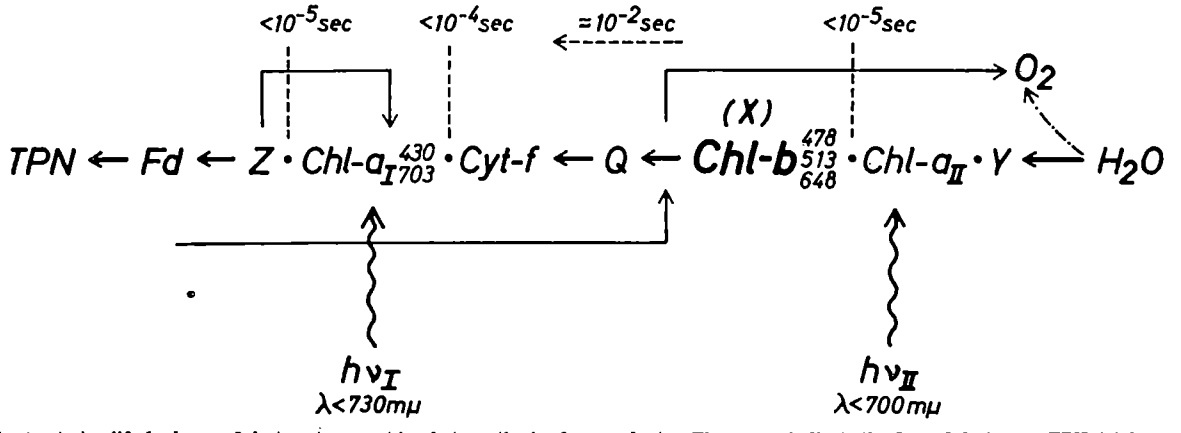

Fig. 1. A simplified scheme of electron transport in photosynthesis of green plants. The arrows indicate the flow of electrons. TPN, triphosphopyridinenucleotide; *Fd*, ferredoxin; Cyt-*f*, cytochrome-*f*; *Q*, plastoquinone; Chl-a_I, chlorophyll *a* absorbing at 430 and 703 mμ; Chl-a_{II}, special chlorophyll *a* (ref. 9); Chl-*b*, chlorophyll *b* absorbing at 478 and 648 mμ, which on illumination absorbs at 513 mμ (formerly this Chl-*b* was symbolized by *X*. Whether Chl-*b* is a true intermediate in the electron-transport or an indicator for an unknown substance in this position is an open question). *Z* and *Y* are unknown substances. The 'feed-back' of electrons from *Z* to Chl-a_I may include Cyt-*f*

Recent measurements (unpublished), however, show that, under special conditions, for example by exciting photosynthesis with flashes shorter than 10^{-2} sec, one can distinguish between the kinetic behaviour of the absorption changes of X and Q. These experiments lead to the assumption that X indicates an intermediate in the electron-transport system between Q and Chl-a_{II}.

In this work evidence is given that X is obviously identical with a chlorophyll b (designated Chl-b-478-513-648).

The difference spectrum of X (and Q) can be separated chemically by addition of DPIP and ferricyanide in excess[12]. In this case changes of absorption of X could be observed about 478 and 513 mμ; but no changes due to X could be observed in the region between 600 and 800 mμ. Changes of X in this region may be compensated by changes which occur by the redox reaction of DPIP. Therefore, an attempt was made to separate the difference spectrum of X physically. This was done in whole *Chlorella* cells by different intensities and qualities of background light.

Fig. 2 (top) shows the flashing light-induced difference spectrum under conditions of weak detecting light (incident intensity $\leqslant 380$ ergs/cm² sec) and background light $\lambda = 728$ mμ (incident intensity 7,100 ergs/cm² sec). The far-red background light stimulates only light reaction $h\nu_I$. The observed changes at 478 and 513 mμ are caused by X and those at 703 mμ by Chl-a_I. Fig. 2 (bottom) shows the result of the same experiment with background light $\lambda = 650$ mμ (incident intensity 2,200 ergs/cm² sec). This light stimulates preferably the light reaction $h\nu_{II}$. In this case the absorption changes of Chl-a_I about 703 mμ are strongly reduced. The same result can be obtained without any background light. So under conditions where light reaction $h\nu_I$ is not continuously stimulated a difference spectrum can be separated which consists of the two bands of X at 478 and 513 mμ and, in addition, a band at 648 mμ. The disappearance of the absorption changes of Chl-a_I at 703 mμ with decreasing far-red background light is demonstrated in more detail in Fig. 3 (top). (Fig. 3 (bottom) shows the influence of far-red background light on the absorption changes of 515 mμ; this will be discussed later.)

First, an explanation is given for the disappearance of the difference spectrum of Chl-a_I by the assumption of a Z-Chl-a_I-Cyt-f-complex and, secondly, it will be shown that the remaining difference spectrum characterized by

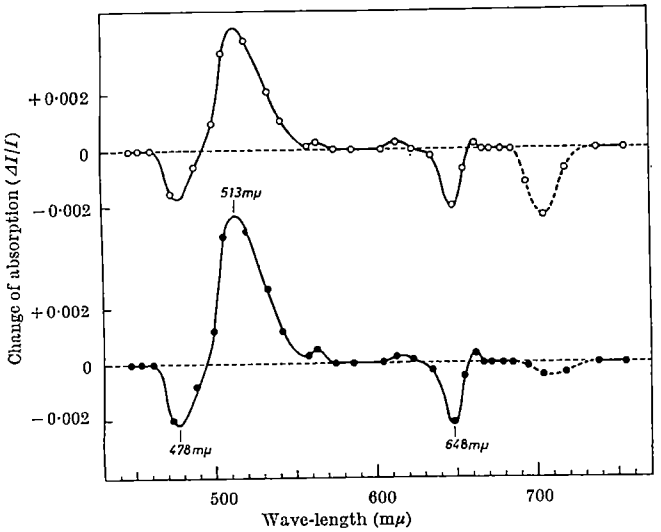

Fig. 2. Difference spectra in *Chlorella* cells. The changes were induced by flashing light: duration 3×10^{-5} sec, wave-length 620–720 mμ (range $\lambda < 575$ mμ) and 390–490 mμ (range $\lambda > 575$ mμ), saturating intensity. Detecting light: intensity $\leqslant 380$ ergs/cm² sec, half band-width ≈ 10 mμ (two Schott interference filters). Background light: wave-length 728 mμ, intensity 7,100 ergs/cm² sec (top); wave-length 650 mμ, intensity 2,200 ergs/cm² sec (bottom); half band-width ≈ 20 mμ (Schott interference filter). Temperature 20° C, pH value 9 (0·04 M/l. carbonate), chlorophyll content $1{\cdot}7 \times 10^{-5}$ M/l., optical path 15 mm

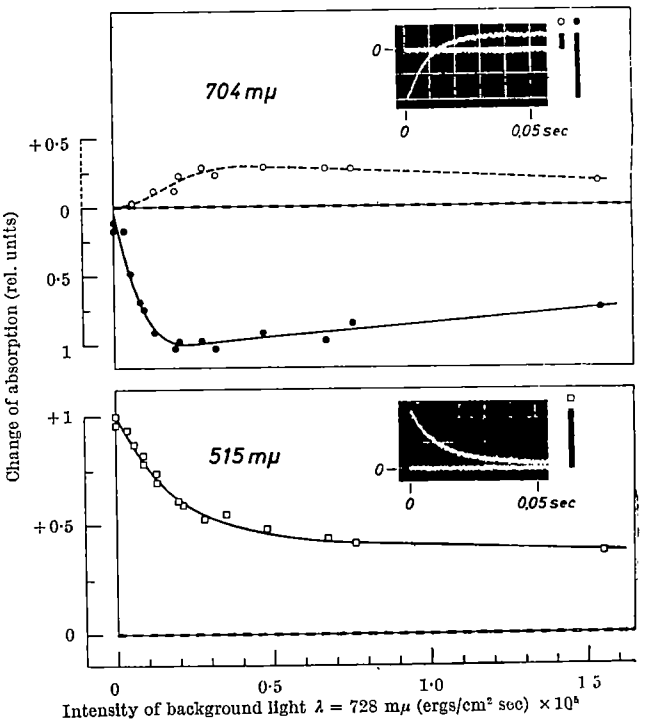

Fig. 3. Changes of absorption in *Chlorella* cells at 704 mμ (and 515 mμ as a function of the intensity of background light $\lambda = 728$ mμ. The changes were induced with flashing light: duration 3×10^{-5} sec, wave-length 620–720 mμ (515 mμ) and 390–490 mμ (704 mμ), saturating intensity. Detecting light: intensity 170 ergs/cm² sec (515 mμ) and 270 ergs/cm² sec (704 mμ), half band-width ≈ 10 mμ (two Schott interference filters). Background light: half band-width 24 mμ (Schott interference filter). Temperature 20° C, pH value 9 (0·04 M/l. carbonate), chlorophyll content $\approx 2 \times 10^{-5}$ M/l., optical path 15 mm. Top right, time-course of the changes

the absorption changes at 478, 513 and 648 mμ is caused by one and the same substance, from which it can be concluded that the substance is chlorophyll b.

Z-Chl-a_I-Cyt-f-complex. When light reaction $h\nu_I$ is continuously stimulated by far-red background light of medium intensity ($\approx 7{,}000$ ergs/cm² sec at $\lambda = 728$ mμ) one has to assume that Cyt-f is kept in the oxidized form, but not Chl-a_I. The following flash oxidizes Chl-a_I. Afterwards Chl-a_I^+ can be reduced only as fast as Cyt$^+$ is reduced, this is within $\approx 10^{-2}$ sec (Fig. 1). Therefore, absorption changes of Chl-a_I at 703 mμ with a life-time of $\approx 10^{-2}$ sec should occur. This has been observed. When light reaction $h\nu_I$ is not stimulated continuously (no far-red background light) Cyt-f remains in the reduced form. The following flash oxidizes Chl-a_I, and Chl-a_I^+ is immediately reduced by Cyt-f. When the electron transfer from Cyt-f to Chl-a_I^+ is a very fast one ($< 10^{-4}$ sec) the corresponding absorption changes at 703 mμ should not be detectable. Since this is the case, we have to assume a very fast electron transfer between Chl-a_I^+ and Cyt-f which is possible only when a complex exists between Z, Chl-a_I and Cyt-f. This is in accordance with the fact that at low temperatures (−150° C) an irreversible oxidation of Chl-a_I as well as of Cyt-f can be observed[3]. This is also only explainable by the assumption of a fast electron transfer within a Z-Chl-a_I-Cyt-f-complex. (These results imply a correction of the formerly derived reaction time of $\approx 10^{-3}$ sec for the reaction between Chl-a_I^+ and Cyt-f.)

In all our earlier experiments absorption changes at 703 mμ were observed also without additional far-red background light. In all these experiments the detecting light at 703 mμ has already acted as far-red background light. Therefore, for the experiments reported here detecting light of low intensity was used.

When light reaction $h\nu_I$ is stimulated by far-red background light of strong intensity ($> 10{,}000$ ergs/cm² sec at 728 mμ) Cyt-f and Chl-a_I should be kept in the oxidized form. Then the following flash can only act on light

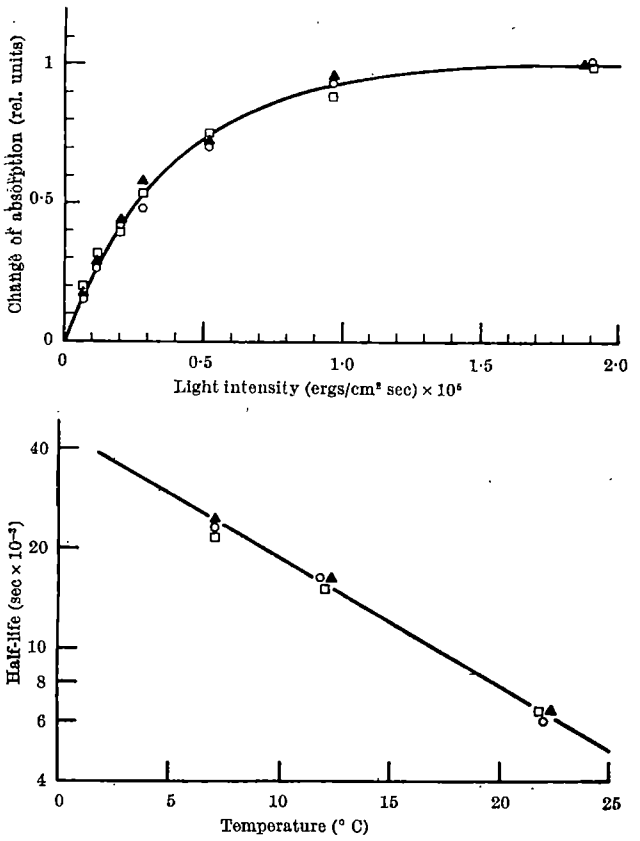

Fig. 4. Top, Absorption changes in *Chlorella* cells at 473 (○), 513 (□) and 648 (▲) mμ as a function of actinic light intensity. Actinic light: duration 1 sec, wave-length 686 mμ, half band-width 21 mμ (Schott interference filter). Detecting light: intensity 350 ergs/cm² sec, half band-width ≈10 mμ (two Schott interference filters). Temperature 20° C, *p*H value 9 (0·08 M/l. carbonate), chlorophyll content $\approx 2 \times 10^{-5}$ M/l., optical path 15 mm. Bottom, half-life of the absorption changes in *Chlorella* cells at 473, 513 and 648 mμ as a function of temperature. Qualities of actinic light (see Fig. 2). Intensity of detecting light: 500 ergs/cm² sec. Pre-illumination (10 sec) with red light ($\approx 10^6$ ergs/cm² sec). Temperature 20° C, *p*H value 9 (0·08 M/l. carbonate), chlorophyll content $\approx 2 \cdot 10^{-5}$ M/l., optical path 15 mm. (From the measurements it follows an energy of activation of ≈15 kcal/mol.)

reaction $h\nu_{II}$ which provides electrons from water for the reduction of Cyt-f^+ and Chl-$a_I{}^+$. Under these conditions positive absorption changes of Chl-a_I at 430 and 703 mμ should be observed. This is indeed the fact and has already been described in detail[4,10,12]. (With respect to *Chlorella* cells the enrichment of Chl-$a_I{}^+$ by far-red background light depends on the condition of the cells. Positive absorption changes up to 50 per cent of the full absorption changes at 703 mμ have been observed.)

Identification of chlorophyll b. The absorption changes of the separated difference spectrum (Fig. 2, bottom) were measured as a function of the intensity of the actinic light (Fig. 4, top). The half-life of these absorption changes was measured as a function of the temperature (Fig. 4, bottom). In all these cases (and in others not published here) the behaviour of the absorption changes at 478, 513 and 648 mμ is identical. From this it follows that the difference spectrum characterized by these absorption changes is caused by one and the same substance. The decreases of absorption at 478 and 648 mμ occur just within the two absorption bands of chlorophyll *b in vivo*. This indicates that very probably a chlorophyll *b* is in action which is transformed in light in a product with a band at 513 mμ. (Therefore, we replace the symbol *X* by Chl-*b*-478-513-648.) This conclusion is in agreement with the fact that the absorption changes take place only in green plants, which are the only ones which contain chlorophyll *b*. In earlier experiments it was shown that the extinction coefficient of *X* at 475 mμ is $2 \cdot 10^4$ 1/M cm[18]. This is also in agreement with the assumption that *X* is a chlorophyll *b*.

All properties of *X*[10,18] which were derived from the behaviour of the absorption changes at 478 and 513 mμ are now guilty for Chl-*b*-478-513-648: reaction in light within $< 10^{-5}$ sec, relaxation within $\approx 10^{-2}$ sec, long wave-length limit of the action spectrum at ≈700 mμ, concentration ≈1/1,000 of the bulk of chlorophyll, redox potential ≈0 V, *p*H region 5–8, temperature of inactivation 45° C (5 min), high sensitivity to ageing, high sensitivity to the poison chlorophenyl-dimethylurea (CMU).

Feed-back. The limit of the action spectrum at ≈700 mμ is observed only when light reaction $h\nu_I$ is separated chemically from light reaction $h\nu_{II}$ (refs. 9 and 12). In the whole system the limit of the action spectrum is extended to ≈730 mμ (refs. 9, 16 and 17). But on the whole system only half the full amplitude of the absorption changes of Chl-*b* at 515 mμ can be induced by far-red illumination. This is demonstrated in Fig. 3 (bottom). Both effects can be explained when one assumes a feed-back of electrons from light reaction $h\nu_I$ to Chl-*b* as indicated in Fig. 1.

I thank Prof. H. T. Witt for his advice.

MORPHOLOGY OF SYNTHETIC FIBRES; A STUDY ON DRAWN POLYETHYLENE

By I. L. HAY and Dr. A. KELLER
H. H. Wills Physics Laboratory, University of Bristol

IDEAS on the nature of a crystalline polymer have undergone profound changes during recent years. Whereas previously it was believed that long-chain molecules by their very nature form bundle-like crystals intermeshed with an amorphous matrix, more recent research has revealed that against all expectations the crystalline units are distinctly lamellar and built of folded chains (cf. refs. 1 and 2). This was first established in the case of solution-grown crystals; the relevance of this finding to melt crystallized material has been disputed for a long time in spite of steadily accumulating experimental material in its favour obtained on surfaces—free and

fracture[1]. Obviously, while the nature of the standard melt crystallized materials was still in dispute, the new developments had little impact on the existing concepts on drawn fibres. An important turning point has been, therefore, the recent discovery by Palmer and Cobbold[2] that bulk polyethylene could be dispersed by digestion with nitric acid. This demonstrated incontestably the lamellar nature of the melt crystallized material[3]. Further, by this technique many close similarities to chain-folded solution-grown crystals have been revealed[4]. In addition, layer-shaped disintegration products were also demonstrated in the drawn form of polyethylene[5] which opens up a new line of enquiry concerning the nature of fibres. In this connexion we have observed that on treatment with nitric acid drawn polyethylene breaks up in a characteristic fashion.

Strips of square cross-section were cut from sheets 6 mm thick of low- and high-pressure polyethylenes, 'Alkathene' and 'Rigidex' respectively. Such strips extended 4·5 times when drawn at room temperature. The X-ray patterns showed the normal highly oriented fibre diagrams. On exposure to 70°–85° C—the temperature of the subsequent nitric acid treatment—these fibre patterns remained unaffected except for a slight disorientation in 'Alkathene' at 85° C which nevertheless is of no consequence for the conclusions to be drawn.

The main features of the nitric acid treatment were as follows. At 70° C in both 'Alkathene' and 'Rigidex' deep transverse cracks were produced, the effect being more

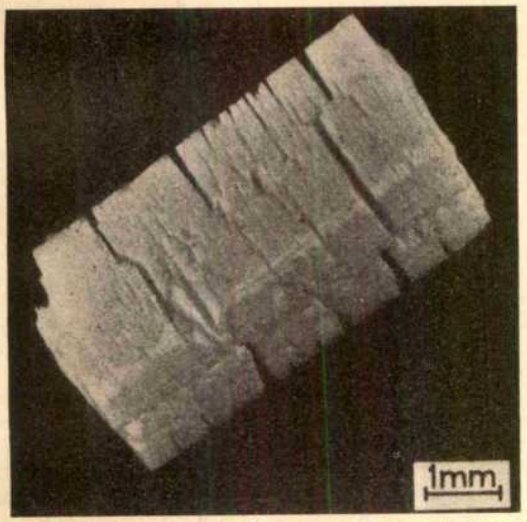

Fig. 1. Linear polyethylene ('Rigidex') drawn 5 times, after 72 h nitric acid treatment at 70° C

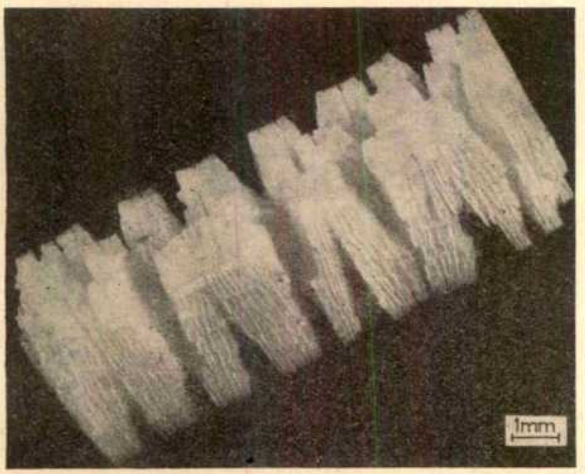

Fig. 2. Branched polyethylene ('Alkathene') drawn 4·5 times, after 12 h nitric acid treatment at 70° C

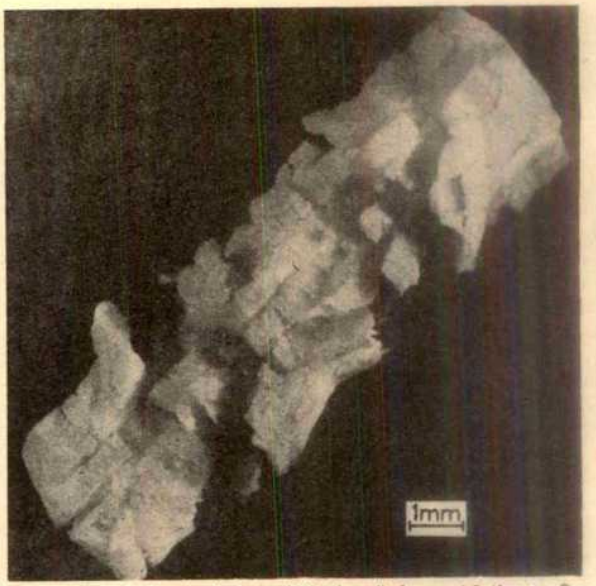

Fig. 3. Branched polyethylene ('Alkathene') drawn 4·5 times, after 3·5 h nitric acid treatment at 85° C

conspicuous in 'Alkathene' (Figs. 1 and 2). These cracks develop in 'Alkathene', for example, after some 8 h, and become very pronounced after 12 h. Further treatment up to 100 h does not appear to sever the specimens completely. On the contrary, shrinkage of the specimen occurs, closing up the cracks. The effects on 'Rigidex' are similar but less pronounced.

At 85° C longitudinal cleavage occurred on 'Alkathene' after about 1·5 h (Fig. 3). Some perpendicular cracking also occurred, and this developed on longer treatment. The plane of the longitudinal cracks was preferentially parallel to that of the plane of the original sheet. Initial cracks of this type were already apparent in the 70° C samples (Figs. 1 and 2) even in 'Rigidex', where in contrast to 'Alkathene' they did not develop further at 85° C. Neither X-ray nor birefringence revealed any orientation with respect to the surface of the sheet (before or after drawing). Accordingly some lamination must have occurred on extrusion which escapes the usual structural tests, yet it gives rise to planes of weakness which are revealed by the nitric acid digestion.

As seen, the nitric acid treatment gives rise to spontaneous internal crack surfaces in a rather striking manner. The study of such surfaces raises the possibility of exploring the fibre interior without externally introduced fracture, a technique already utilized by Palmer and Cobbold[2] in connexion with unoriented material. In the case of fibres in particular this should provide an alternative to the examination of the dispersed material with the important added advantage that it can give information not only on the basic building units but also on the manner in which they are arranged in the fibre interior.

For this purpose the transverse surfaces were exposed by snapping pieces as in Figs. 1 and 2—they broke at the lightest touch—and these were replicated for electron microscopy by means of a one-stage carbon replica process. Figs. 4 and 5 show results on 'Rigidex' and 'Alkathene' respectively. Both reveal lamellæ as seen flat on, the structure in 'Rigidex' being the more regular. Replication of longitudinal cleavage surfaces was not successful owing to their extreme roughness. Meaningful results, however, were obtained by first cutting the samples in a plane parallel to the draw direction and then taking a two-stage replica of this surface after a short exposure (2–4 h) to nitric acid. These revealed pronounced striations transverse to the direction of draw (Fig. 6). These we interpret as layers seen edge-on with very deep grooves etched in between them. In fact, Fig. 5 can be regarded as incipient stages of what is seen in Figs. 1 and 2 but on a much

smaller scale. It is not possible to make an accurate assessment of the lamellar thickness but as seen it is between 100 and 500 Å. Similar structures in 'Alkathene' were indicated. In one case where the periodicity was particularly clear it was in the 100 Å range. This is all in broad agreement with the periodicity revealed by low-angle X-rays which is ~200 Å for 'Rigidex' and ~100 Å for 'Alkathene' before treatment. After treatment, low-angle X-ray information was much more difficult to obtain owing to intense diffuse scatter; but where this was achieved, no spacing change of consequence for the present was observed (in fact there was a decrease of about 25 per cent on prolonged treatment, to be published elsewhere). However, whenever the reflexions were originally split (four point diagram), corresponding to spacings oblique to the fibre axis, they became meridional on the nitric acid treatment in line with the finding that the lamellæ were seen perpendicular to the draw direction.

Accordingly, drawn polyethylene should consist of lamellæ stacked one on another. As the lamellæ are perpendicular to the draw direction the molecules must be perpendicular to the lamellæ. While some changes might have occurred during the nitric acid treatment—see previous remark on the low-angle X-ray patterns—this is unlikely to alter the basic conclusion on the morphology. The action of the nitric acid is not clear in all details. It is known, nevertheless, that it removes some disordered material, that it severs links between lamellæ and that it may cut folds[3].

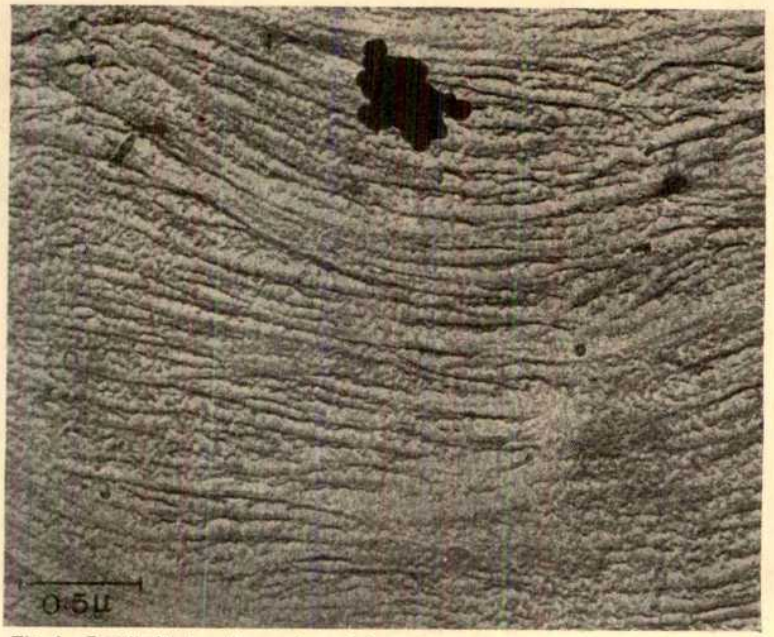

Fig. 6. Longitudinal section surface of drawn linear polyethylene ('Rigidex') etched with nitric acid at 70° C for 4 h. Draw direction vertical. Electron micrograph; replica

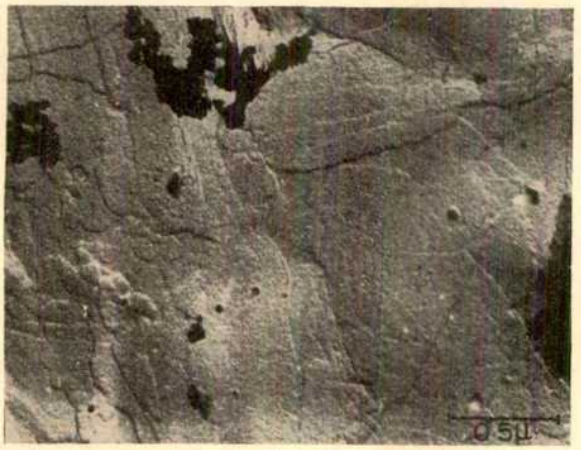

Fig. 4. Transverse cleavage surface of drawn and nitric acid treated (70° C, 100 h) linear polyethylene ('Rigidex'). Electron micrograph; replica

Fig. 5. Transverse cleavage surface of drawn and nitric acid treated (70° C, 44 h) branched polyethylene ('Alkathene'). Electron micrograph; replica

From the earliest, solution-grown crystals were sedimented in forms of oriented mats for X-ray examination[5,6]. It was remarked there that so far as the diffraction patterns were concerned—both wide and low angles—such mats could have been transverse sections of a fibre. Now this analogy can be taken further; a fibre is in fact seen to consist of a stack of lamellæ, as is a mat of sedimented solution-grown crystals contrary to all accepted concepts on fibre structure[7]. In addition, in a different line of work[8] the crystalline units (which by the work recorded here should be lamellar) were found to slide past each other revealing an unexpected individuality in contrast to the intimate molecular connectedness between consecutive crystallites usually envisaged.

Based on these findings we suggest that the molecules in the lamellæ are to a large extent folded. Some molecular ties naturally must exist to provide cohesion. The possibility of folded chains within a drawn fibre has already been raised[2,9] and theoretical evaluation of X-ray patterns on the basis of a mixture of folded molecules and non-folded ones passing through crystals has already been presented[10]. The distinctness of the lamellar morphology and the close similarity to single crystals revealed now are surprising even so. We do not claim universal validity for the chain folded lamellar concept for fibres in general, certainly not for extreme elongations. Nevertheless, it is noteworthy that this has now been found in materials which in normal technical usage would be considered as drawn fibres.

We thank R. P. Palmer and A. J. Cobbold, Imperial Chemical Industries, Ltd., for advanced communication of their technique and results and G. A. Bassett for his advice on electron microscopy.

LETTERS TO THE EDITOR

RADIO ASTRONOMY

Microwave Observations of the Galactic Centre Region

THIS communication describes a new set of observations of the region surrounding the radio source Sagittarius *A*, at present assumed to be the galactic centre. The observations were made at a frequency of 5 Gc/s, and the results are summarized in the form of a contour map showing the various components of radiation in this region. The position of the Sagittarius *A* source appears to differ slightly from the zero of the $^{III}b^{II}$ co-ordinate system. The spectral index of the source, derived by comparing the flux density at 5 Gc/s with other measurements in the microwave band, indicates that it is non-thermal.

The observations recorded here were made with a parametric receiver connected to a paraboloid antenna, 85 ft. in diameter, giving a circular beam-width of 10·8 arc min to half power. The receiver was a modified Dicke type, switched electronically between the main receiving antenna and a comparison antenna directed at the zenith. The parametric amplifier, operating in the degenerate mode, was followed by a zero intermediate frequency system of band-width 100 Mc/s. An output time constant of 1 sec set the minimum detectable temperature for any individual scan at 0·25° K. Forty-five drift scans, spaced 3·6 arc min apart, were taken in an area bounded by galactic longitudes −358·5° to +1·5° and galactic latitudes −1° to +1°. The peak antenna temperature for Sagittarius *A* was approximately 20° K. The survey was made at night, during the summers of 1963 and 1964, at times when the galactic centre region was at meridian transit ±2 h. At transit, the region was at an elevation of 30° above the horizon.

Table 1. CO-ORDINATES OF SAGITTARIUS *A* (1950·0)

Frequency (Gc/s)	Antenna beam (arc min)	Right ascension	Declination
5 (ref. 1)	10·8′	17h42m27s ±2s	−28°58·0′ ±0·5′
3 (ref. 2)	6·7	17 42 30 ±2	−28 58·7 ±0·5
14·5 (ref. 3)	5·9	17 42 26 ±6	−28 58·2 ±1·0
Galactic centre as defined by $^{III}b^{II}$ system		17 42 26 ·5	−28 55·2

The precise position of Sagittarius *A*, the bright central component, was determined by comparison with position measurements at meridian transit of 10 other radio sources, spanning a declination range −45° to +58°. This position is shown on the first line of Table 1. The second and third lines of Table 1 show other position measurements made with pencil beams at 3 Gc/s and 14·5 Gc/s. All the observations agree within the quoted error limits. The fourth line of the table gives the equatorial co-ordinates for the zero in longitude and latitude of the $^{III}b^{II}$

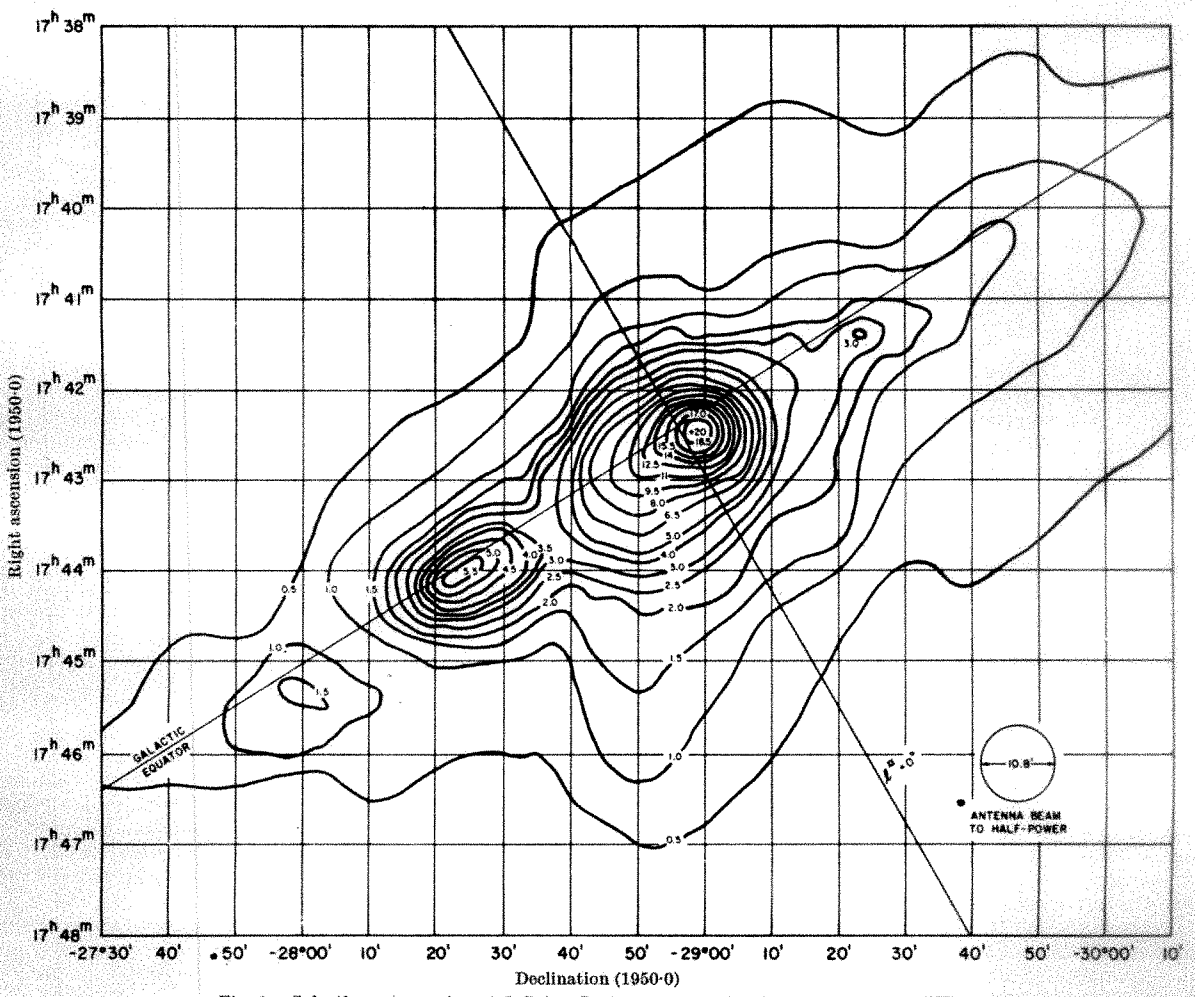

Fig. 1. Galactic centre region at 5 Gc/s. Contours represent antenna temperature (°K)

co-ordinate system. The existing data indicate that in right ascension the position of the central radio component agrees with the zero of the $l^{II}b^{II}$ system, but that in declination it differs by approximately 3 arc min.

The temperature contours determined from the present set of observations are given in Fig. 1. The contour map shows the main central source and the two well-known sources of somewhat lesser intensity, situated on the galactic plane on each side of the galactic centre and separated from it by about 0·5°. The small spur source adjacent to the galactic centre, first distinguished by Drake[4], is not resolved with the present 10·8 arc min beam-width, but appears as an asymmetric extension along the galactic plane of the contours surrounding the centre. These sources lie on a line parallel to, but 2 arc min south of, the galactic equator in the $l^{II}b^{II}$ system. A source has also been detected at right ascension 17h 45m 20s and declination −28° 00′.

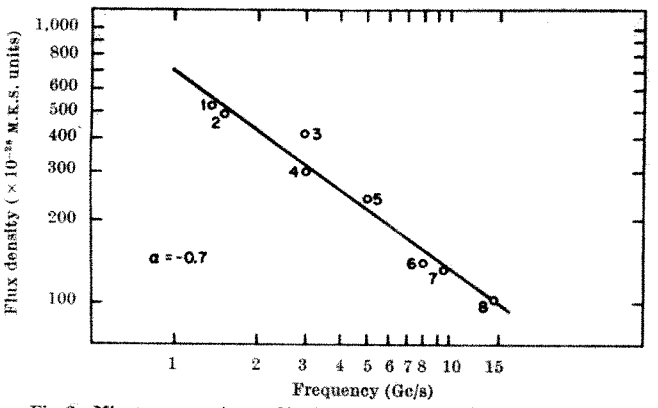

Fig. 2. Microwave spectrum of Sagittarius *A*. The flux values have been corrected to an assumed source diameter of 3·5 arc min. Corrections have also been made for the background ridge component. (1) Davies and Jennison[7]; (2) Kerr[8]; (3) Sloanaker and Nichols[9]; (4) Cooper and Price[2]; (5) Maxwell and Downes[1]; (6) Williams[10]; (7) Haddock and McCullough[11]; (8) Hollinger[3]

The flux from the source Sagittarius *A* at 5 Gc/s is estimated as 240 × 10^{-26} W m^{-2} $(c/s)^{-1}$, on the assumption that the flux density of *M* 87 at the same frequency is 70 × 10^{-26} units[5]. The diameter of the source was assumed to be 3·5 arc min[2,6], and a 10 per cent correction was made for the ridge of background radiation near the galactic centre. Under these assumptions, the estimated uncertainty in the flux value is about 10 per cent. The flux value at 5 Gc/s has been compared with measurements of flux densities made at other frequencies in the microwave band, as shown in Fig. 2. Results plotted in the figure are confined to measurements made in the frequency range 1·36–14·5 Gc/s with paraboloid antennæ of beam-widths within the limits 6–18 arc min. Measurements made with antennæ of greater beam-widths or with fan beams have been rejected, since, in comparing flux measurements to obtain a spectrum for a complex source, it is advisable to compare data taken with antennæ the beam-widths of which are reasonably similar. All the results on the graph have been corrected to a source diameter tentatively assumed to be 3·5 arc min[2,6]. Where necessary, further corrections to the published flux values have been made for radiation from the background ridge; for most frequencies in the microwave band, this correction does not exceed 10 per cent. Corrections have not been made for antenna skirt responses to the small spur source 10 arc min from Sagittarius *A*; for most cases this effect is estimated as being only a few per cent. The solid line in Fig. 2 is a linear least square solution fitted to the plotted data points. Its slope gives the microwave spectral index for the Sagittarius *A* source and this index is −0·72 ± 0·05. Such a spectral index does not uphold previous suggestions that the source is thermal[2,4,6,12], but strongly indicates that it is non-thermal in nature.

This work was supported by the U.S. National Science Foundation. We thank Dr. D. R. W. Williams and Dr. F. J. Kerr for permission to refer to unpublished data.

ASTROPHYSICS

Lunar Luminescence

Following the report of the characteristic red luminescence of enstatite achondrite meteorites under proton excitation[1], Kopal and Rackham photographed the Moon through interference filters with passbands near the maximum and minimum of the enstatite emission profile, in a search for regions which might show this characteristic emission. They reported finding such a region around the crater Kepler[2], and concluded that this crater might therefore have been produced by a large enstatite achondrite meteorite. However, a difficulty is that after an impact the material spread around would probably be largely lunar surface material, with only a small proportion—perhaps one part in a thousand[3]—of material from the actual meteorite. This view is fairly widely held, but does not seem to have been mentioned specifically in the correspondence which has followed these observations.

An alternative explanation is that the lunar surface may in parts consist of minerals which are capable of luminescence, but it also seems likely that they would have become so damaged by prolonged exposure to radiation that no appreciable luminescence would be seen. A coating of mainly non-luminescent dust of micrometeoritic origin would have the same effect. However, any disturbance to the surface, for example by the arrival of a large enough meteorite of any type, or even by volcanic activity, would distribute and expose undamaged material from just below the original surface. If the disturbance occurred in a region consisting of luminescent material, luminescence might then be observed at times of sufficiently intense excitation. Cameron[4] has suggested that such times might be around full Moon, because of an anti-solar 'tail' of charged particles trapped by the Earth's magnetic field. The luminescence would continue to be possible for a time depending on the rate of damage and of dust arrival; this time might easily be of the order of 10^4–10^5 years. Regions observed to luminesce could thus be regarded as the sites of geologically recent disturbances. This explanation has the advantage that it does not require a large specimen of a rather rare type of meteorite to produce large luminescent patches of the type seen by Kopal and Rackham—any large enough meteorite, or volcanic disturbance, will do. It is also possible that the very small patches of red luminescence observed by Greenacre and Barr[5] are of the same type. A disturbance in the terraced rim of Aristarchus would tend to throw material preferentially along the terrace and produce the shape of one of the patches they observed.

It is interesting that Urey[6] and, more recently, Cameron[7] have suggested that enstatite is probably a constituent of the lunar surface.

GEOPHYSICS

Mass of the Canyon Diablo Meteoroid

Nordyke[1] has derived empirical scaling laws for the apparent radius R and the apparent depth D of craters produced by both chemical and nuclear explosions in desert alluvium at the Nevada Test Site. The scaling equations are $R = R_s W^{1/3.4}$ and $D = D_s W^{1/3.4}$, in which R_s and D_s are the appropriate dimensions for a 1 kt (kiloton) explosion of TNT and W is the yield in kt of the explosion in question.

If the dimensions of the Canyon Diablo meteorite crater scale in accordance with the same empirically derived equations as the dimensions of the explosion craters examined by Nordyke, then his equations can be used for calculating the energy required for production of this meteorite crater. The apparent crater for the Canyon Diablo meteorite is generally quoted as having a 4,000-ft. diameter and a 570-ft. depth[2]. The ratio of apparent radius to apparent depth is then 3·5. A value of 3·5 for the ratio of apparent radius to apparent depth occurs in Nordyke's plots close to the surface (at a scaled depth of not more than 20 ft./kt$^{1/3.4}$) and again at a scaled depth of about 200 ft./kt$^{1/3.4}$.

If the energy used in producing the Canyon Diablo crater was expended near the surface of the Earth, Nordyke's scaled apparent crater depth indicates that $W^{1/3.4} = 570/30$ kt, such that the energy necessary to produce the crater is $W = 2{\cdot}2 \times 10^4$ kt. A comparable calculation, using the apparent crater radius, gives $W^{1/3.4} = 2{,}000/110$ kt, such that $W = 1{\cdot}9 \times 10^4$ kt. Thus, if the energy which produced the Canyon Diablo meteorite crater was expended at a scaled depth less than 20 ft./kt$^{1/3.4}$, it amounted to a yield equivalent to about 20 megatons of TNT. At a yield of 20 megatons, a scaled depth of 20 ft./kt$^{1/3.4}$ is a depth of 400 ft., so, when we say that the equivalent point of detonation is at a scaled depth less than 20 ft./kt$^{1/3.4}$, we are saying that the explosion occurred somewhere between the surface and a depth of 400 ft.

At a scaled depth of 200 ft./kt$^{1/3.4}$ the equivalent yield of TNT calculated from the apparent crater dimensions is about $1{\cdot}1 \times 10^4$ kt. For a yield of 11 megatons of TNT a scaled depth of 200 ft./kt$^{1/3.4}$ is more than 3,000 ft.—a value which appears to be in excess of the depth to which the meteorite penetrated, hence will not be considered further in this communication.

Based on this information we can calculate the mass of the meteoroid that would have had to hit the Earth to release an amount of energy comparable to 20 megatons of TNT. An energy of 1 kt is[3] 10^{12} calories, or $4{\cdot}2 \times 10^{19}$ ergs, so 20 megatons is comparable to $8{\cdot}4 \times 10^{25}$ ergs. If we assume that the energy W comes solely from the kinetic energy gained from gravitational attraction, $W = 8{\cdot}4 \times 10^{25} = G\frac{mM}{r} = (6{\cdot}26 \times 10^{11})\ m$ ergs, in which $G = 6{\cdot}67 \times 10^{-8}$, the mass M of the Earth is $5{\cdot}98 \times 10^{27}$ g and the Earth's radius r is $6{\cdot}38 \times 10^8$ cm. The mass of the meteoroid is then $m = (8{\cdot}4 \times 10^{25})/(6{\cdot}26 \times 10^{11}) = 1{\cdot}34 \times 10^{12}$ g. The magnitude of this mass could have been less if the meteoroid had a measurable velocity relative to the Earth prior to its entry into the gravitational field of the Earth. Since retrograde motion of objects in solar orbit are essentially unknown, a maximum velocity of 30 km/sec for the meteoroid relative to the Earth appears to be a reasonable assumption. With a kinetic energy produced by a relative velocity of 30 km/sec added to the gravitational energy, a meteoroid mass of $1{\cdot}6 \times 10^{11}$ g is needed to provide an energy of $8{\cdot}4 \times 10^{25}$ ergs at the time of contact with the surface of the Earth.

The mass found by this empirical method is intermediate between those theoretically predicted by Öpik[4] and by Bjork[5]. In general, the empirically determined mass appears to be in better agreement with Öpik's predictions. The higher mass value of $1{\cdot}34 \times 10^{12}$ g overlaps Öpik's predictions whereas the lower limit of $1{\cdot}6 \times 10^{11}$ g corresponds closely to the upper limit of Bjork's predictions.

MINERALOGY

Pyrochlore Minerals as a Potential Source of Reactor-grade Niobium

For many years the chief source of niobium has been the mineral 'columbite', a member of the columbite–tantalite series (Fe, Mn) $(Nb\ Ta)_2O_6$. As the name of the series implies, niobium (columbium) and tantalum occur in varying ratios, but even at the columbite end the proportion of tantalum is still appreciable, the ratio of niobium to tantalum being generally of the order of only 6 : 1.

An important application of niobium is in nuclear power production, where what is known as 'nuclear-grade' niobium must contain less than 0·15 per cent by weight of tantalum (0·05 per cent in the United States). This requirement is based partly on physical properties and partly on the nuclear characteristics of the metal. In the production of pure niobium metal an essential step, therefore, is the careful separation of niobium and tantalum. In current industrial practice this is achieved by liquid/liquid extraction from an aqueous acid solution, using hexone (methylisobutylketone)[1].

Attention has been increasingly directed during the last decade to another source of niobium, 'pyrochlore', essentially a calcium niobate $(Na, Ca)_2\ Nb_2\ O_6\ (OH, F, O)$. Significant sources of this mineral have been discovered in several countries, but so far most of these are still the subject of intensive mineral processing research. Like columbite, pyrochlore is a member of an isomorphous, although not necessarily continuous, series, the end-members of which are pyrochlore and microlite. There is, however, an important distinction between the two series, columbite–tantalite and pyrochlore–microlite, in the way they occur in Nature. While the commonly occurring columbites always contain appreciable concentrations of tantalum, most analyses of the pyrochlore–microlite series, on the other hand, are close to one end or the other, so far as the niobium and tantalum contents are concerned[2]. This finding, supported by extensive data published recently[3], appeared to us to be of special significance, because of the prospect that high-purity niobium might be produced in future from a suitable pyrochlore source, without the expensive niobium–tantalum liquid–liquid separation step.

We have therefore examined a number of samples from sources which were either producing commercial quantities of pyrochlore concentrate already, or which might become of commercial interest in the future as a source of niobium.

The niobium in the samples was determined by an adaptation of the method described by Pickup[4], in which the sample materials were decomposed by digestion with hydrofluoric acid, the precipitated fluorides removed, and the niobium solutions evaporated with sulphuric acid. The determinations were completed spectrophotometrically, using the colour given by niobium with hydrogen peroxide in a sulphuric–phosphoric acid solution.

The tantalum determination, based on the procedure of Atkins and Smales[5], involved measuring the activity of the separated tantalum after irradiation of the sample materials in *Bepo* reactor for 12 days at a neutron flux of 2×10^{12} n/cm² sec. Following irradiation, an inactive tantalum solution was added as carrier, and decomposition effected by evaporation with hydrofluoric acid. The tantalum was precipitated from a sulphuric–tartaric acid solution with tannin at *p*H 2·3, and converted to oxide. This was dissolved in a hydrofluoric–nitric acid mixture, the tantalum present extracted into methylisobutylketone, back-extracted into hydrogen peroxide solution and reprecipitated with tannin at *p*H 2·3. The tannate was ignited to oxide, weighed and the activity of the tantalum-182 isotope measured.

The results are given in Table 1

Table 1

Sample	Ta (p.p.m.)	Nb (%)	Nb/Ta
Pyrochlore concentrate, Mrima, Kenya	565	28·6	506
Pyrochlore soil, Mrima, Kenya	61	1·27	208
Pyrochlore, picked crystals, Sukulu, Uganda	17,060	46·6	27
Pyrochlore, Nkombwa, Rhodesia	405	51·7	1,277
Pyrochlore, soil, Araxa, Brazil	232	3·29	142
Barium pyrochlore, Araxa, Brazil	559	38·7	692
Pyrochlore, Chilwa, Nyasaland	73	42·4	5,808
Pyrochlore crystals, Leushe, Kivu, Congo	446	48·2	1,081
Pyrochlore, Panda Hill, Tanganyika	6,300	40·5	64
Pyrochlore crystals, Lokupoi, Uganda	444	46·3	1,043
Pyrochlore concentrate "A", Oka, Quebec, Canada	4,170	35·9	86
Pyrochlore concentrate "B", Oka, Quebec, Canada	1,563	40·5	259
Pyrochlore concentrate "C", Oka, Quebec, Canada	1,453	41·5	286
Pyrochlore concentrate, Busumbu, Uganda	31,690	29·3	9·2
Pyrochlore concentrate, Søve, Norway	4,210	38·8	92

On the face of it, the interest might be restricted to pyrochlores with niobium/tantalum ratios of around 700 : 1 (2,000 : 1 in the United States), corresponding to the desirable concentration of 0·15 per cent tantalum in the metal. However, this need not be the case, in that in processing the ore, from concentrate to metal, some preferential depletion of tantalum occurs, even without the hexone separation step. Thus, niobium/tantalum ratios as low as 500 : 1 may be satisfactory for reactor grade metal and also for alloy production[6]. Specifications for other applications of pure niobium metal (for example, niobium-base super-conducting alloys) are less stringent concerning tantalum concentration in the metal. It is expected that for such applications most of the pyrochlores listed in Table 1 would be suitable without the hexone extraction step. Thus, the availability of pyrochlores as a source of niobium metal can be expected to make an important contribution to an eventual reduction in the cost of this element for industrial applications.

PHYSICS

Gravitational Collapse

Hoyle and Narlikar[1] have recently considered the gravitational contraction of large spherically symmetric masses. They claim that according to the field equations of general relativity a sufficiently large mass must collapse to a space–time singularity, provided that the equation of state of the matter is realistic. Much of their argument is based on the alleged absence of suitable static spherically symmetric interior solutions.

I wish to point out that a relativistic solution exists for a static pressure-free sphere of arbitrary size and mass provided that the matter carries an appropriate electric charge. This is the counterpart of the classical solution in which gravitational attraction and electric repulsion just balance. The metric outside the sphere can be put in the form:

$$ds^2 = -\left(1 + \frac{m}{r}\right)^2 (dr^2 + r^2 d\theta^2 + r^2 \sin^2\theta d\varphi^2) + \left(1 + \frac{m}{r}\right)^{-2} dt^2, \quad (1)$$

and the electrostatic potential is $e/(r + m)$, where $|e| = m$ in relativistic units, or $|e| = m\sqrt{G}$ in dimensional units, G being the gravitational constant. It is known[2] that there exist interior solutions which: (*a*) satisfy the correct boundary conditions at the surface; (*b*) are regular and have positive mass density throughout the interior. The internal electric charge density is everywhere proportional to the mass density, which is arbitrary. It will be noted that the metric (1) has no Schwarzschild singularity.

The total electric charge of the sphere is fairly small compared with the mass: a sphere of neutral hydrogen which had lost a fraction 10^{-18} of its electrons could satisfy the conditions.

There also exist static solutions for a sphere carrying no total charge but inside which there is a separation of positive and negative charge. In this case the exterior field is a Schwarzschild one, but the interior would carry, say, an excess of positive charge near the centre balanced by an envelope of negative charge. Although solutions satisfying the boundary conditions exist[2], it is not known whether they permit an isotropic positive pressure which may be a desirable feature from the physical point of view.

These considerations suggest that charged interior solutions may be relevant to the problem of gravitational collapse.

Non-thermal Biological Effects of Laser Beams

Investigating the effects of pulsed and continuously emitting lasers, we were able theoretically and experimentally to establish that non-thermal effects exist which have to be considered biologically more important than the thermal effects, such as the discrete coagulation of tissue which is therapeutically used, for example, in eye surgery.

We calculated that the laser field has an important electrical vector which has to be considered responsible for causing biological effects of the following classification: (*a*) thermal; (*b*) specific-thermal; (*c*) specific-electric; (*d*) chemical; (*e*) kinetic.

If the output of a laser is focused optically on an absorbing area, it is possible to produce a very high

radiant energy density. To a first order, the diameter of the focal spot is given by $d = f\,\Theta$, where f is the focal length of the optical element and Θ the angle of the beam. For $\Theta = 0{\cdot}01$ radian (about 0·5° angle), and $f = 1$ cm, then d is equal to 0·01 cm. The area of the focal spot is then of the order of 10^{-4} cm². Much smaller spots can be obtained by using high-quality optical elements such as are used in microscopes (as low as 10^{-8} cm²). For a 1-kW ruby laser output, the focused power density will reach about 10^{7} W/cm². At this concentrated power density, the electrical field E V/m is very high. Because $E = \sqrt{\eta I}$, where η is the impedance of free space and I is the intensity of the beam in W/cm², we set for our example $I = 10^{15}$ W/m², then E will be of the order of 6×10^{8} V/m or about 360 V across a red corpuscle. This has to be considered as a very high electrical gradient, even much higher in stronger laser devices, which is doubtless capable of initiating chemical effects, such as polarization of molecules, resonance effects, Debye relaxation, and many more. We call these effects 'specific electric' because they are of non-thermal nature. We see also kinetic effects such as the crater-effect where matter is pushed up around the area where the laser beam impinges.

Considering the laser to be a coherent microwave emission, it occurred to us that this principle should produce

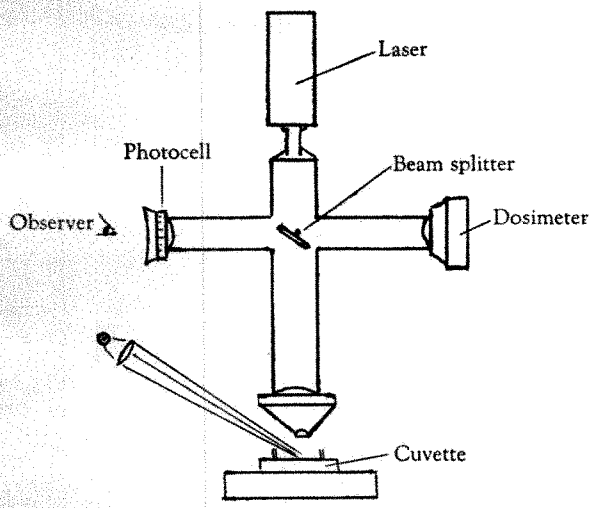

Fig. 1. The laser microscope. Microscope device for irradiation of samples with concentrated laser beams. At the top, a laser head is attached. Two side tubes connected optically through a rotating beam splitter serve for observation and dosimetry respectively. A side lamp with a hair cross optics illuminates the sample in a cuvette and indicates the spot where the laser beam will hit. For coagulation studies, a photocell can be attached to the side tube; this permits opacity changes to be recorded in a sample

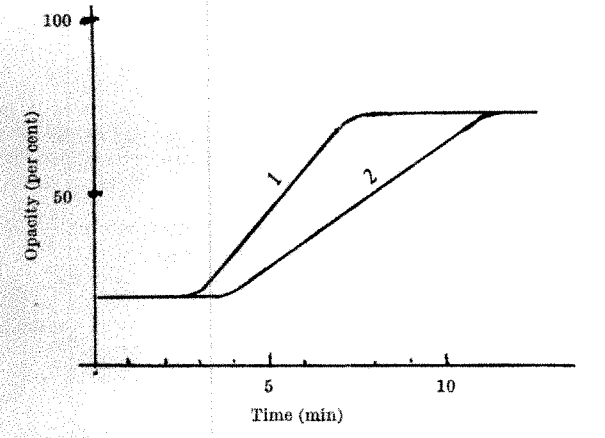

Fig. 2. Two curves of coagulation of citrated blood plasma. Curve No. 1 is a reference sample; curve No. 2 is a sample irradiated with a laser beam

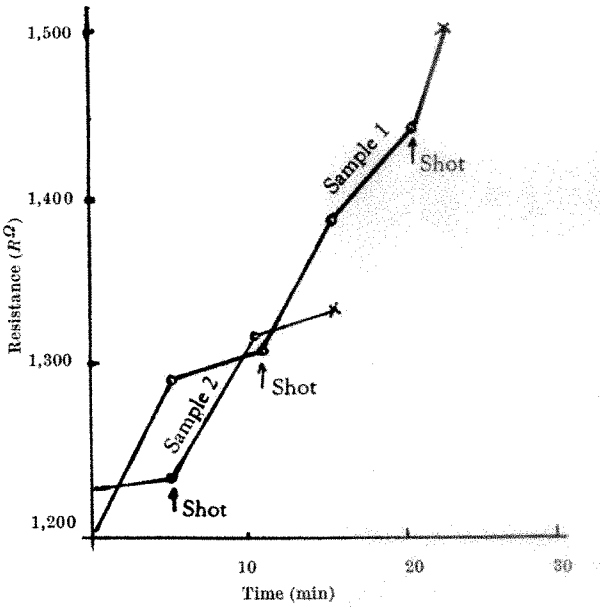

Fig. 3. Blood plasma (citrated) irradiated with a laser. The increase of resistance is shown in the two samples, when a shot (0·5 ms) of the laser is applied

the same biological effects and interactions as microwave beams. We investigated, therefore, the specific-thermal and specific-electric effects of lasers[1,7,8].

One of the appropriate tests, as I found, is the change of the dielectric constant, the change of the electrical conductivity and the specific change of the coagulation rate of plasma[7].

We used the principle of an inverted microscope (Fig. 1) introduced earlier for laser-welding purposes[1]. At the side of the ocular the laser head is attached. Then, there are two side tubes, one going to a dosimeter, the other going to an ocular by which an observer is able to see the object on the slide holder. The optical axis of the two side tubulars crosses a rotating beam splitter inside the microscope tube. First a sample of material is fixed on a substrate and placed on the slide holder. Then the beam splitter is manually rotated to the side of the observer ocular tube and the microscopic adjustment is used to focus the laser head on the right spot of the sample to be irradiated. A side lamp with a lens and a hair cross is set in such a way that the area where the laser will hit is indicated. Then the beam splitter is rotated in the direction of the dosimeter tube. When the laser is fired, the dosimetric device (electric calorimeter or radiometer) indicates simultaneously the power obtained.

We irradiated a sample of citrated plasma in this way. Then we added calcium chloride solution in order to initiate slowly progressing coagulation characterized by a gradual opacity. The rate of it was observed photometrically, by attaching to the side tubular a photocell with diaphragm and filter, and using the technique described elsewhere[3,4]. We obtained the pattern as indicated in Fig. 2. Then a xenon lamp, adjusted through an optical system, filter (7000 Å) and shutter, was used to give the same power output as the pulsed ruby laser beam. Both coagulation rate curves were compared and showed that the non-coherent light source did not produce the same effect of the coagulation process as was obtained using a laser. Therefore, we conclude that the coherent light of the laser is able to produce chemical or electro-chemical effects which are of a non-thermal nature.

In other experiments we measured, by the same technique of comparison, the electrical conductivity changes in proteins. In Fig. 3 are shown the results obtained but which could not be obtained by using ordinary light of the same power and wave-length. In Fig. 4 is shown the crater

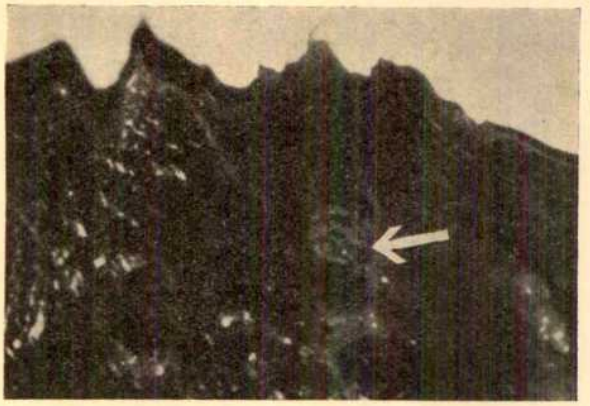

Fig. 4. Crater effect of a concentrated laser beam. The photograph shows a slice of tissue with a laser coagulation mark on it. Through the kinetic effect of the light, the walls around the mark are pushed up

effect produced by a ruby laser on a sliced tissue layer. The output of the beam was 0·2 joules, the pulse time about 0·5 msec (ref. 7). Here also it must be concluded that the concentrated laser beam is able to produce a kinetic effect which may have biological consequences. These mechanical effects are similar to that observed on paddle wheels of radiometers which are turned by the kinetic effect of light.

These results show that laser radiations behave in a similar manner to electromagnetic waves when the interaction with matter is specifically considered. Furthermore, mechanical effects due to the kinetic effect of light are obtained when a high-power output is used. These kinetic effects may also be responsible for some biological actions.

Molecular Excitations in Liquid Helium

Cell theories of liquid helium have been proposed by several investigators[1]. They distinguish successfully between the statistics of helium-3 and helium-4 but are unable to reconcile the measured energy gap with the distance of the observed nearest neighbour. Co-operative motion of the cells accounts without difficulty for the phonon spectrum, but the assumption of weak coupling between the diatomic rotors and the acoustical vibrations is inadequate. The analysis recorded here is a new attack on the nature of the excitations which account for the normal component.

In the normal co-ordinate representation of Born[2] the Schroedinger equation of a normal mode is:

$$\frac{\partial^2\psi}{\partial q_i^2} + (\lambda - \alpha^2 q_i^2)\,\psi = 0$$

where $\lambda = 8\pi^2 m W/h^2$ and $\alpha = 4\pi^2\, m\, \nu_0/h$. The wave function of the whole system in n dimensions is:

$$\Psi = \psi_1(q_1)\,\psi_2(q_2)\,\psi_3(q_3)\,\ldots\,\psi_n(q_n)$$

and the eigenvalues will be:

$$W = \left(v + \frac{n}{2}\right) h\nu_0$$

where the zero point energy is $n/2$. The quantum weight of each of these states is:

$$\omega = \frac{(v + n - 1)\,!}{v\,!\,(n - 1)\,!}$$

The partition function is:

$$f = \sum_{v=0}^{n} \omega e^{-(v+n/2)\,h\nu_0/kT} = e^{-nh\nu_0/2kT}\,(1 - e^{-h\nu_0/kT})^{-n}$$

The energy then is:

$$E = \frac{\partial \log f}{\partial\theta} = \frac{nh\nu_0}{e^{-h\nu_0\theta} - 1} + \frac{h\nu_0}{2}\left(n + \theta\,\frac{\partial n}{\partial\theta}\right) - \log\left(1 - e^{h\nu_0\theta}\right)\frac{\partial n}{\partial\theta}$$

where $\theta = -1/kT$.

If n were Avogadro's number, N_0, the theory would reduce to the usual expression for the Debye theory, and the zero-point energy would be a constant. The present proposal identifies n as the number of rotationally excited atomic pairs:

$$n = \frac{\sum_{2,4\ldots}(2J + 1)\,e^{-J(J+1)B/kT}}{\sum_{0,2,4\ldots}(2J + 1)\,e^{-J(J+1)B/kT}}\,N_0$$

The rotational constant B has the usual value $B = h^2/8\pi^2\,\mu r^2$ with r the nearest neighbour distance of 3·7 Å. The summation over $J = 0, 2$ is sufficient to approximate the system below the λ point. The energy then becomes:

$$E = N_0\,\frac{5e^{-6B/kT}}{1 + 5e^{-6B/kT}}\left[\frac{h\nu_0}{e^{h\nu_0/kT} - 1} - \frac{6B}{1 + 5e^{-6B/kT}}\left(\log\,(1 - e^{-h\nu_0/kT}) + \frac{h\nu_0}{kT}\right) + \frac{h\nu_0}{2}\right]$$

in which the first term only is of importance. It is noted that the terms associated with the zero-point energy are dependent on temperature and become zero at low temperature.

The internal energy observed in the laboratory is well represented below 2° K by:

$$U = \frac{4\pi V}{c^3}\left(1 + \frac{300e^{-6B/kT}}{1 + 5e^{-6B/kT}}\right)\int \frac{h\nu}{e^{h\nu/kT} - 1}\,\nu^2 d\nu$$

in which the first term measures phonons and the second term the normal component. The coefficient of the normal component is sixty times that provided by theory and will be justified later. In the low-temperature approximation the internal energy becomes:

$$U = \frac{4\,\pi^5\,V\,k^4\,T^4}{15\,c^3\,h^3}\left(1 + \frac{300e^{-6B/kT}}{1 + 5e^{-6B/kT}}\right)$$

Fig. 1 compares the heat capacity, the normal component, and the density for the Landau theory, the present theory, and experiment. The theoretical heat capacity does not deviate from experiment below 1·9° K. Landau has derived a relation between internal energy and density of the normal component. Phonon and roton excitations are treated as separate components using $\rho_n = 4\,U/3\,c^2$ with $c_1 = 237$ m/sec and $c_2 = 18{\cdot}5$ m/sec. Normal component measurements by different laboratories do not agree. The theory fits the most recent measurements in the region of greatest reliability. The density is derived from a theory of perfect solution of normal and Debye components having the same expansion coefficients but differing by 1·2 per cent in intrinsic volume. (In liquid hydrogen the *ortho* form has a density 0·5 per cent greater than the *para* form.) The variation in density is, therefore,

a combination of expansion and transformation from superfluid to normal component of greater density.

Ice shows analogous anomalies in heat capacity and density. The Debye theory is adequate to 3° K where an anomaly begins. The anomaly is most pronounced at 10° K. Since independent *ortho* and *para* forms have been demonstrated, molecular rotation can be assumed[3]. The lowest *ortho–ortho* transition in the vapour ($1_{-1} \rightarrow 1_{+1}$) has an energy of 18·6 cm^{-1}, equivalent to 27·8° K. The transition has nuclear degeneracy but no rotational degeneracy. Assuming a transition energy of 15 cm^{-1} the proposed theory fits the data through the maximum of the anomaly. In water, two hydrogen atoms are unambiguously identified with one oxygen atom. If this was not true, *ortho* and *para* forms could not endure. In helium, however, each helium atom is surrounded by about eight nearest neighbours and a rotating pair can be formed with any of these. Isihara[4] has recently calculated the pair distribution function of a dilute hard sphere Boson gas. He finds the number of pairs to be very nearly n^2 or a little more than the required factor of 60 for helium.

The number of excitations may be counted:

$$N = \frac{4\pi V}{c^3} \frac{300e^{-6B/kT}}{1 + 5e^{-6B/kT}} \int \frac{\nu^2 d\nu}{e^{h\nu/kT} - 1}$$

If N is taken as Avogadro's number, a temperature may be calculated equivalent to the Debye temperature. At this temperature the number of excitations or quasi-particles equals the number of molecules. This occurs at 2·7° K, the λ point of the theory. The counting is in error by a factor of two, since $N_0/2$ would give 2·2° K. In the case of ice, the Dulong-Petit limit is reached before the number of excitations reaches Avogadro's number and no λ point is observed.

In helium-3 – helium-4 solutions, only ^{4}He–^{4}He pairs show the quantum properties required by the theory. If this pairing is random, the number of pairs of interest will

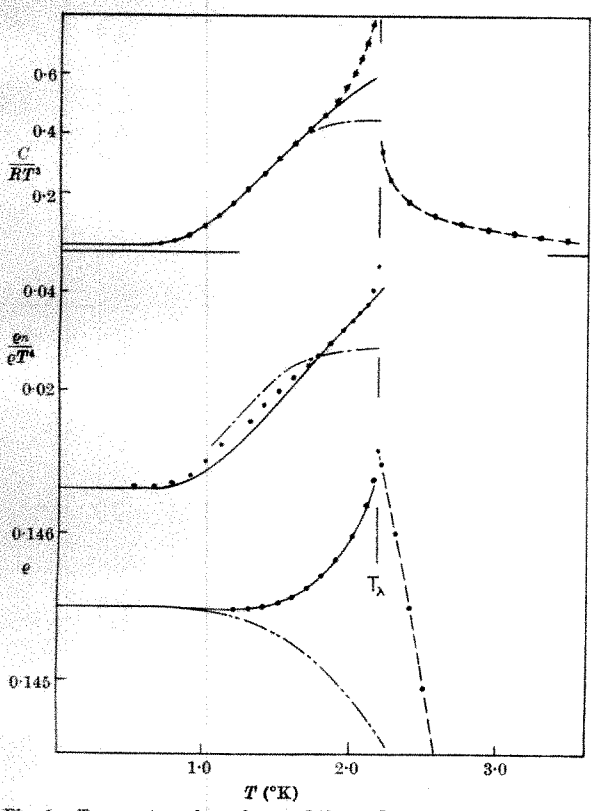

Fig. 1. Temperature dependence of thermodynamic variables. Continuous line, proposed theory; dot-dash, Landau theory; dash-double-dot, Debye theory. Top, heat capacity; centre, normal component; bottom, density

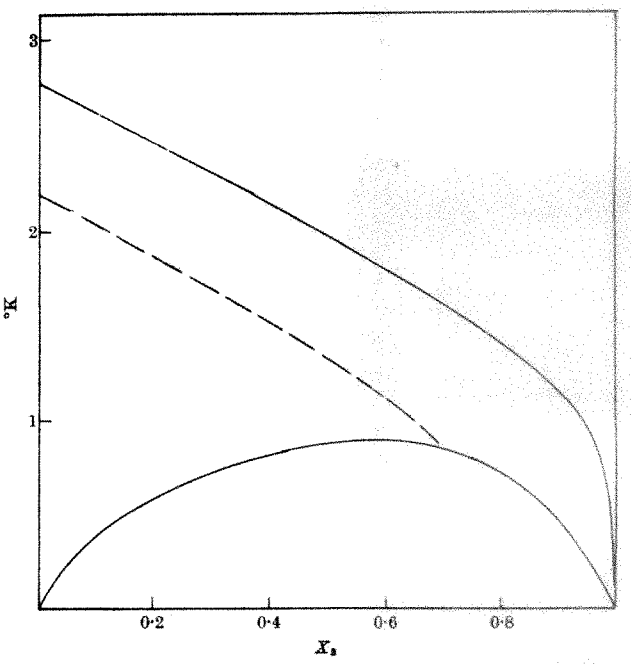

Fig. 2. Phase diagram helium-3–helium-4 solutions. Atomic fraction helium-3 plotted horizontally. Upper line, calculated lambda temperature; dashed line, observed lambda temperature, Lower line, phase separation boundary

be proportional to the square of the atomic fraction of helium-4. The calculated λ temperatures (Fig. 2) show the correct concentration dependence but are 0·5° K above the experimental data.

The character of the excitations of which the normal component is composed is quantitatively described by the normal co-ordinate representation of Born if restricted to rotationally excited atomic pairs. The superfluid (more accurately the Debye liquid) is a substrate within which the excitations exist as a distinguishable component.

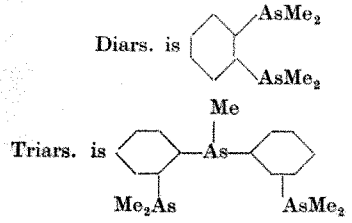
CHEMISTRY

Seven Co-ordinate Vanadium Complexes with Metal-to-metal Bonds

IN contrast with the dimeric carbonyls of transition metals with odd atomic number, hexacarbonylvanadium, with the electron configuration d^5, is mononuclear and paramagnetic with one unpaired electron. It is of interest to enquire, therefore, whether: (1) by partial substitution of the carbonyl groups, dimeric compounds containing vanadium–vanadium bonds can be stabilized; (2) complexes containing M-V(CO)$_6$ groups (M = Cu, Ag, Au), analogous with other complexes recently described[1], can be prepared. The corresponding halides are unknown.



Hieber and Winter[2] have reported that the complex $\{V(CO)_4[P(cyclohexyl)_3]_2\}_2$ is diamagnetic and evidently contains a vanadium–vanadium bond. Other phosphines used gave rise to monomeric, paramagnetic compounds, for example, V(CO)$_4$(PPh$_3$)$_2$. We now report the isolation of the dimeric compound [V(CO)$_4$(diars)]$_2$, [diars = *o*-C$_6$H$_4$(AsMe$_2$)$_2$]. This is formed readily by reaction of the hexacarbonyl with the di(tertiary)arsine in light petroleum at room temperature. It is diamagnetic in the solid state

and in solution, implying a metal–metal linkage; other properties are shown in Table 1. Spectrophotometric titration of the complex with iodine indicates the formation of the product $V(CO)_4$(diars)I, one equivalent of iodine per vanadium being consumed.

Table 1

Complex*	Colour	Molecular weights† Found	Calc.	C—O stretching freq. (I.R., cm^{-1})
$[V(CO)_4(Diars)]_2$	Light yellow	863‡	898	2,085 (*w*), 1,970 (*m*), 1,890 (*sh*), 1,870 (*s*)‡
$Ph_3PAu—V(CO)_6$	Yellow-orange	670§	678	2,043 (*s*), 1,991 (*m*), 1,960 (*m*), 1,925 (*vs*), 1,890 (*sh*), 1,870 (*m*)¶
(Triars)Cu—$V(CO)_6$	Light yellow	710§	734	2,020 (*m*), 1,925 (*m*), 1,885 (*sh*), 1,858 (*s*)

* All are analytically pure and diamagnetic in the solid state.
† Measured osmometrically (concentrations ≃ 0·01–0·05 M).
‡ In CH_2Cl_2.
§ In C_6H_6.
¶ In *cyclo*hexane.

Reaction of the salt $[Na(diglyme)_2][V(CO)_6]$ with the compounds Ph_3PAuCl and (triars) CuBr {triars = $[C_6H_4(AsMe_2)]_2AsMe$} in tetrahydrofuran yields the products Ph_3PAu-$V(CO)_6$ and (triars)Cu-$V(CO)_6$ respectively. Physical data, presented in Table 1, fully support these formulations. Iodine oxidations, using two equivalents of the halogen, yield the complexes Ph_3PAuI or (triars)CuI and hexacarbonylvanadium. Attempts to prepare an analogous compound containing a silver–vanadium bond have led, so far, to reduction to metallic silver. The possible use of substituted carbonyl anions of vanadium is being investigated together with other systems containing vanadium-heavy metal linkages. These metal–metal bonded complexes provide examples of seven co-ordinate vanadium(0), a co-ordination number which was, until recently, very uncommon in the first transition series.

Iodine as a Scavenger for Hydrogen Atoms in Irradiated Ethanol

As with most organic compounds, one of the principal end-products resulting from the effect of high-energy ionizing radiation on pure ethanol is hydrogen gas. Much interest has been shown recently in the radiolysis of alcohols, and this paper presents data on hydrogen atom yields, which help to distinguish the various possible mechanisms.

The yield of hydrogen gas is decreased, but not reduced to zero, by the presence during radiolysis of a radical scavenger. This leads to the concept of molecularly detached hydrogen gas produced from entities which decompose without the formation of reactive intermediate species. Schematically, the reaction for the production of hydrogen may be represented as:

$$C_2H_5OH \rightsquigarrow H + H_2 + \ldots$$

where H_2 represents molecularly detached hydrogen and H the hydrogen atom, which may react to give hydrogen molecules in the pure solvent, or react with a scavenger when such a suitable radical trap is present.

By isotopic labelling of the ethanol molecule with deuterium, Burr[1] has concluded that the hydrogen atoms formed during radiolysis undergo an abstraction reaction of the type:

$$H\cdot + C_2H_5OH \rightarrow \cdot C_2H_4OH + H_2$$

which leads to the production of one molecule of hydrogen gas for each hydrogen atom taking part in the abstraction reaction.

The kinetics of two competing reactions has been used[2] to measure the hydrogen atom yield, assuming that:

$$C_2H_5OH \rightsquigarrow H + H_2 + \ldots \quad (1)$$

is followed by:

$$H\cdot + C_2H_5OH \xrightarrow{k_1} \cdot C_2H_4OH + H_2 \quad (2)$$

where alternatively the hydrogen atoms in the presence of a scavenger react as follows:

$$H\cdot + S \xrightarrow{k_2} HS \quad (3)$$

in which (2) and (3) are the competing reactions.

Using benzoquinone (Q) as a scavenger, and from a plot of $\frac{1}{G(H_2)_{max} - G(H_2)}$ against $\frac{1}{[Q]}$, Adams, Baxen-

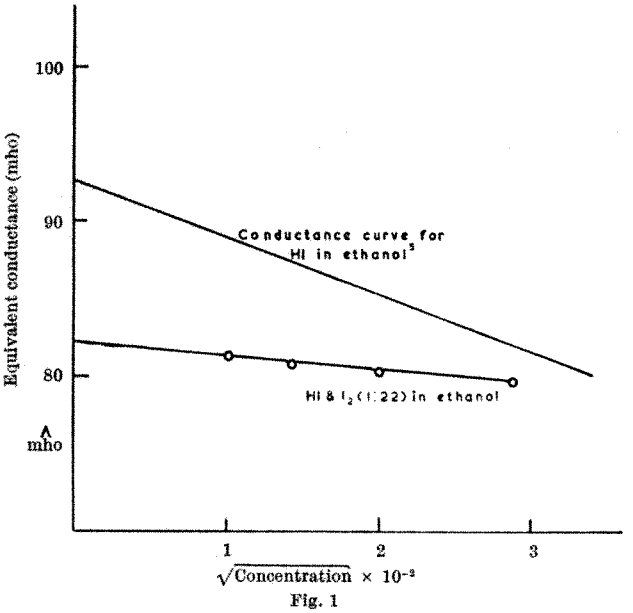

Fig. 1

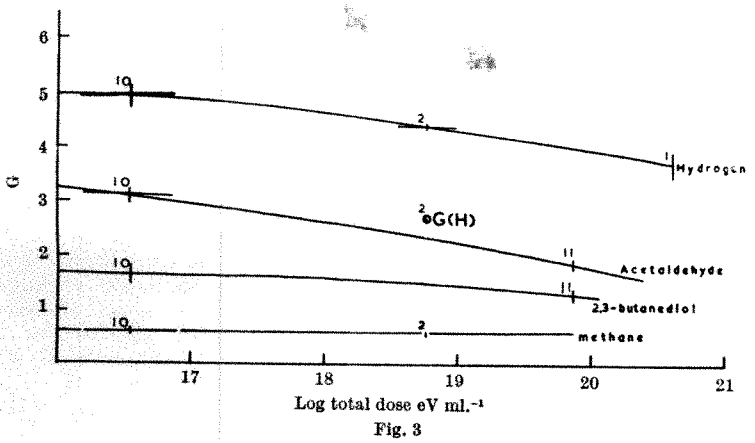

Fig. 3

dale and Sedgwick[2] have found the intercept on the $\frac{1}{G(H_2)_{max} - G(H_2)}$ axis to be 0·37, which, assuming the kinetics of the foregoing reactions, gives a value for $G(H)$ of 2·7.

An alternative scavenging agent is iodine, and we have used two methods to measure the quantity of hydrogen iodide formed. The first depends on the fact that, in a polar solvent such as ethanol, the hydrogen iodide ionizes to form solvated protons and iodide ions, the latter forming an equilibrium mixture of triiodide ions with excess iodine.

$$H\cdot + I_2 \rightarrow HI + I\cdot \quad (4)$$

$$HI \rightleftharpoons H^+ + I^- \quad (5)$$

$$I^- + I_2 \rightleftharpoons I_3^- \quad (6)$$

Equilibrium (6) has been investigated spectrophotometrically in water[3] and methanol[4].

Similar results in ethanol show the triiodide ion to have two well-defined absorption peaks at 292 mμ and 360 mμ which lie between the ethanol–iodine interaction peak at 445 mμ and the charge-transfer band at 224 mμ. If the concentration ratio of I^- to I_2 is maintained below 1 : 20, then equilibrium (6) is sufficiently displaced to the right to produce a constant concentration of I_3^- ions for varying ratios of I^- to I_2. Under these conditions ε_{max} at 360 mμ for I_3^- ions is 24,400 while at the same wave-length ε for I_2 is 84. Hence, by observing the increase in optical density at 360 mμ in irradiated solutions of iodine in ethanol, the concentration of I_3^- ions may be calculated. From this value the concentration of HI may be calculated.

The second method utilizes the ionic dissociation of hydrogen iodide in ethanol and the variation of equivalent conductivity (Λ) with change of concentration, which has been investigated by Goldschmidt[5]. Fig. 1 shows the modification to the conductance curve for HI in ethanol by the addition of a 20-fold excess of iodine over the concentration of HI. This modification is caused by the difference in mobility between the I^- and I_3^- ions. Thus, by measuring the change in resistance of irradiated solutions of iodine in ethanol a measure of the HI produced may be obtained.

Solutions of iodine in pure dehydrated ethanol were prepared in light-screened vessels. Measurements showed that visible light initiated the decomposition of iodine–ethanol solutions. Dehydration and purification of ethanol were carried out as for conductance experiments[6] when the alcohol showed a specific resistance greater than 10^8 ohms. The iodine–ethanol solutions were de-aerated by vacuum techniques and irradiated by γ-rays either from a 200-c. cæsium-137 source or a 300-c. cobalt-60 source.

The total dose variation was 4×10^{17} to $2{\cdot}4 \times 10^{18}$ eV ml.$^{-1}$. The dose rate was varied from $1{\cdot}4 \times 10^{16}$ to $6{\cdot}8 \times 10^{16}$ eV ml.$^{-1}$ min^{-1}. The initial iodine concentration range was 7×10^{-4} to 10^{-2} molar. The irradiation time varied from 5 min to 3 h. The results showed that $G(HI)$ depended on the duration time of irradiation and also the total absorbed dose as shown in Fig. 2.

The time dependence is consistent with results obtained by Meshitsuka and Burton[7] for HI production in irradiated iodine–*cyclo*-hexane solutions. The variation in $G(HI)$ with time has been attributed to the scavenging properties of HI (ref. 7). Fig. 2 shows that extrapolation to zero dose zero time gives $G(HI) = 5{\cdot}6$.

In order to correlate $G(HI)$ at zero dose with $G(H_2)$, a knowledge of the variation of $G(H_2)$ with total energy input is required. This has been investigated in the case of the bombardment of ethanol with 28-MeV helium ions by Newton and McDonell when it was found $G(H_2)$ was an inverse function of the total energy input[8]. Johnsen reports an inverse relationship between $G(H_2)$ and the total energy input when ethanol is irradiated with cobalt-60 γ-rays from a total dose of 10^{18}–10^{22} eV ml.$^{-1}$ (ref. 9). Table 1 shows various yields of $G(H_2)$ obtained using cobalt-60 γ-radiation.

Table 1

Reference	$G(H_2)$	Total dose eV ml.$^{-1}$
10	$4{\cdot}87 \pm 0{\cdot}2$	$1{\cdot}6 - 8{\cdot}0 \times 10^{18}$
2	4·35	$3{\cdot}8 - 8{\cdot}9 \times 10^{18}$
1	$3{\cdot}66 \pm 0{\cdot}26$	$3{\cdot}9 \times 10^{20}$

Fig. 3 shows these results to lie on a smooth curve when log total dose in eV ml.$^{-1}$ is plotted against $G(H_2)$. Also in Fig. 3 are the yields of acetaldehyde 2, 3-butanediol and methane plotted against log of the total dose as obtained by various workers. There are insufficient data to extrapolate accurately the curve for $G(H_2)$ to zero dose, but an approximation may be made at $G(H_2) \simeq 5{\cdot}6$, the same value for $G(HI)$ at zero dose. $G(H)$ at zero dose may not be estimated as only one value is available.

Primary processes may only be postulated in the knowledge of radical and molecular yields at zero dose. Further experimental work is in progress to measure hydrogen gas yields in the presence and absence of iodine and to establish the nature of the energy input effects.

Circumstances of Multi-spot Paper Chromatograms of Sodium Orthophosphates: *in situ* Identification of the Species

The formation of more than one zone containing phosphate when the sodium orthophosphates are chromatographed on paper suggests that these spots contain different molecular species originating in proton transfer equilibria of the kind:

$$H_2PO_4^- + B^{-n} = HPO_4^{=} + HB^{-(n-1)}$$

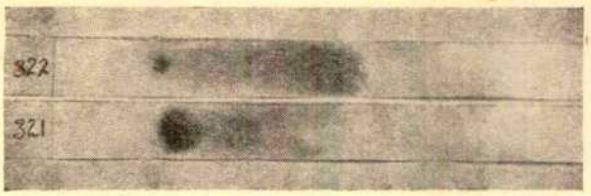

Fig. 1. Paper chromatograms of Na_3PO_4 (321) and NaH_2PO_4 (322) formed with butanol/water

where B^{-n} is a base[1,2]. The speed of proton transfers, for example, the half-life for the reaction of hydronium and hydroxyl ions is 10^{-8} sec[3], argues against this as such equilibria yield multiple spots only if the transition time is comparable with the time required for the formation of the chromatogram[4]. It is natural to question next if the zones are actually of different species since discontinuities in either the immobile or mobile phases can also produce the result[4]. Chromatograms of orthophosphoric acid and of the primary, secondary, and tertiary sodium salts were formed on 55 cm × 2·8 cm strips of Whatman No. 1 filter paper, acid washed, which had also been washed in 2 M acetic acid followed by three successive rinsings in distilled water[5]. The chromatograms were formed either with pyridine/ethyl acetate/water (the faster solvent) or butanol/water. Fig. 1 is a photograph of 10 μl. of 0·01 M trisodium phosphate (No. 321) and 10 μl. of 0·01 M sodium dihydrogen phosphate (No. 322) formed simultaneously with BuOH/15 per cent H_2O. The origin was the vertical pencil line adjacent to the numbers. When revealed, the colour process was that employing ammonium molybdate and benzidine hydrochloride[6]. In certain select cases, the multiple spots were irradiated in the University's *Triga* reactor[7,8]. Both sodium and phosphorus undergo (n,γ)-reactions to form radioactive isotopes which decay as follows[9,10]:

$$^{24}Na = {}^{24}Mg + \beta^- \ (1{\cdot}39 \ \text{MeV}) + \gamma \ (1{\cdot}38,\ 2{\cdot}76 \ \text{MeV}) \ (\text{half-life} = 14{\cdot}97 \ \text{h})$$

$$^{32}P = {}^{32}S + \beta^- \quad (1{\cdot}712 \ \text{MeV}) \quad (\text{half-life} = 341{\cdot}3 \ \text{h})$$

The nuclear cross-sections, the natural existence of each element as a single isotope, the absence of interfering reactions[11], and the difference in half-lives, make the pair ideal for simultaneous determination of the two when mixed. Applied to known salts without chromatography, the resolution of the activity versus time curve gave $Na/P = 1{\cdot}0, 1{\cdot}2$ for NaH_2PO_4; $Na/P = 2{\cdot}0, 2{\cdot}0$ for Na_2HPO_4; and $Na/P = 3{\cdot}1, 3{\cdot}0$ for Na_3PO_4. Table 1 gives the pertinent results from the chromatograms. R_F-values are not given since, in order to obtain clear unambiguous separation, it was necessary that the mobile phase flow from the end of the chromatogram. With Pyr-EtAc/H_2O, the fast spot has a composition nearly that of orthophosphoric acid while the slow spot has one approximately that of primary sodium orthophosphate regardless of the solution applied. The circumstances of double spot formation with a mobile phase of BuOH/H_2O are different, but again there is a spot of composition very much different from the solution applied with a much higher degree of protonation.

Table 1. Na/P Ratio of Zones of Paper Chromatograms of Phosphoric Acid and the Sodium Orthophosphates

Solution applied	Forming solvent	Na/P	
		Slow	Fast
0·01 M H_3PO_4	Pyr-EtAc/15 per cent H_2O	—	0·03
0·05 M H_3PO_4	Pyr-EtAc/15 per cent H_2O	—	0·14
0·10 M H_3PO_4	Pyr-EtAc/15 per cent H_2O	—	0·05
0·01 M NaH_2PO_4	Pyr-EtAc/15 per cent H_2O	—	0·24
0·01 M Na_2HPO_4	Pyr-EtAc/15 per cent H_2O	0·75	0·19
0·01 M Na_3PO_4	Pyr-EtAc/15 per cent H_2O	1·2	0·19
0·01 M Na_3PO_4	Pyr-EtAc/24 per cent H_2O	1·3	0·39
0·01 M NaH_2PO_4	BuOH/10 per cent H_2O	1·2	0·38
0·01 M Na_3PO_4	BuOH/10 per cent H_2O	0·80	—

Multiple-spot formation depends on a number of factors. The first of these is prewashing the paper with acid. With water alone or a solution of disodium dihydrogen ethylenediamine tetraacetate (EDTA), an excellent chelating agent for rare-earth cations, the phosphate does not migrate from the origin or else produces a smear. With acetic acid, acetic acid and EDTA, or hydrochloric acid, migration occurs and multi-spots can be produced. Since the effect of the acid overwhelms that of the EDTA, it seems that removal of the rare earths is not as important as exchange of protons for cations, principally sodium. Neutron activation studies of the sodium content of the paper showed that washing with acetic acid reduced the sodium content by a factor of 7–8 while chromatography further reduced it by a factor of 12 below that of the washed paper. The forming solvent must contain water. With 5 per cent or less water in the Pyr-EtAc solvent, there was no migration from the point of application. Between 5 per cent and saturation (24 per cent) water enhanced zone disengagement. Multi-spot formation depended on the total phosphate concentration and the Na/P ratio. These were adjusted by adding sodium acetate. As a rule, the slow spot appeared at 0·02 M phosphate when $Na/P = 1$ and 0·01 M phosphate when $Na/P = 2$. The size of the second spot increased with the Na/P ratio at 0·01 M. This is independent of the acidity of the solution applied. Identical double spots formed from Na_3PO_4 for *p*H-values of 2·1–12·3. The secondary salt is critical, for both single spots and double spots could be obtained. This did not depend on the *p*H. The primary salt and the acid gave a single spot at *p*H-values from 2·2 to 12·0. In all these cases the *p*H was adjusted with ammonia and hydrogen chloride.

The phenomena can be explained if the system consists of phosphate species, hydronium ion, the carboxyl groups of the paper, and their conjugate bases, all in competition for protons. The forming solvent, in passing from the reservoir to the point of application, passes through paper from which it extracts protons, placed there by the acid prewash, to give an acid front. The acidity drops sharply a small distance behind the advancing front much like the water concentration in chromatograms formed with absolute ethanol[12]. This pulse of acid, on entering the solute zone, converts part of the phosphate to approximately phosphoric acid, with advances at a higher rate than less-protonated phosphate ions. This conversion stops once the acid front passes the origin and the remainder of the phosphate proceeds as a less-protonated species approximating NaH_2PO_4.

The Na/P ratios were determined at positions within the spots where the phosphate had the greatest activity. In some cases shoulders were observed on the radiographic profiles which decayed swiftly, indicating a far higher sodium content than in other portions of the same spot. A region of high sodium activity between the solvent front and the phosphate spot was observed in chromatograms of 0·01 M Na_3PO_4 formed with BuOH/H_2O, which indicates a separation of cation from the original anion[13]. The Na/P ratio in the phosphate spot was 0·80, which suggests that in this case the normal salt was sufficiently protonated to produce the NaH_2PO_4 but not the fast H_3PO_4. The exchanged sodium moved away from the phosphate.

Rapid Determination of D_2O Content in Water using a Vapour Pressure Osmometer

I HAVE carried out determinations of D_2O content in water using the vapour pressure osmometer 'Mechrolab, Model 301 *A*', designed to perform molecular-weight determinations. Briefly, the principle of this instrument is as follows[1,2]: two thermistors, charged with a drop of solvent and arranged in a d.c. Wheatstone bridge, are at the same temperature in an ambient atmosphere saturated with the vapour of the selected solvent. The bridge is equilibrated, and a drop of a solution of the same solvent is placed on one of the two thermistors (called the sample thermistor). Solvent condenses on this drop of solution until vapour pressure equilibrium is approached, and the temperature of the thermistor increases. Its resistance variation depends on the concentration of the solution and it is determined by rebalancing the bridge.

Vapour pressures of heavy and light water are also different and, in principle, it is possible to use the vapour pressure osmometer for carrying out heavy-water analysis. But in this case a complication arises from the deuterium exchange between the heavy-water drop and 'light' water vapour and between D_2O vapour and the 'light' water drop placed on the reference thermistor. Because of the usual inertia of thermal instruments it is not possible to shorten the time of measurement in order to reduce the exchanged amount of deuterium to a negligible value. Indeed, about 2 min are necessary to reach the stationary condition in the standard measurements of molecular weight with this vapour pressure osmometer. The difficulty can be overcome by determining the progressive decrease of resistance difference (ΔR) between the reference and sample thermistor during the course of the measurement. If $\log \Delta R$ is plotted against time a straight line is obtained. The exchange reactions are described by the following relationship:

$$\frac{C_1}{C_0} = \frac{S_1}{S_1 + S_2} + \frac{S_2}{S_1 + S_2} \exp\left\{ - \rho t \left(\frac{1}{S_1} + \frac{1}{S_2} \right) \right\} \quad (1)$$

$$\frac{C_2}{C_0} = \frac{S_1}{S_1 + S_2} - \frac{S_1}{S_1 + S_2} \exp\left\{ - \rho t \left(\frac{1}{S_1} + \frac{1}{S_2} \right) \right\}$$

where C_i is the concentration of label in compartment i at the time t; S_i is the amount of exchangeable material in compartment i; and ρ the exchange rate. In the relationship (1) the following initial conditions are used: at $t = 0$, $C_1 = C_0$ and $C_2 = 0$.

Table 1

D_2 molar fraction	ΔR_0 (ohms)	ΔR_0 normalized to $2{\cdot}91 \times 10^3$	$\Delta P/P_{H_2O}$ calculated
0·9980	330 ±3	0·113	0·112
0·6921	226 ±2·5	0·0777	0·0781
0·4499	147 ±2	0·0505	0·0511
0·2783	91·2 ±1·2	0·0313	0·0318
0·2478	82·6 ±0·2	0·0284	0·0283
0·1952	65·4 ±0·1	0·0225	0·0223
0·1196	40·3 ±0·2	0·0138	0·0137
0·0475	16·2 ±0·2	0·0056	0·0054
0·0343	11·5 ±0·2	0·0039	0·0039
0·0118	4·00 ±0·06	0·0014	0·0014

In our case C_1 and C_2 can be replaced by P_1 and P_2 (vapour pressure of water placed on the reference and sample thermistors). The vapour pressure difference (ΔP) is given by:

$$\Delta P = \Delta P_0 \exp\left\{ - \rho t \left(\frac{1}{S_1} + \frac{1}{S_2} \right) \right\} \quad (2)$$

ΔP_0 can be determined by the extrapolation of a linear plot of $\ln \Delta P$ against t at zero exchange time, that is, the time at which the heavy-water sample was placed on its thermistor. The half-exchange time ($T_{1/2}$) is not only dependent on ρ but also on $(1/S_1 + 1/S_2)$ and, therefore, on the drop sizes. Variations of $T_{1/2}$ values are expected, but this fact does not affect the determination of Δp_0.

For our purpose formula (2) can be re-written as follows:

$$\Delta R = \Delta R_0 \exp\left\{ - \rho t \left(\frac{1}{S_1} + \frac{1}{S_2} \right) \right\} \quad (2')$$

ΔP being proportional to ΔR.

Water samples with different D_2O contents were prepared by dilution of a heavy-water sample (99·8 per cent D_2O) supplied by CISE Laboratories of Milan. The vapour pressure osmometer 'Mechrolab Model 301 *A*' was equipped for determinations at 37° C. The measurements were

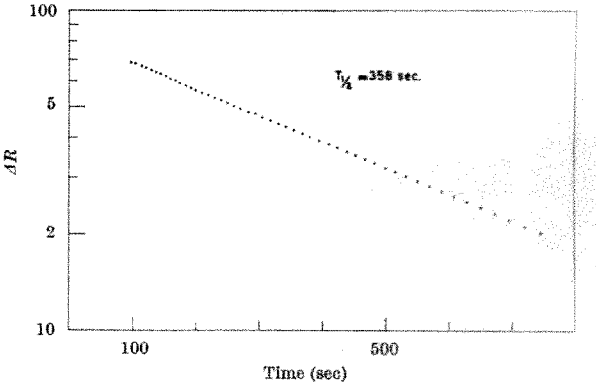

Fig. 1. Plot of ΔR against time

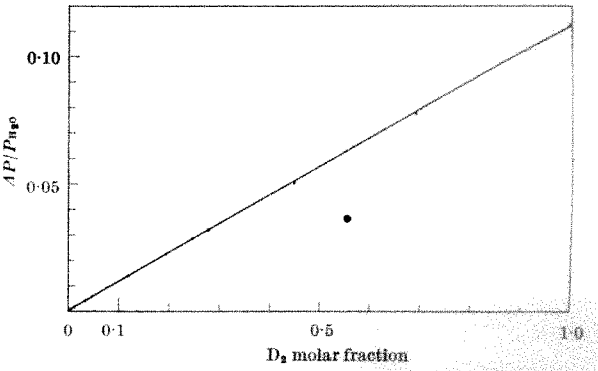

Fig. 2. Behaviour of vapour pressure of heavy water samples against D_2 molar fraction

carried out as follows: as soon as possible, four drops of heavy water were successively placed on the sample thermistor and the moment at which the fourth drop was placed on the thermistor was chosen as zero time. Readings started after about 90 sec and the decrease of ΔR was followed for about 2 times $T_{1/2}$. A typical plot is shown in Fig. 1. The reproducibility of $T_{1/2}$ is about ± 10 per cent with a mean value of 350 sec, as was foreseen, but the reproducibility of ΔR_0 readings is 1·0–1·5 per cent (Table 1).

The theoretical values of the vapour pressure of heavy-water mixtures P_m are deducible from the following relationship:

$$P_m = P_{H_2O}\,\gamma_{H_2O} + P_{HDO}\,\gamma_{HDO} + P_{D_2O}\,\gamma_{D_2O} \qquad (3)$$

where γ_i is the molar fraction of compound i and P_i its vapour pressure. The value of γ_i can be deduced from the mole percentage of deuterium (x) with respect to the total hydrogen, and the value of the equilibrium constant of the reaction: $H_2O + D_2O \rightleftarrows 2HDO$.

Therefore:

$$P_m = P_{H_2O}(1-x)^2 + 2P_{HDO}x\,.\,(1-x) + P_{D_2O}x^2 \qquad (3')$$

Using the P_i values reported in ref. 3, we obtain for our case:

$$\frac{\Delta P}{P_{H_2O}} = -0{\cdot}003\,x^2 + 0{\cdot}115\,x$$

where $\Delta P = P_{H_2O} - P_m$

This equation is plotted in Fig. 2 together with experimental ΔR_0 values, normalized to $2{\cdot}91 \times 10^3$ (see also Table 1). The agreement between calculated and experimental data is good, so that the method described may be considered practicable, especially in view of its rapidity and the small volume of sample required.

I thank Prof. M. Silvestri for advice.

Carbonium Ion Mechanism and Results of Solvolysis of (+)-2-Bromo-octane

The remarkable prevalence of re-arrangement in simple alkyl groups during the formation of alkyl halides, and the concomitant loss in optical purity have been loosely ascribed to the intermediate formation of a carbonium cation[1]. The conversion of an alkyl halide into the alcohol, ester, or ether must therefore be scrutinized for points of correlation. There are few published examples of alkyl rearrangement in the solvolysis of straight chain alkyl halides. Isopropanol was formed in the mercury catalysed solvolysis of *n*-propyl bromide in aqueous formic acid, and the carbonium ion mechanism was postulated[2].

By a mechanism designated 100 per cent S_N1 (that is, the carbonium ion mechanism) (+)-2-bromo-octane was solvolysed in 60 per cent aqueous ethanol at 80°, resulting in the formation of (−)-2-octanol showing some 60 per cent loss in optical purity[3,4]. It remained to be seen if rearrangement of the alkyl group also occurs in this system. We find by gas-liquid chromatography[5] that isomerically pure 2-octanol and ethyl 2-octyl ether were obtained when 2-bromo-octane (M/40) was heated under reflux (72 h) in 60 per cent aqueous ethanol. In another example, with (+)-2-bromo-octane, α_D^{20} + 40·24° (l = 1) (0·31 molar instead of M/40) the (−)-2-octanol, b.p. 77·5°/10 mm, n_D^{20} 1·4256, α_D^{18} −3·62° (l = 1) showed 51 per cent loss in optical purity, but was accompanied by only < 0·5 per cent rearranged products. It is true that hydrogen bromide is a product of the solvolysis; but (+)-2-octanol lost no optical purity when it was heated under reflux (72 h) with 60 per cent aqueous ethanol containing hydrobromic acid (0·155 molar).

We have therefore an example of a system involving considerable loss in optical purity, previously attributed entirely to the carbonium ion mechanism, yet showing no rearrangement in the alkyl group.

Photodimerization in Crystalline 9-Cyanoanthracene

Robertson[1] has pointed out that the type of crystal structure adopted by an aromatic molecule appears to depend on the molecular shape. Thus, those in the form of elliptical planes crystallize with an anthracene-type (A) structure on which weak coupling between molecules in the electronically excited state is responsible for a slight shift in the fluorescence spectrum with respect to the molecular spectrum, and the vibrational structure is largely preserved. Disk-shaped molecules such as pyrene and coronene, on the other hand, exhibit strong coupling with a close-packed type B structure in which pairs of molecules present as a structural 'unit' or as an imperfection are responsible for the emission of the characteristic excimer band, red-shifted by some 6,000 cm^{-1} from the molecular spectrum and devoid of vibrational structure[2].

It has been shown[3] that a change in the molecular shape of anthracene by the substitution of a 9-cyano group or phenyl groups in the 9,10 positions produces a change from the molecular to the excimer fluorescence spectrum which is undoubtedly due to a corresponding change in the crystal structure from type A to type B (ref. 4). In the former case the replacement of the green structureless-fluorescence by a blue structured 'molecular' fluorescence spectrum during exposure to ultra-violet radiation was attributed[3] to the photochemical consumption of dimeric exciton traps, the logical alternative photomorphic change being difficult to visualize.

We have now taken X-ray diffraction photographs of powdered 9-cyanoanthracene in its original green-fluorescent form and of the blue-fluorescent photoproduct together with that of the photodimer precipitated from a saturated outgassed solution in toluene during exposure to ultra-violet radiation. From a comparison of the Guinier photographs shown it is clear that crystalline 9-cyanoanthracene undergoes photodimerization which may be promoted by strong interaction in the lowest excited singlet state of the close-packed type B structure. The blue, structured fluorescence of the photoproduct must originate from residual molecules of 9-cyanoanthracene dispersed in the photodimer matrix.

Although the photodimerization of anthracene itself in solution is well known[5], there is no reported evidence for this process in its (type A) crystal form. It therefore appears that in so far as molecular shape determines the type of lattice adopted by an aromatic molecule, this may also influence its photochemical behaviour in the crystalline state. It must also be concluded that, since photodimerization competes with excimer fluorescence, these two processes cannot be associated with parallel and

Nonaboronnonachloride

The recent preparation of the borane B_9Cl_8H (ref. 1) prompts us to report some of our mass spectral work on the products arising from the thermal decomposition of diboron tetrachloride. When diboron tetrachloride decomposes spontaneously at temperatures more than 0° the main product is boron trichloride with lesser amounts of yellow B_4Cl_4 (ref. 2), red B_8Cl_8 (ref. 3) and dark red $B_{12}Cl_{11}$ (ref. 4); a dark purple solid has also been detected but in amounts too small to allow accurate classical analysis[4].

The diboron tetrachloride used in this work was prepared by reducing boron trichloride in a mercury discharge[5] and had been allowed to decompose slowly during a period of 20 months at room temperature. A series of fractional condensations and sublimations performed in a thoroughly baked-out, all-glass vacuum apparatus allowed separation of the several species; if the baking-out process had not been carried out sufficiently well traces of a permanganate-coloured hydrolysis deposit appeared on the vessel walls. A deep blue crystalline solid, volatile at about 40° (10^{-2} mm) was isolated in a virtually pure state and evaporated into a mass spectrometer at 49°; an intense group of mass peaks (407–428) was observed corresponding to the ion $B_9Cl_9^+$; the cracking pattern contained all the peaks for the ions $B_nCl_x^+$ where $n \geqslant x$ (Table 1). The amounts of this blue solid were too small to allow other analytical techniques to be used, but due to the similarity of the volatility and cracking pattern to B_9Cl_8H we suggest the solid is a new boron sub-chloride, nonaboronnonachloride, B_9Cl_9.

Table 1. Relative Intensities of Several Peaks in the Cracking Pattern of B_9Cl_9

Mass No. for $^{11}B_n{}^{35}Cl_x^+$		Relative intensities, $B_7Cl_5^+ = 100$

B_5Cl_4,	195	*ca.* 1·5
B_5Cl_3,	160	25·6
B	55	0·9

Forstner, Haas and Muetterties[1] describe a group of peaks in the mass spectrum of B_9Cl_8H due to the ion $B_{10}Cl_{10}^+$ which they believe arose from recombination reactions in the mass spectrometer. The mass spectrum of one of our nonaboronnonachloride samples also showed peaks due to $B_{10}Cl_{10}^+$, $B_{10}Cl_9^+$ and $B_{10}Cl_8^+$. This spectrum was obtained at a lower pressure than those not showing $B_{10}Cl_{10}^+$ peaks, which would appear to rule out the possibility of recombination reactions since they would be expected to occur most readily at the highest pressures. There is therefore a distinct possibility that decaboron-decachloride, $B_{10}Cl_{10}$, exists as a stable entity and was present as an impurity in one sample of nonaboron-nonachloride. Products containing boron and chlorine in a ratio 1 : 1 are to be expected since diboron tetrachloride produces BCl radicals during its thermal decomposition[6].

We thank Dr. W. L. Mead and Dr. R. A. Saunders for recording the mass spectra on A.E.I. instruments (*MS*9 and *MS*8, respectively).

Auxiliary Electrodes in Mosaic Membrane Systems: Porosity Mosaics

Any heterogeneity in the pore structure of an ionic membrane, such as differences in pore width, charge density at the pore walls, or the sign of these charges, renders the membrane electrochemically a mosaic[1]. When such a mosaic membrane is interposed between two electrolytic solutions of different composition its different parts will ordinarily give rise to different potentials. Consequently, the various parts of the mosaic interact electrically; spontaneous local circuits arise, somewhat analogous to those causing metal corrosion[1-3].

The small dimensions of the component parts of true mosaic membranes impede their direct physicochemical examination. Macromosaic models have largely overcome this difficulty[1,4-7]. The examination of macromodels can be greatly furthered by the introduction of a pair of current-carrying symmetrical auxiliary electrodes which do not contribute to the effective electromotive force of the system. This method has been applied recently to the measurement of the electro-osmotic water transport in 'sign of charge' mosaic systems[7]. We want to point out that such auxiliary electrodes are a tool of general usefulness in studying mosaic membranes, and demonstrate this in an additional instance, water transport investigations in 'width of pore' mosaics.

The general approach, technique, and apparatus used were the same as described in detail for a 'sign of charge' mosaic model[7]. The only difference was that, instead of two membranes of opposite charge, two membranes of the same charge but of different porosities were used. The model examined was:

Ag	AgCl	dilute electrolyte	dense membrane	concentrated electrolyte	porous membrane	dilute electrolyte	AgCl	Ag

←

the arrow indicates the flow of the positive current when electronegative, preferentially cation permeable membranes are used. This model is based on the fact that the water transport per faraday is larger across porous membranes than across denser ones[8]. The anticipated effect in this scheme is the difference between the larger flow (per faraday) across the porous membrane into the concentrated solution and the rather small outward movement across the dense membrane.

In such 'width of pore' models, we determined the rate of volume change of the concentrated solution on open and on closed circuit, and the current; the difference between the two rates is the expected electro-osmosis.

The membranes used were (electronegative) polystyrene sulphonic acid-collodion membranes[9], the denser ones being permselective and permeable to non-electrolytes having molecular weights less than 100. The more porous ones, prepared by swelling a permselective membrane in 97 per cent ethanol[10], were permeable only to molecules with molecular weights lower than 100,000. The concentration potential 0·1 M/0·01 M across such permselective membranes is +54 to +55 mV for KCl or LiCl; across the more porous membranes it is about +10 to +15 mV with KCl, and differs not much from zero with LiCl. LiCl was chosen as the electrolyte for the model experiments because of the large hydrated size of the Li^+. In electro-osmosis Li^+ carries more water per faraday than other univalent cations[7]; also, with LiCl there is a larger difference between the potentials arising across the dense membrane and across the porous membrane than with other uni-univalent salts. The solute concentrations were the same as previously[7]; LiCl was 0·2 M in the more concentrated solution, and 0·002 M in the dilute solution with 0·25 M sucrose added to minimize the effect of normal osmosis.

In one experiment with such a 'width of pore' mosaic model, a current of 1·3 m.amp was obtained; the concomitant electro-osmotic flow was 34 moles of water/faraday into the compartment of the concentrated solution. In another test the current was 1·9 m.amp accompanied by an electro-osmosis of 42 moles of water/faraday.

The results obtained with the 'width of pore' model give additional support, more convincing than that furnished before[1,4], to the concept that anomalous osmosis in ordinary membranes is due to heteroporosity[2]. In a true micromosaic the differences in pore size are likely to be considerably less than in our model; this would reduce the electro-osmotic effect. On the other hand, as stressed previously[7], the linear pathways of the current in micromosaic systems are smaller by two or more orders of magnitude, and the sum of the local currents and the concomitant water transport are correspondingly higher. This view of the mechanism of anomalous osmosis is not necessarily incompatible with Schlögl's very ingenious idea concerning this problem[11]. It does not seem improbable that the two mechanisms might be component parts of the basic mechanism which still awaits quantitative elucidation.

Auxiliary electrodes have now been applied successfully in the study of three different mosaic membrane systems, two previously reported[5,7] and one presented here. Thus it seems most probable that a variety of other effects in mosaic systems might be studied to advantage by the use of such electrodes. Obvious problems include: the transport of both electrolytes and of co-existing non-electrolytes in 'sign of charge' mosaics with various combinations of permselective and more porous membranes; the transport of electrolytes and of co-existing non-electrolytes in 'width of pore' mosaics.

BIOPHYSICS

An Investigation of Soluble Ribonucleic Acid by Zone Electrophoresis

Structural and physical chemical investigations of transfer RNA, whether fractionated or not, in general require that the material be reasonably pure and essentially free from contaminant RNAs of different kinds. Most of the methods at present used for preparation of *s*RNA from the cell supernatant involve only removal of the proteins, and as Brown has pointed out in a recent review[1], the presence of contaminants in the form of other relatively low molecular weight RNA without transfer function is not to be ruled out. Nor has any method been available for the detection of such impuri-

Fig. 1. Polyacrylamide-gel electrophoresis of 'Sephadex G-100' fractions of yeast *s*RNA; *a–d* are successively eluted fractions from the column, and *e* is the unfractionated sample. The start line is indicated

ties, although an apparent sedimentation heterogeneity in a number of preparations has been noted[2,3]. It therefore appeared desirable to evolve techniques both for observing the purity of *s*RNA preparations, and of purifying them on a preparative scale if necessary.

The technique which we have developed to meet the first of these requirements is zone electrophoresis in acrylamide gels. High resolution of protein mixtures has been achieved in this medium, in virtue of a molecular sieve action, whereby larger molecules are retarded more than smaller ones[4,5]. In addition it is possible to take advantage of zone sharpening effects by selection of buffer systems containing ions of appropriate mobilities relative to each other[4].

We have used the disk electrophoresis procedure of Ornstein and Davis[5] with a *tris*-barbital buffer system of *p*H 8·9, and an acrylamide concentration of 10 per cent w/v. Staining was effected with a precipitating solution containing acridine orange, lanthanum acetate and acetic acid, and the stain was removed from the background electrophoretically. The resultant gels show orange zones in a clear background, and the relative proportions of the various components may be estimated by densitometry. A large number of samples have been examined, in particular of yeast *s*RNA; these were prepared by the now standard phenol extraction procedure of Holley[6]. A typical result with one such preparation by General Biochemicals, Inc., is shown in Fig. 1*e*. Many components are clearly present: in the absence of any evidence to suggest that different amino-acid specific transfer RNAs differ in size or shape, one must suppose that the electrophoretic separation is largely unrelated to amino-acid specificity. Extraction of the zones, followed by their examination in the analytical ultracentrifuge (Spinco model *E*, equipped with ultra-violet absorption optics), has shown that the migration rate through the gel is correlated with sedimentation coefficient.

Extraction from the polyacrylamide gel is possible; but this method does not lend itself to the purification of large quantities. We have therefore used 'Sephadex' gel filtration. The best results so far have been achieved by the use of 'Sephadex *G*-100'. The column-length is 150 cm, and the eluent 0·1 M sodium chloride. The flow rate with a column of 5 cm diameter is maintained at about 25 ml./h, and 250 mg of RNA may be fractionated in each experiment without much loss of resolution. The elution curve indicates partial resolution of a lower molecular weight component from most samples. The fractions making up the different regions of the elution profile were pooled, the RNA recovered by ethanol precipitation or dialysis and lyophilization, and aliquots were examined by polyacrylamide gel electrophoresis.

The results for the four major fractions are shown in Fig. 1, together with that for the unfractionated material. Fraction *c* represents the major portion from the centre of the peak, and it is seen to be very largely homogeneous, with the contaminants suppressed to a level which is probably acceptable for most purposes. Assays for arginine and serine acceptor activity revealed that the activity was predominantly concentrated in the main portion of the peak, fraction *c*. Fraction *d* shows substantial enrichment in the low molecular weight components, and the earlier fractions *a* and *b* are enriched in a remarkable series of higher-molecular-weight components which have been reproducibly present in all preparations of phenol-extracted yeast *s*RNA so far examined. The nature of these contaminants is not clear: the small components may be transfer RNA degraded by endogenous nuclease[7], or indeed similarly degraded ribosomal or messenger RNA. The higher molecular weight components may again be messenger or ribosomal degradation products; but the sharpness of these zones strongly indicates that they are each monodisperse, and may therefore represent other RNA species of at present unknown function. At least one such species has been previously reported[8], and it may be profitable to search among such minor nucleic acid components of the cell supernatant for specific inhibitor molecules, or perhaps ribosomal RNA precursors.

Fig. 1 shows clearly the separation which may be achieved by 'Sephadex' filtration, and at the same time emphasizes its limitations of resolution, when confronted with a mixture of relatively small molecules of rather narrow polydispersity. It is important in this connexion to emphasize that high molecular weight ribosomal RNA migrates very slowly under our conditions, and remains near the gel interface.

Very recently Schleich and Goldstein[9] have reported that 'Sephadex' fractionation of *E. coli* *s*RNA reveals the presence of inactive *s*RNA aggregates; on treatment with urea, disaggregation occurs, together with restoration of acceptor activity. We have found no evidence for such a phenomenon in our samples of yeast *s*RNA: the electrophoresis has been performed in the presence of 6 M urea, without heating, and the distribution of components remains unchanged. Similarly, heating the RNA in the presence of 4 M urea for 15 min at 70° C produced no change in the electrophoresis pattern. It is not yet clear whether the apparent absence of aggregation depends on the preparation of the samples, or in our use of yeast, rather than *E. coli*, *s*RNA.

The polyacrylamide gel electrophoresis technique, of which full details will shortly be published[10], would seem to have wider applications, and is at present being used for the investigation of degradation products of both transfer and ribosomal RNA.

We thank Miss Jacqueline Large, Mr. J. A. Coll and Mr. G. Forte for their assistance.

BIOCHEMISTRY

Infra-nuclear Distribution of Transaminases

It has previously been shown[1] that isolated calf thymus nuclei prepared by the sucrose-$CaCl_2$ procedure[2] contain a free amino-acid pool. Of the free amino-acids, glutamic acid represents about 40 per cent. The presence of such a relatively large amount of glutamic acid suggests its rapid synthesis, or its formation by metabolic conversion from other substances, such as those resulting from transaminase-catalysed reactions. The intracellular distribution of transaminase activity has been extensively investigated, particularly in rat liver[3–6], and most of the enzymatic activity has been found in the mitochondrial fraction. Little is yet known, however, about the intranuclear distribution of transaminases. Techniques for separating nuclear proteins into various morphologically-defined fractions made possible the present investigation, undertaken to assay the calf thymus cells for two transaminase activities. It will be shown that the cell nucleus contains significant transaminase activities, mostly localized in the nuclear sap, resolvable by chromatography.

Calf thymus was homogenized in sucrose-$CaCl_2$ medium following the procedure of Allfrey *et al.*[2]. The cytoplasmic suspension was clarified by centrifuging twice at 2,500*g*, and the mitochondria were collected in the pellet centrifuged at 1,500*g*. The supernatant was ultracentrifuged to give the microsomes and the soluble fraction[7]. All cellular fractions were purified by repeated suspension and centrifugation.

Fractionation of nuclear proteins was carried out as previously described[7]. Briefly, the nuclei were extracted with buffered physiological saline and the resulting nuclear extract was ultracentrifuged. The pellet obtained from this centrifugation was treated with sodium deoxycholate to give the nuclear ribosomes and the deoxycholate-soluble (DOC-sol) fraction[7]; the supernatant, which contained the nuclear-soluble proteins and which constituted the bulk of the nuclear sap[8,9], was further separated into a *p*H 5 fraction and a *p*H 5 supernatant[7,10] by acid precipitation. The remaining nuclear residue, after washing with buffered saline, was afterwards extracted with 1 M NaCl to yield an NaCl extract and residual protein, the latter consisting of nucleoli and residual chromatin[9,11–13]. The 1 M NaCl extract was then diluted to 0·14 M with respect to NaCl to precipitate the DNA-histones, which are the chromatin substances[9,14]. The supernatant solution, designated as NH-sol[7], was lyophilized.

Cytoplasmic and nuclear fractions were obtained in this way and assayed for glutamic-oxaloacetic transaminase (GOT) activity according to the method of Lowry *et al.*[15], and for glutamic-pyruvic transaminase (GPT) activity by Lowry's method as described by Rosen *et al.*[16].

Table 1. Intra-cellular and Nuclear Activities of Transaminases of Calf Thymus

Fraction	Specific activity (μmoles/h/mg protein) Glutamic-oxaloacetate	Glutamic-pyruvate
Homogenate	7·7	0·47
Nuclei	2·3	0·13
Mitochondria	14·3	0·70
Microsomes	3·3	0·39
Soluble fraction	8·2	0·24
Nuclear fractions		
Soluble proteins	19·0	0·24
*p*H-5 fraction	0·0	0·0
*p*H-5 supernate	28·0	0·32
Ribosomes	1·5	0·17
DOC-soluble	2·1	0·13
NH-sol	2·6	0·02
Residual protein	2·4	0·09

* Average of two determinations.

Table 1 shows the intracellular and nuclear specific activities of GOT and GPT of the calf thymus cells. As can be seen, GPT activity is on the average 1/20 that of GOT among the cellular components. Mitochondria clearly have the highest specific activities. The activities of GOT and GPT of the nuclear fraction are 16 per cent and 19 per cent, respectively, of those represented by mitochondria. Transaminase activity of the nuclear fraction has generally been attributed to contamination by mitochondria, but nuclei containing 33 per cent of the total cellular GOT activity has also been reported[6]. Since the nucleus represents a greater part of the thymus cell, it is unlikely that most of the nuclear transaminase activities could be due to cytoplasmic contamination.

Unlike the microsomes, the cytoplasmic soluble fraction exhibited high GOT activity. High GOT activity in the soluble fraction of rat liver has been reported[3,4], although the contrary has also been noted[6]. Since the release of the enzymatic activity from mitochondria is possible only after considerable structural damage[3], the transaminase activities in the thymus soluble fraction may be regarded as significant.

Because the cytoplasmic soluble fraction contains considerable GOT and GPT activities, it seemed probable that topographically most of the nuclear transaminases might be localized in the nuclear sap. The assay results of GOT and GPT activities of the various nuclear fractions indicate that such is the case. It can be seen that the nuclear *p*H 5 fraction is devoid of either enzyme, and all the GOT and GPT activities present in the nuclear sap are located in the *p*H 5 supernate.

We have previously reported a number of enzymes associated with the nuclear ribosomes[17], like ribosomes from other sources. The presence of some GOT and GPT activity in the nuclear ribosomes (and the DOC-sol fraction) may similarly be interpreted as suggesting that the ribosomes are the site of protein synthesis. This may also include the residual protein fraction the possible involvement of which in protein synthesis has been demonstrated and suggested[7,12,18].

Like the residual protein, the DNA-associated NH-sol fraction contains low GOT and GPT activities. It has previously been shown that this nuclear protein fraction differs from the nuclear soluble proteins in preparation[19], in metabolic activities[7], and in chromatographic behaviour[20]. The present work further emphasizes their distinction by the localization of the transaminase activities. Since most of the GOT and GPT activities are associated with the nuclear soluble fraction, the nuclear soluble proteins were subjected to DEAE-cellulose fractionation[20], and the enzymatic activities of the column fractions were determined. Fig. 1 shows

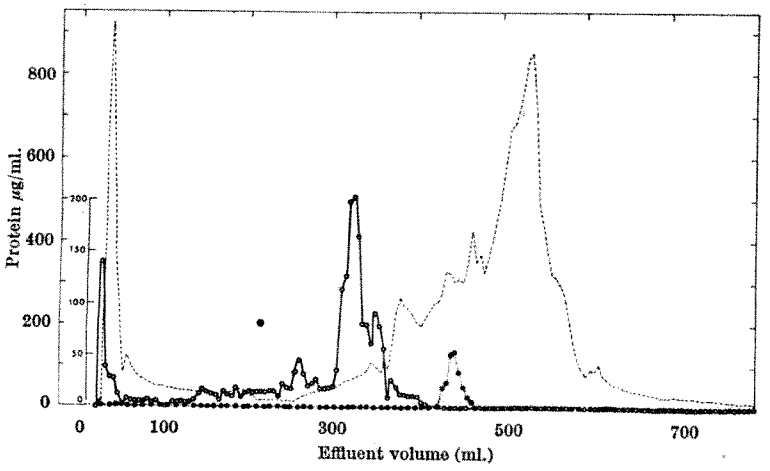

Fig. 1. Transaminase activities of nuclear soluble proteins chromatographed on DEAE-cellulose. Open circles: GOT activity, in μmoles/h/mg protein; closed circles: GPT activity, in × 10^{-2} μmoles/h/mg protein

such a chromatogram. It can be seen that all GOT and GPT activities are eluted before the major peak. GPT is completely separated from GOT as a single peak at higher salt elution, while GOT activity appears in several locations eluted with very low salt concentration, including the unadsorbed peak. Similar experiments made on the NH-sol fraction showed that the transaminase activities were localized only in the unadsorbed buffer peak. Such separation of GOT activity may be indicative of the existence of different molecular species of the enzyme (isozymes), or of the combination of the enzyme with other proteins.

Failure of Physiological Concentrations of Epinephrine to affect Glycogen-levels in the Isolated Rat Liver

ALTHOUGH it is generally believed that the hyperglycæmia which follows the administration of epinephrine is due, at least in part, to hepatic glycogenolysis, attempts to demonstrate a direct effect of epinephrine on liver glycogen-levels have led to conflicting conclusions. In the rat, for example, Cori, Cori and Buchwald[1] found that a decrease in liver glycogen occurred during the first 15 min after subcutaneous epinephrine injection, and considered this to represent a direct action of epinephrine on the liver. On the other hand, Sherlock[2] found that portal veining infusions of epinephrine did not affect liver glycogen- or blood glucose-levels and concluded that the hormone did not exert a direct effect on hepatic glycogen metabolism of rats. We repeated and extended the experiments of Cori, Cori and Buchwald and also observed the transient hepatic glycogenolysis which they had described[3]. However, we presented evidence that this represented an indirect rather than a direct effect of epinephrine and suggested that it might be due to stimulation of endogenous glucagon release.

Because of the difficulty in distinguishing between primary and secondary events in experiments with intact animals, we have investigated the effects of different concentrations of epinephrine on glycogen-levels of the isolated perfused rat liver. This experimental system permits the investigation of hepatic glycogenolysis under precisely controlled conditions, uncomplicated by secondary hormone secretion, lactate release from muscle, or other events which often make interpretation of animal experiments difficult. It is superior to liver slice techniques for the study of glycogenolysis[4]. In previous work with Miller[4,5] we demonstrated that both glucagon and epinephrine were active in this system; however, the concentrations of these hormones then tested were far above any encountered in Nature.

Livers from well-fed male Sprague–Dawley rats were excised and perfused with approximately 120 ml. of diluted heparinized rat blood to which antibiotics had been added, using techniques and apparatus similar to those described by Miller *et al.*[6]. Blood entered the liver by free flow through a cannula in the portal vein, at a pressure of 13–15 cm of blood. A cannula in the inferior vena cava returned blood to the reservoir, whence it was recirculated through the liver. In all experiments, an equilibration period of at least 30 min was allowed after initiation of the perfusion. At various intervals thereafter, minor hepatic lobes were removed for glycogen determination, and a final specimen was obtained from the right lobe at the conclusion of the experiment. It was usually possible to obtain 4 or 5 liver samples for analysis. Samples of the perfusing blood were withdrawn at regular intervals for glucose determination. Solutions of synthetic epinephrine or crystalline glucagon were added to the blood reservoir after baseline liver and blood samples had been obtained. This technique was used rather than continuous infusion into the system[4,5] so that the peak concentrations of these agents reaching the liver could be known with certainty. Thus, when glycogenolysis was observed, it was possible to affirm that it was initiated by a specific concentration of hormone. The volume of blood in the system was large enough to maintain hormonal levels near this original concentration for 8–15 min before inactivation in the liver exerted a major effect. Epinephrine was diluted in rat plasma rather than saline to protect it from oxidation, and the dilute solutions were prepared just before use.

In control experiments, the blood glucose concentration, which had risen initially to about 200 mg per cent because of glycogenolysis during the operative procedure and establishment of the perfusion, remained stable or declined slowly after the equilibration period. Liver glycogen values ranged from 1 per cent to 4 per cent (wet weight basis) and remained quite stable during 3 h of perfusion. Variations in glycogen concentration among successive samples from the same liver averaged 3 mg/g (0·3 per cent) and rarely exceeded 5 mg/g.

Various amounts of epinephrine were added to the blood reservoir after appropriate baseline samples had been obtained for glycogen and glucose determinations. Single or multiple additions of 0·1–3·0 μg (yielding peak plasma concentrations of approximately 1·4–40 μg/l.) exerted no measurable effect on either liver glycogen-levels or the glucose concentration of the perfusing blood (Fig. 1). Slight to moderate vasoconstrictor effects were observed at the higher concentrations, however; in one perfusion, for example, the hepatic blood flow dropped from 11 ml./min to 6 ml./min after the addition of 3 μg of epinephrine.

When 10 μg of epinephrine was added to the blood reservoir (resulting in a peak concentration of approximately 140 μg/l. of plasma) small increases in blood glucose (20–40 mg per cent) and borderline decreases in liver glycogen concentration (2–5 mg/g) were seen. Multiple additions resulted in cumulative effects (Fig. 2). This concentration also produced substantial reductions of the blood flow rate. In order to differentiate between a specific effect of epinephrine on glycogen metabolism and a non-specific effect due to reduction of blood flow and hepatic anoxia, experiments were performed in which

phentolamine was added to the blood reservoir before this amount of epinephrine. This virtually abolished the vasoconstrictor effect, but slight glycogenolysis was still observed. Higher concentrations of epinephrine could not be tested without the use of a blocking agent because blood flow virtually ceased. With phentolamine, however, it proved possible to test the effect of 30 μg (peak plasma concentration, approximately 400 μg/l.). This induced distinct glycogenolysis, as is seen in Fig. 3.

To confirm the sensitivity of this test system, experiments were performed in which small amounts of glucagon were added to the blood reservoir. These investigations, which will be reported in detail elsewhere[7], indicated that concentrations of glucagon within the range which has been observed *in vivo*[8] are glycogenolytic for the isolated rat liver. Fig. 4 presents the data from one perfusion of this series. It is evident that glycogenolysis induced by 0·3 μg of glucagon (peak plasma concentration, approximately 4 μg/l.) was as intense as that following the 100-fold greater amount of epinephrine.

These experiments confirm the conclusions previously reached from *in vivo* investigations[3] that epinephrine can exert a direct glycogenolytic effect on the liver, but that very high concentrations of this hormone are required for such action. The threshold plasma level needed for minimal hepatic glycogenolysis in this investigation appeared to be about 140 μg/l. This is far higher than any concentration known to occur spontaneously in mammalian species, and also well above values observed after intense stimulation of adrenomedullary secretion. Heiffer, Mundy and Mehlman[9] found that the baseline arterial plasma epinephrine concentration of rats was 0·7 μg/l., and observed peak levels of about 50 μg/l. after pharmacological stimulation with cystamine. The resting level of epinephrine in the circulation of dogs[10] and humans[11] is also less than 1 μg/l. of plasma. It is elevated to concentrations of 2–3 μg/l. during the stress of insulin-induced hypoglycæmia[10,12] and during infusions of epinephrine at a rate rapid enough to induce cardiovascular effects and distress symptoms[13]. The highest systemic plasma epinephrine concentration ever recorded in man, to our knowledge, was 14 μg/l., observed by Goldfien *et al.*[11] in a patient with a pheochromocytoma, during its surgical removal. Although there are species differences in sensitivity to epinephrine, it seems unlikely that dog and human livers should be 50 times more sensitive than that of the rat to the glycogenolytic effect of this hormone. Thus, it is probable that the direct contribution of epinephrine to hyperglycæmia, in these species also, is limited to its peripheral effects.

We conclude that while glucagon may serve as a physiological glycogenolytic agent for the liver, epinephrine cannot. Furthermore, it is unlikely that even moderate pharmacological doses of this hormone would

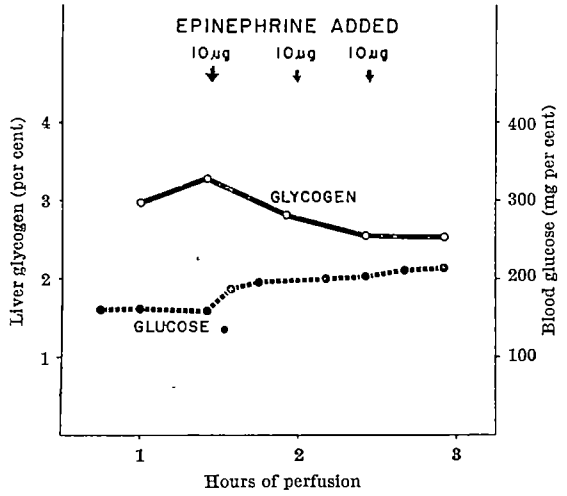

Fig. 2. Slight glycogenolytic effect of 10 μg of epinephrine (peak plasma concentration, 140 μg/l.)

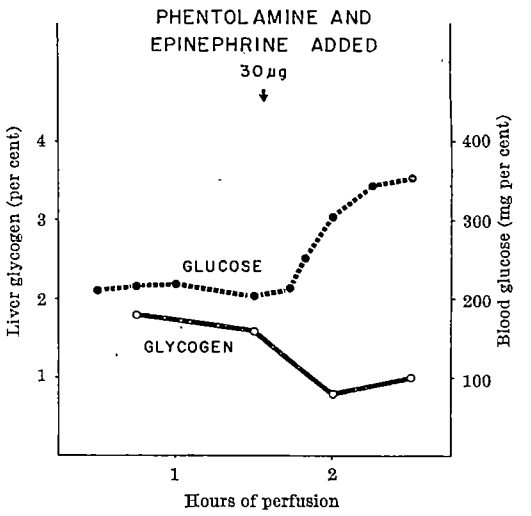

Fig. 3. Glycogenolytic effect of 30 μg of epinephrine (peak plasma concentration, 400 μg/l.). Phentolamine was added before epinephrine in order to reduce the intense vasoconstriction caused by this concentration of the hormone

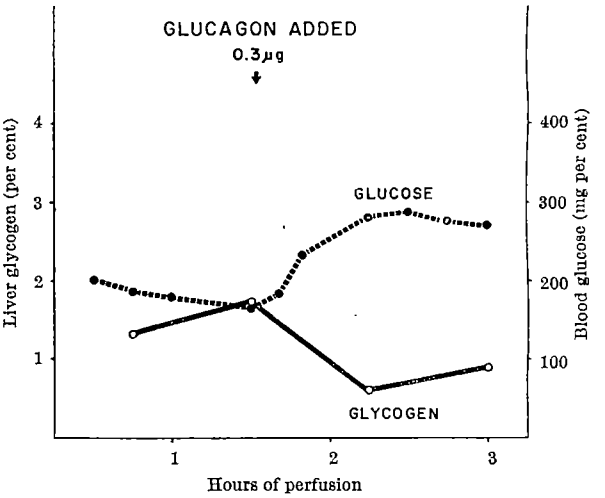

Fig. 4. Glycogenolytic effect of 0·3 μg of glucagon (peak plasma concentration, 4 μg/l.), demonstrating the sensitivity of this test system

result in sufficiently high plasma concentrations to exert a direct effect on hepatic glycogen metabolism.

Lactic Dehydrogenase Isozymes and Ageing of Erythrocytes

DURING the life span of erythrocytes several of their enzymes undergo some modification[1–3]. Lactic dehydrogenase (LDH) is of special interest, because of the knowledge we have of its isozyme composition[4,5]. To investigate whether ageing affects each isozyme to the same degree, the electrophoretic pattern of LDH isozymes of young and old red cells were compared.

Young and old red cells from rabbits were separated by centrifugation in the presence of bovine serum albumin. In this procedure the upper layer consists of young cells, whereas the lower layer contains the heavier, older red cells. In one experiment, leucocytes (the density of which is similar to that of young red cells) were eliminated by agglutinating the red cells with phyto-agglutinins followed by slow centrifugation to remove the leucocytes. The clotted red cells were then hæmolysed after washing.

Both layers of hæmolysed cells were submitted to starch-gel electrophoresis, in borate buffer according to Smithies[7]. Isozymes were visualized by nitro blue tetrazolium salts and phenazine methosulphate, according to Markert[8] and Nachlas[9].

Under these conditions, two main anodic bands were found for both old and young red cells; they moved faster than hæmoglobin, and the faster one was the broader: these fractions seem to correspond to fractions 4 and 5.

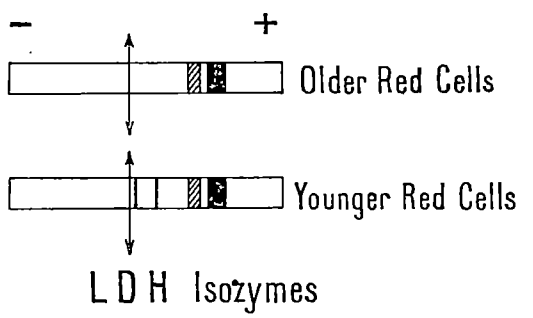

Fig. 1. LDH isozymes in older and younger red cells

In younger cells, two additional faint bands were observed; these were also anodic, but slower than the main bands. The migration rate of one of them was close to that of hæmoglobin. The same pattern was seen in the experiment where white cells were removed by centrifugation after agglutinating the red cells. Vesell[5] has pointed out that in many preparations of human hæmolysates, he found a faint supplementary band of slower mobility.

It seems that this band, which does not always occur, corresponds to the bands which we see only in younger cells. Cahn and Kaplan[10] have proposed that the various bands of lactic dehydrogenase are hybrids of four subunits of two different types. We have seen that there are two bands found in younger red cells which do not appear in older ones; it seems that these isozymes are preferentially inactivated or destroyed during the life span of the red cells.

Electrophoresis of an Insect Inorganic Pyrophosphatase

IN our work on the properties of inorganic pyrophosphatase in the boll weevil, *Anthonomus grandis* Boheman[1], we used the enzyme present both in whole homogenates and in an acetone powder. We have since attempted electrophoresis of the enzyme to determine whether activity was present in one or more resolvable components.

All preparations and electrophoretic studies were made at 2° C. Approximately 1,000 frozen adult weevils were homogenized with cold acetone, and an acetone powder was prepared. After removal of the solvent and drying *in vacuo* in the refrigerator, the dry filter cake was extracted with demineralized water for 0·5 h and filtered through glass wool. The filtrate was centrifuged (20,000*g*) to remove particulate debris and other matter, and the clear supernatant was lyophilized. The lyophilized powder was used as the enzyme source.

Separation of the soluble components was achieved by paper electrophoresis, by means of a Durrum-type hanging paper strip electrophoresis cell (Spinco electrophoresis system).

The following conditions were found to give excellent separation in 4 h at 2° C: Buffer, veronal–HCl *p*H 8, 0·02 M; buffer volume, 1,100 ml. (550 ml. each in the (+) and (−) compartments); 3·5 m.amp, at 100 V; sample sizes, 1–3 mg of lyophilized powder in 10 μl.

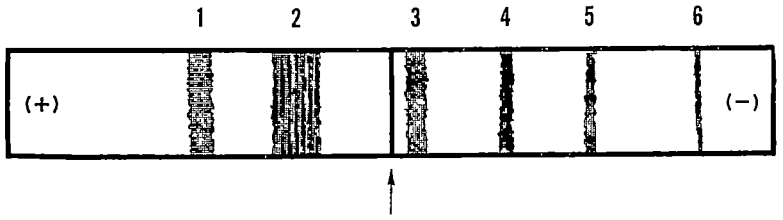

Fig. 1. Diagrammatic sketch of the ninhydrin-positive components in water extract of the boll weevil acetone powder. The arrow marks the line of application

of demineralized H_2O; 1·6 mg satisfactorily combined resolvability of the enzyme activity and colour intensity on the sprayed strips.

After 4 h of electrophoresis the strips were removed. Half of them were dried at 110° C for 0·5 h, sprayed with 0·2 per cent ninhydrin in acetone, and re-dried for 10 min. The remaining half, used for enzyme analysis, were frozen immediately after electrophoresis and stored at −20° C. The enzyme was assayed by incubating appropriate portions of each strip in a reaction mixture consisting of 0·2 ml. of 0·01 M $MgCl_2$, 0·5 ml. of 0·0025 M pyrophosphate, and 0·3 ml. of veronal–HCl buffer, 0·02 M, *p*H 8, for 2 h. Zero time control and termination of the reaction were achieved with boiled samples and also with certain sulphydryl inhibitors.

Fig. 1 illustrates the resolvable ninhydrin-positive components. Two bands migrated toward the anode (+), and four toward the cathode (−). The development of the bands was very consistent and reproducible. More than 100 separate analyses were made with negligible variation. In several instances electrophoresis was conducted for 6 h, but no further fractionation was observed. The same six bands were detected, but were spread over a wider area, and their centres had migrated a distance 50 per cent farther away from the starting application line than those strips run for 4 h.

The darkest ninhydrin-coloured band was band 2, while cathodic bands 5 and 6 were very pale. Colour intensity of all bands was in direct proportion to the amount of extract applied.

Table 1. Electrophoretic Separation of Inorganic Pyrophosphatases from Lyophilized Water Extract of Boll Weevil Acetone Powder
Enzyme activity: μg phosphorus released/ml. of reaction mixture/2 h at 35° C

Band No.	Charge	Enzyme activity	Percentage of total activity
1	(−)	0·092	2·53
2	(−)	3·097	85·24
3	(+)	0·276	7·60
4	(+)	0·193	5·31
5	(+)	−0·025*	Nil
6	(+)	—	Nil

* Uptake of free orthophosphate.

Once reproducible separations were achieved, it was necessary to determine which band(s) would hydrolyse, inorganic pyrophosphate. By incubating the cathodic and anodic halves of the strips in pyrophosphatase reaction mixture and afterwards analysing for orthophosphate[2] we determined that the enzyme was migrating electrophoretically to the anode; but we still did not know whether it was in band 1 or band 2, or whether any of the cathodic bands had a slight pyrophosphatase activity.

By separate analysis of each band, its position determined by comparison with alternate ninhydrin-developed strips, we were able to show that only band 2 consistently possessed enzyme activity. Pyrophosphatase activity was also found occasionally in bands 1, 3 and 4 (Table 1); but these bands sometimes yielded no activity. Band 5 was negative and actually used up small amounts of the free phosphate present at the start of the reaction. Band 6 was also negative. The high pyrophosphatase activity in band 2 accounted for approximately 85 per cent of the total detectable activity.

Four inhibitors of inorganic pyrophosphatase (iodoacetate, fluoride, alloxan, and Cu^{++} ions) were used in place of boiling water to obtain zero time and 2-h readings. All four were effective in blocking the enzyme action of all the bands.

These data suggest that the boll weevil enzyme extract has four alkaline inorganic pyrophosphatases capable of producing orthophosphate from pyrophosphate, but that the majority of this activity is located in an anionic protein (band 2).

The presence of a complex assortment of phosphatases is not unusual. Others have shown that phosphatases in general, including inorganic pyrophosphatases[3,4], can exist as a group of several isoenzymes capable of acting on a single substrate. To determine whether or not these four active bands represent four distinct enzymes will require a complete description and comparison of their individual characteristics.

Metabolic Fate of 2,4-Dichlorophenoxyacetic Acid in the Stem Tissue of *Phaseolus vulgaris*

In this Department previous investigations[1,2] of the metabolic fate of a series of chlorinated phenoxyacetic acids in stem tissues of *Avena sativa* have demonstrated that the formation of glucose esters or hydroxylation followed by conversion to a glucoside are major pathways. In this tissue 2,4-dichlorophenoxyacetic acid (2,4-D) is converted principally into 1-0-(2,4-dichlorophenoxyacetyl)-β-D-glucose. In contrast, in the stems of *Phaseolus vulgaris* the principal metabolite isolated was seemingly a glucoside of a phenolic acid[3] which was not a hydroxy-2,4-dichlorophenoxyacetic acid[3–5]. Further investigation has identified the presence of a mixture of 2,5-dichloro-4-hydroxyphenoxyacetic acid and 2,3-dichloro-4-hydroxyphenoxyacetic acid.

The following procedures were used for the isolation of the aglycones. The whole of the aerial portions of seedlings of *P. vulgaris* var. 'Canadian Wonder', grown in a greenhouse for 12 days, were gathered and the cut ends immersed in a solution of 2,4-D-^{14}C (30 mg/l.) at *p*H 5 for 12 h in the light. After a further 24 h in the dark the stem and petiolar tissue was macerated and extracted with hot 20 per cent aqueous ethanol. The solvent was removed and the residue partitioned between hydrochloric acid (5 per cent) and ether. The ether solution contained about 85 per cent of the carbon-14 and was shown to consist almost entirely of 2,4-D. The dilute acid solution after saturation with ammonium sulphate was extracted with butanol and the residue, following the removal of the butanol, dissolved in a minimum quantity of methanol. A considerable amount of material containing very little carbon-14 was precipitated from the methanol solution by the addition of four volumes of ether; the supernatant liquid was evaporated to dryness and treated with β-glucosidase in aqueous solution at *p*H 5. The resulting ether soluble aglycone was freed from non-radioactive material by paper chromatography using isopropanol/ammonia (*d*, 0·88)/water (10 : 1 : 1) and then chloroform saturated with 50 per cent aqueous acetic acid as developing solvents. In this way 11 mg of a crystalline solid was obtained from 4·5 kg of stems.

There was some evidence that this product was not homogeneous, and thin-layer chromatography on silica

gel using ether/light petroleum (b.p. 60°–80° C)/formic acid (50 : 50 : 2) effected a separation of two phenolic acids having R_Fs 0·45 and 0·3 present respectively in a ratio of approximately 10 : 1.

While this work was in progress it was shown by Faulkner and Woodcock[6] that 2,5-dichloro-4-hydroxyphenoxyacetic acid was a product of the metabolism of 2,4-D in *Aspergillus niger*. Comparison of the major constituent of the phenolic acid mixture from *Phaseolus* with authentic 2,5-dichloro-4-hydroxyphenoxyacetic acid showed that they were identical.

The minor constituent proved to be identical with authentic 2,3-dichloro-4-hydroxyphenoxyacetic acid prepared from 2,3-dichlorohydroquinone[7].

The criteria for verification of the identity of these two acids with authentic materials are given in Table 1.

Table 1

Compound	R_F	Diazodye colour	λ_{max} *p*H 2	λ_{max} *p*H 11	M.p. of methyl-ether	Spectra
2,3-Dichloro-4-hydroxyphenoxy-acetic acid	0·3	burgundy red	295 mμ	318 mμ	—	ultra-violet
2,5-Dichloro-4-hydroxyphenoxy-acetic acid	0·45	beige brown	298 mμ	315 mμ	165–6°C	ultra-violet and infra-red

It is now apparent that the intriguing shift of the chlorine atom in 2,4-D by *Aspergillus* can be brought about by a higher plant. In *Phaseolus*, however, the products are accumulated as the β-glucosides so that the possibility of the occurrence of secondary reactions during the extraction processes is unlikely. Again the possibility of any considerable contamination of the 2,4-D used with 2,3-dichlorophenoxyacetic acid or 2,5-dichlorophenoxyacetic acid is remote. These impurities have been specifically sought for and are not present in amounts exceeding 0·5 per cent, which is the limit of resolution of the methods used.

Rose Bengal De-iodination *in vitro*

Rose bengal as well as bromsulphalein and indocyanin green are utilized for the study of liver chromo-excretion. Changes of these dyes in the organism were intensively studied and it was ascertained that bromsulphalein is conjugated with glutathione and excreted in the bile. Similar metabolites were not proved for rose bengal and indocyanin green. In earlier work we described the isolation of the pure tetra-chloro-tetra-iodo-fluorescein from the commercial preparations of rose bengal[1,2]. We ascertained further that up to 8 per cent of ^{131}I is split off after the intravenous application of rose bengal, labelled with ^{131}I, to rats, and that it is excreted as a colourless compound in the urine. We have since studied the de-iodination of rose bengal-^{131}I *in vitro* by homogenates of heart, liver and bone muscle in conditions described by Georgi and Hartmann[3] for thyroxine and di-iodotyrosine de-iodination. Our work was stimulated by a certain similarity in chemical structure between rose bengal and these compounds. We homogenized the

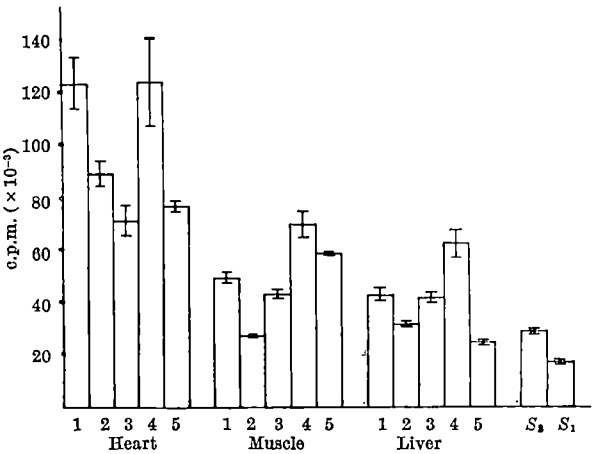

Fig. 1. Counting rates of supernatants from individual homogenates. 1, 3 ml. of homogenate + 0·5 ml. of rose bengal-^{131}I, incubated for 24 h at 37° C. 2, 3 ml. of homogenate + 0·5 ml. of rose bengal-^{131}I, not incubated. 3, 3 ml. of homogenate + 0·5 ml. of rose bengal-^{131}I + sodium pyruvate (its final concentration in solution is 1 mmole/ml.), incubated for 24 h at 37° C. 4, 3 ml. of homogenate heated to 100° C + 0·5 ml. of rose bengal-^{131}I, incubated for 24 h at 37° C. 5, 3 ml. of homogenate heated to 100° C + 0·5 ml. of rose bengal-^{131}I, not incubated. S_2, 0·5 ml. of rose bengal-^{131}I + 3 ml. of phosphate buffer, incubated for 24 h at 37° C. S_1, 0·5 ml. of rose bengal-^{131}I + 3 ml. of phosphate buffer, not incubated

organs (heart, liver, muscle) from 10 rats by pulverizing with liquid air and mixing with 0·2 phosphate buffer at *p*H 8·0 so that the total organ concentration was 0·03 g/ml. calculated for the wet organ weight.

The homogenates were distributed in 3-ml. portions into centrifuging tubes, and 0·5 ml. solution of rose bengal-^{131}I with specific activity 12 μc./ml., was added. The homogenates of each organ were then distributed between 5 groups. The first group was incubated for 24 h at 37° C, the second group was not incubated, and the third group contained sodium pyruvate in concentration 1 mmole/ml. and was incubated for 24 h at 37°. The fourth and fifth groups contained homogenates previously heated to 100° C. Rose bengal and proteins were precipitated with concentrated hydrochloric acid and separated by centrifugation. The radioactivity of 2 ml. aliquots of the supernatant was measured by the scintillation counter with the NaI (Tl) well-crystal. The results are expressed as the mean of 10 samples with introduced middle square deviations (Fig. 1). It is clearly demonstrated that more ^{131}I is split off by tissue homogenates than by the buffered solution of rose bengal-^{131}I alone. The quantity depends on the organ, and decreases in the order: heart, muscle, liver. Boiling the homogenates before mixing with the rose bengal effects no reduction, and even enhances the effect in the case of the muscle and liver homogenates. The addition of sodium pyruvate affects the ^{131}I splitting inhibition, particularly in the case of heart homogenate. Thus, rose bengal behaves similarly to thyroxine or mono-iodoacetic acid in contrast to di-iodotyrosine, the de-iodination of which is increased by the admixture of pyruvate[3]. The mechanism of rose bengal de-iodination is not entirely clear. From the fact that it is produced by the untreated and by boiled homogenates, and since the effect of the boiled homogenate is even higher in some cases, it cannot be assumed that de-iodination is controlled by a sensitive enzymatic system. These results suggest that a thermostable factor is present in the organs, in different concentrations. It is in accord with some earlier studies, which demonstrate that de-iodination takes place also in the presence of flavine mononucleotide[4–6], or of the other low-molecular fluorescent substances (fluorescein, eosine, acriflavine)[5]. It has also been demonstrated[6] that some proteins have a stimulative effect on the de-iodination. Differences in the effect of flavine mononucleotide, in the different tissues studied, are perhaps to be explained by the

activating or inhibiting effects of different proteins within these tissues.

Influence of Red and Far-red Light on the Photo-oxidation of Ascorbic Acid and Photoreduction of its Oxidized Forms

Photo-oxidation of ascorbate and photoreduction of its oxidized forms have been demonstrated in leafy tissues[1,2]. In these investigations evidence was obtained that photoreduction was a separate photochemical reaction from photo-oxidation, being differentiated from the latter by: (1) a different time sequence in its initiation by light; (2) its insensitivity to cyanide; (3) its more heat-labile nature; (4) the ability of red light (710–720 mμ) to activate photo-oxidation but not photoreduction.

Our attention was first directed to the possibility that these reactions might be influenced by previous exposure of the leaf to light of different wave-lengths, when we observed that both reactions occurred at a much greater rate on illumination of darkened leaves if these had previously been exposed to daylight rather than to incandescent light. The rate of photo-oxidation of ascorbate stimulated by the activating light immediately following a dark period (10–30 min) after daylight was five times greater than the corresponding rate observed in leaves which had been exposed to a short period (5 min) of light from a tungsten lamp (5,000 lux) prior to the dark period.

We have now demonstrated with the use of suitable filters that these photochemical reactions, activated by light energy of the visible spectrum, are themselves conditioned by the previous exposure of the leaf to either red or far-red light. When strawberry leaves after a period in the dark (30 min) following daylight illumination are exposed to the green activating light (100 lux of wave-length 500–550 mμ) complete photoreduction of the dehydro-L-ascorbate in the darkened leaf occurs within a period of 4–5 sec, and this is followed by a rapid photo-oxidation of ascorbate until a new steady-state level is reached. If, however, following a dark period (30 min) after removal from daylight the leaf is illuminated for 5 min with far-red light (700–900 mμ, light source, tungsten) and this again followed by a further dark period (10 min), on subsequent illumination with green activating light only slight photoreduction and no photo-oxidation is observed. It might be noted that unfiltered incandescent light gives total inhibition of both processes. In fact the leaf in this condition behaves entirely like a darkened leaf. Conversely, if the far-red light is replaced by red light (600–690 mμ; light source fluorescent) the leaf responds normally and shows a rate of photoreduction and oxidation equal to that observed after exposure to daylight (Fig. 1). Similar effects were found with unfiltered fluorescent light.

We were also able to show that the inhibition of photoreduction and oxidation induced by exposure of the leaf

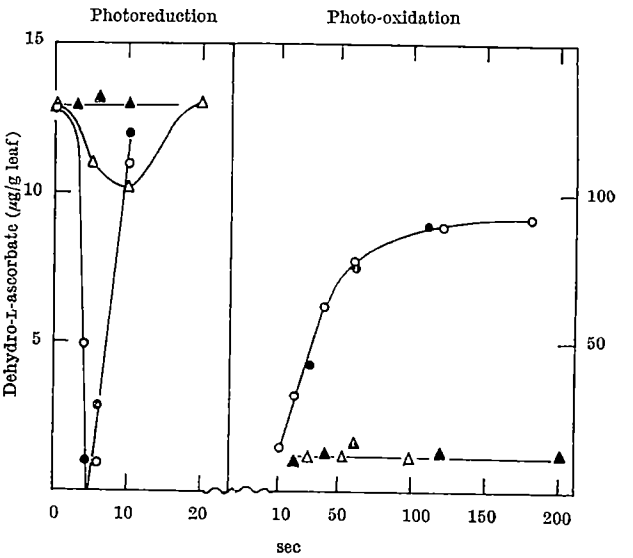

Fig. 1. Inhibition of photoreduction and photo-oxidation by far-red light. Pre-treatment of leaf, ▲, *DL*→*D*–30→*TL*–5→*D*–10→*AL*; △, *DL*→*D*–30→*FR*–5→*D*–10→*AL*; ○, *DL*→*D*–30→*R* or *FL*–5→*D*–10→*AL*; ●, *DL*→*D*–30→*FR* or *TL*–5→*D*–5→*R* or *FL*–5→*D*–10→*AL*. *DL*, Daylight; *R*, red light (600–690 mμ); *D*, dark; *FR*, far-red light (700–900 mμ); *TL*, incandescent light (5,000 lux); *AL*, activating light (500–550 mμ) 100 lux; *FL*, fluorescent light (5,000 lux)

to far-red light may be easily reversed by subsequent exposure of the leaf to red light (Fig. 1), and the converse is equally true, namely, that the activating effect of red light may be reversed by subsequent exposure to far-red light. Similarly, the effect of tungsten light can be reversed by fluorescent light.

Finally, we were also able to show that the photoreduction, which alone may be observed in leaves poisoned with cyanide (5×10^{-5} M) (ref. 1), is also inhibited by prior exposure to far-red light, but promoted with prior exposure to red light (Fig. 2).

These results suggest some connexion between the reactions of the photosynthetic electron transfer chain, the ascorbate system, and phytochrome. At present the results suggest that visible light energy activated by the photosynthetic or other photochemical system can drive

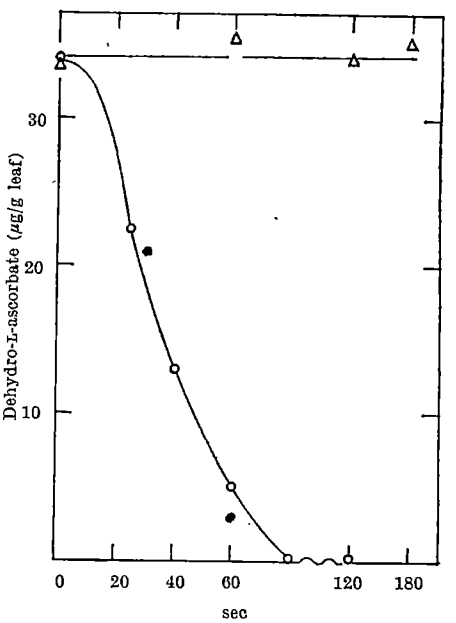

Fig. 2. Photoreduction in cyanide-poisoned leaves. Pre-treatment: ○, *DL*→*D*–30→*AL*; △, *DL*→*D*–30→*TL*–5→*D*–10→*AL*; ●, *DL*→*D*–30→*FL*–5→*D*–10→*AL*

reactions only if an active phytochrome or similar system is present.

Determination of 2-Phenylethanol in Cider

Methods used for the determination of 2-phenylethanol in fermented beverages have utilized solvent extraction of the beverage or of a distillate, followed by measurements of absorption spectra[1–3] or by gas chromatography[4–8]. The compound is not included in the determination of fusel oils by the colorimetric procedures usually adopted[8,9]. The methods described have certain disadvantages: preliminary extraction may be incomplete unless prolonged, absorption measurements may involve previous purification of the fraction containing 2-phenylethanol, and in the gas chromatographic methods described the retention time of the compound may exceed 1 h with column temperatures above 100°. The method to be described is simple in operation and has been found satisfactory for cider: by the use of a column of low capacity of the type described by Hishta *et al.*[10] the retention time of 2-phenylethanol has been reduced to 8 min.

Cider (50 ml.) was distilled without fractionation and 25 ml. of distillate collected; 25 ml. of water was added to the flask and a further 25 ml. distillate collected. The process was repeated and the third distillate containing only traces of 2-phenylethanol collected separately. To the third distillate was added sodium chloride (3 M) and it was then extracted at about 5° C with two volumes each of 15 ml. ethyl chloride. These extracts were used to extract the main distillate after addition of sodium chloride; it was then extracted twice further with 10 ml. ethyl chloride. The combined ethyl chloride solutions were washed with minimal volumes of water, freed from water droplets by passage through a layer of sodium sulphate (anhydrous) and concentrated to one-third volume by distillation of the solvent. The solution was transferred to a weighed tube, 2 ml. of 50 per cent aqueous ethanol added and the ethyl chloride removed by a slow stream of dry air. The solution, of known weight, was used directly for gas chromatography, using 5 μl. injections.

The apparatus used for gas chromatography was built in this laboratory and consisted of a 122 cm × 4·5 mm. internal diam. glass column packed with 0·2 per cent 'Apiezon *L*' on 60 mesh (A.S.T.M.) glass micro-beads, run isothermally at 80° with flame ionization detector. The flow-rate was approximately 15 ml./min with nitrogen–hydrogen in 1 : 1 mixture as carrier gas. Under these conditions 2-phenylethanol gave a reasonably narrow peak so that the amount present could be estimated from peak height taking as standards solutions of 2-phenylethanol in 50 per cent aqueous alcohol that gave peaks of comparable size.

The retention times relative to benzene of the main fusel oil components found in cider[11,12] were, as shown below, well separated from that of 2-phenylethanol; they all emerged within 2 min, whereas the latter gave a peak maximum at 7 min 42 sec.

Table 1. Fusel Oil Components of Cider and their Retention Times (relative to benzene)

Methanol	1·32
Ethanol	1·37
1–Butanol	1·59
1–Hexanol	5·05
2–Methyl-1-propanol	1·39
3–Methyl-1-butanol	2·90
β–Methyl-propyl ethanoate	1·75
γ–Methyl-butyl ethanoate	8·45
2–phenylethanol	44·85

The chromatograms showed two main peaks, the more volatile components forming one unresolved peak, the second being that corresponding to 2-phenylethanol. There is as yet no evidence for the presence of other cider components contributing to the second peak. The chromatograms were readily reproducible and estimates of the amount of 2-phenylethanol present did not vary by more than ± 5 per cent.

Extraction with ethyl chloride gave recoveries of 2-phenylethanol exceeding 90 per cent from synthetic fusel oil solutions corresponding to the composition of cider, or from distillates of the solution. Continuous extraction with *n*-pentane required more than 14 h for completion; direct extraction with ether or ether–pentane mixtures gave recoveries below 80 per cent. Persistent emulsions were formed when cider itself was shaken with solvents. The extraction of cider distillates with ethyl chloride was therefore adopted, this being the most efficient and selective solvent.

As the method of determination is based solely on a comparison of retention time with that of a standard, a semi-quantitative isolation of 2-phenylethanol from cider was made using a sample estimated to contain 100 p.p.m. The distillate from cider (1,560 ml.) was extracted with ether (5 vol. of 200 ml.) and the ether extract washed with N caustic soda and with water. The ether was removed, the liquid residue (10 ml.) extracted with ethyl chloride and the extract washed with water and dried. After removal of the solvent the liquid residue (3·1 g) was distilled in a slow air stream at 24 mm and 50° C until the residue had no odour of amyl alcohols. On raising the temperature to 70° a fraction with an odour of 2-phenylethanol condensed in the distillation head, from which it was removed with ether; 90 mg of this material was collected. 50 mg converted to the 3 : 5 dinitrobenzoate gave an 88 per cent yield of crude product, giving 62 mg of m.p. 105° C, raised by re-crystallization to 107°; mixed with an authentic specimen of m.p. 107° C the m.p. was unchanged. The infra-red spectra of the two specimens were identical.

Table 2. 2-Phenylethanol Content of Ciders

No.	Fermentation	p.p.m.
1	Yeasted	9
2	,,	7
3	,,	9
4	,,	15
5	Not yeasted	100
6	,, ,,	102

The amounts of 2-phenylethanol found in ciders were found to vary widely (as shown in Table 2); the amounts in yeasted fermentations were below 20 p.p.m., whereas sulphited juices fermented by members of the natural yeast flora (Nos. 5, 6) gave products containing about 100 p.p.m. A figure of 121 p.p.m. for a cider has been found by Morgan[13].

PHYSIOLOGY

Participation of Rat Liver Nuclei in Movements of Sodium

In vitro investigations of movements of sodium with muscular tissue seem to have shown that the non-extracellular sodium belongs to more than one phase[1]. The existence of either a membranous and a cellular phase[2] or of two cellular phases with different degrees of order[3] has been discussed. We wish to present some experimental findings which may well contribute to the interpretation of sodium transfer processes in animal tissue.

Previously, it was reported[4] that in rat liver nuclei, isolated by the non-aqueous technique[5], the sodium concentration is 10 times that of the cytoplasm: 160 μmoles Na^+/g dry nuclei or 72 μmoles Na^+/g fresh nuclei, compared with 16 μmoles Na^+/g dry cytoplasm or 6 μmoles Na^+/g fresh cytoplasm. Since nuclei comprise about 10 per cent of the liver cell, total intranuclear sodium roughly equals total cytoplasmic sodium.

Relations between extracellular and intranuclear sodium now were investigated with the aid of sodium-22. Rats which were deprived of food and drinking water for 16 h received 5 μc. sodium-22 in 0·1 ml. saline by injection into the jugular vein. After different times, whole blood, serum and liver were obtained from each of 50 animals per group. The livers were processed for nuclei as already described[5]. Sodium concentrations were determined by flame photometry, and the radioactivity by means of a scintillation counter. The experimental conditions, especially adapted for the work with nuclei, neither permit a shorter time-interval than 10 min nor a calculation of transport rates. The error in timing for taking blood and liver samples is about 15 per cent with the 10 min experiment but less than 2 per cent with all other time-intervals. Due to a breakdown of a scintillation counter during the experiments, another instrument had to be used for the 10 min readings which appear to be too low; a correction was not made. However, at each given time, the figures for blood, serum and nuclei are quite comparable with each other.

Table 1. Specific Activities of Blood, Serum, and Liver Nuclei of Rats after Administration of Sodium-22

1	2	3	4
10	710	820	860
30	910	985	1,125
60	810	840	855
120	685	670	710
240	650	590	610
480	585	555	575

Each experimental group consisted of 50 rats. The figures for nuclei are mean values of two separate determinations in the pooled livers. The figures for blood and serum are mean values from 25 samples, obtained of each two rats, determined twice.

1, Time-interval between injection of ^{22}Na and death (min). 2, Specific activity of sodium in blood (μc./μequiv Na^+). 3, Specific activity of sodium in serum (μc./μequiv Na^+). 4, Specific activity in isolated nuclei (μc./μequiv Na^+).

As can be seen in Table 1, the specific gravity of intranuclear sodium is found at the same level as the specific activity of serum sodium during the whole time-interval of 10 min–8 h after injection of sodium-22. Therefore, extracellular and intranuclear sodium reach their equilibrium within a surprisingly short time. It is rather improbable that this rapid equilibration occurs by a passage of extracellular sodium through the cellular membrane–cytoplasm–nuclear membrane since a remarkable difference in potential at the nuclear membrane has been described[6]. More likely, extracellular sodium enters the nucleus via channel-like structures which directly connect the extracellular with the intranuclear space, such as the endoplasmatic reticulum.

Obviously, it is not possible from these experiments with liver nuclei to draw definite conclusions with respect to muscle nuclei. However, in the interpretation of sodium fluxes in muscular tissue, it is worth considering muscle nuclei as possible separate compartments which actually contain much of the intracellular sodium and the link of which with the extracellular space may well be a more direct one than that of the cytoplasm proper.

PHARMACOLOGY

Lowering Effect of Neostigmine on Plasma Free Fatty Acids

The actions of a number of drugs provide evidence that the sympathetic nervous system functions in the mobilization of free fatty acids. Epinephrine, norepinephrine and isoproterenol cause an elevation of free fatty acid levels whereas blocking drugs such as dichloroisoproterenol[1], pronethalol[2] and *N*-isopropyl methoxamine[3,4] have been reported to block the elevation of free fatty acid due to injection of one or more of these sympathomimetic substances. The present communication describes the ability of another type of agent, the cholinesterase inhibitor neostigmine methylsulphate, to lower fasting levels of plasma free fatty acid in the conscious dog and to antagonize the epinephrine-induced release of free fatty acid from the rat epididymal fat pad *in vitro*.

The dogs used were fasted for about 20 h. Blood samples were taken according to the times noted in Table 1 and plasma free fatty acids were measured by the method of Dole[5]. The same dogs were used for treatment and control investigations. At least two weeks were allowed to elapse between experiments on individual animals. As shown in Table 1, each of the animals under control conditions demonstrated the moderate elevation of plasma free fatty acid which is usual in fasted dogs subjected to repeated

Table 1. Effect of Neostigmine on Fasting Levels of Plasma Free Fatty Acid in the Conscious Dog

Dog No.	Treatment	Neostigmine methylsulphate (μg/kg s.c.)	FFA (μequiv./l.) change from control level 1 h	2 h	3 h
KC–4	Saline	—		+210	+435
KC–4	Neostigmine	3·5	−163	−219	−417
KC–5	Saline	—	—	+172	+257
KC–5	Neostigmine	3·5	−162	−368	−306
C–6	Saline	—	+30	+150	+274
C–6	Neostigmine	7·0	−200	−266	+234
C–6	Neostigmine	28·0	−266	−532	+190
C–12	Saline	—	−43	+197	+197
C–12	Neostigmine	7·0	−397	−311	−243
C–12	Neostigmine	28·0	−134	−588	+30
C–14	Saline	—	+118	+260	+288
C–14	Neostigmine	14·0	−303	−119	−199
C–33	Saline	14·0	+129	+271	+361
C–33	Neostigmine	14·0	−380	−66	+172

The values at the various time-intervals represent the change in plasma free fatty acid levels from a control value obtained separately for each dog and for each experiment by averaging the values from the first and second blood samples. These samples were taken 30 min apart. Neostigmine and saline were injected at 0 time immediately after taking the second blood sample.

venipunctures. When neostigmine was administered to these animals, it caused in each instance a significant fall in plasma free fatty acid. Although there is evidently a rather wide variability in the response of individual animals to neostigmine it is noteworthy that dogs C-6 and C-12 experienced a larger fall from 28 μg/kg than from 7 μg/kg. No signs of parasympathetic stimulation, such as defæcation or salivation, were noted in any of the dogs receiving neostigmine.

The *in vitro* studies were done on epididymal fat pads removed from rats weighing approximately 180 g. The results are shown in Table 2. It is evident that neostigmine is much more active than carbachol in blocking the epinephrine-induced release of free fatty acid. A comparison of the present results with previous experiments done in the same manner in these laboratories[3] indicates that neostigmine prevents the release of free fatty acid in much lower concentrations than dichloroisoproterenol, pronethalol or *N*-isopropyl methoxamine.

Table 2. Effect of Neostigmine and Carbachol on the Epinephrine-induced Release of Free Fatty Acid from the Rat Epididymal Fat Pad

Exp. No.	Blocking drug*	Molar concentration of blocking drug	Epinephrine induced release of FFA†	Inhibition of FFA release (%)
1	None	—	3·43 ± 0	—
	Neostigmine methylsulphate	10^{-7}	0·58 ± 0	91
		10^{-9}	1·16 ± 0	72
2	None	—	3·05 ± 0·06	—
	Carbachol	10^{-6}	1·68 ± 0·20	55
		10^{-7}	2·29 ± 0	31

* All incubations contained $2·7 \times 10^{-5}$ M L-epinephrine.

† Free fatty acid release is expressed as μmoles/fat pad/h of incubation ± *S.E.* for 3 incubations. Release of free fatty acid in both experiments in absence of epinephrine and blocking drug was 0·44 ± 0·10. The release of free fatty acid by tissue incubated only with neostigmine (10^{-7} M) was 0·40 ± 0·1 and 0·84 ± 0·02 for tissue incubated only with carbachol (10^{-5} M).

It would seem unlikely, considering the known actions of neostigmine, that its effects in the present study are due to sympathetic blockade. The same would hold true for the *in vitro* effects of carbachol. A more likely explanation would appear to be that some sort of cholinergic mechanism is involved. In this connexion it should be noted that carbachol, although its primary action is on postganglionic parasympathetic effector sites, can also be demonstrated to possess anticholinesterase activity[6]. Cholinesterase, largely in the form of pseudocholinesterase, has recently been found to occur in high concentrations in fat depots[7]. It is of interest also that the parasympathetic blocking drugs, atropine and methantheline, will prevent the fall in fasting levels of plasma free fatty acid in the conscious dog caused by *N*-isopropyl methoxamine. An interpretation which would explain these effects of atropine and methantheline and which would also be consistent with the effects of neostigmine and carbachol in the work recorded here is that there are cholinergic receptors associated with the release of free fatty acid and that, when these receptors are stimulated, inhibition of release occurs.

Urethane Hyperglycæmia and Hypothalamic Activation

An unexpectedly high blood glucose-level was found in rats which had been anæsthetized with ethyl urethane in the course of routine biochemical assays. The blood glucose-level of fasting rats rose from 58 ± 1 mg per cent (mean ± *S.E.*; $n = 40$) to 167·7 ± 7·6 mg per cent 1 h after intraperitoneal injection of 1·25 g/kg urethane.

Intraperitoneal or intravenous injection of anæsthetic doses of urethane produced a similar degree of hyperglycæmia in rabbits and cats. In dogs, only a small and short-lasting rise in blood glucose was found; this is obviously due to the known fast metabolism of urethane in this species, which is also the reason for the absence of an anæsthetic effect.

The fact that urethane produces hyperglycæmia is not widely known. Underhill[1] suggested an unusual sensitivity towards the hyperglycæmic action of adrenaline as the cause of the glycosuria, and Bang[2] claimed pancreatic degeneration to be responsible for the hyperglycæmia.

The wide use of urethane as an anæsthetic in physiological and pharmacological experiments warranted, it was felt, further experimental studies to elucidate the mode of action of the urethane hyperglycæmia. Anæsthetics commonly used in animal experiments such as hexobarbitone, 'Nembutal' and chloralose did not produce hyperglycæmia (Fig. 1).

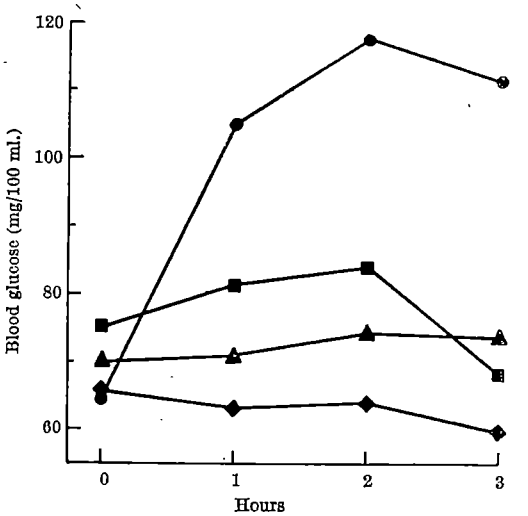

Fig. 1. Blood glucose-levels after administration of ●, urethane (1·25 g/kg intraperitoneally; $n = 5$), ■, hexobarbitone (50 mg/kg intravenously; $n = 3$); ▲, 'Nembutal' (40 mg/kg intravenously; $n = 3$); ◆, chloralose (80 mg/kg intraperitoneally; $n = 3$) to fasting rabbits

The urethane hyperglycæmia could be due to a number of mechanisms such as: direct action on glycogenolysis; increased sensitivity to adrenaline; direct stimulation of the adrenal medulla; increase of central sympathetic activity.

No effect of urethane on *in vitro* glycogenolysis could be found. The urethane hyperglycæmia is absent in rabbits after pretreatment with dibenamine or hexamethonium and in cats after adrenalectomy, cutting of the splanchnic nerves or despinalization. Intramuscular administration of 15 mg/kg guanethidine to rabbits for two weeks reduced but did not abolish the hyperglycæmia (Fig. 3). Guanethidine administered under identical conditions will decrease the noradrenaline concentration in peripheral tissue but not the catecholamine of the adrenal medulla or the noradrenaline of the hypothalamus[3]. Pre-treatment with 2·5 mg/kg reserpine injected intramuscularly 48 and 24 h before anæsthetic doses of urethane abolishes the hyperglycæmia (Fig. 2). Pretreatment with reserpine at this dose-level decreases the amine levels of the adrenal medulla, the central nervous system and the peripheral

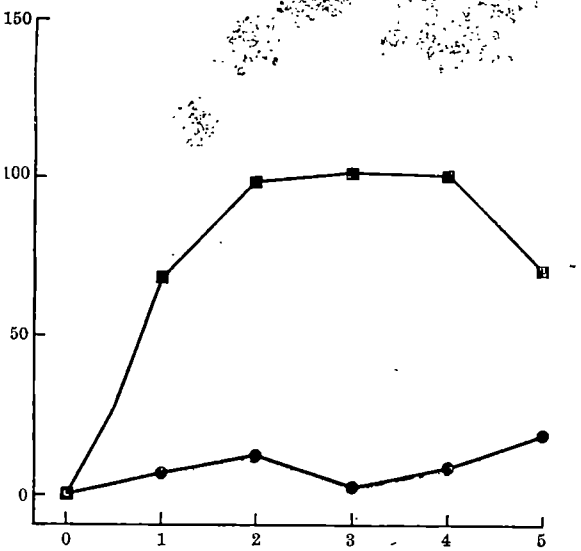

Fig. 2. Rabbit. Ordinate: percentage change of blood glucose from pre-dose level after 1·25 g/kg urethane (intraperitoneal). Abscissa: h. ■, Urethane ($n=7$); ●, after pretreatment with 2·5 mg/kg reserpine intramuscularly 48 and 24 h before urethane

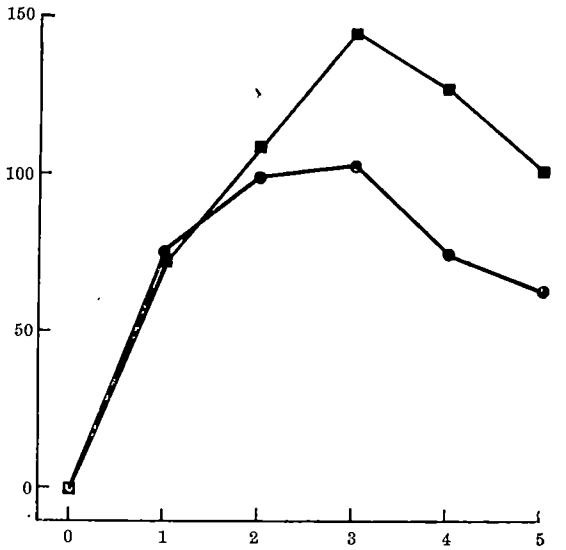

Fig. 3. Rabbit. Ordinate: percentage change of blood glucose from pre-dose level after 1·25 g/kg urethane (intraperitoneal). Abscissa: h. ■, Urethane ($n=4$); ●, after pretreatment with 15 mg/kg guanethidine intramuscularly on alternate days for 2 weeks

tissues. These results exclude an indirect action (sensitization to circulating amine) or a direct action (release of amine) as causes of the hyperglycæmia, but they imply an action via a centrally mediated adrenal catecholamine release. Vogt[4] demonstrated that hypothalamic activation with certain drugs is reflected in a decrease of hypothalamic noradrenaline as well as adrenal catecholamine. If urethane acts via hypothalamic (or general limbic) activation, then, to accord with Vogt's view, hypothalamic noradrenaline and adrenal catecholamine should decrease.

Reserpine (5 mg/kg), urethane (1·25 g/kg), sodium diethyl barbiturate (225 mg/kg) and saline were injected intraperitoneally into different groups of rats 16 h before they were killed by decapitation. The noradrenaline content of the hypothalamus was determined using the method described by Merrills[5]. The results obtained are shown in Fig. 4 and clearly reflect the decrease of hypothalamic noradrenaline after urethane and reserpine while no change from the control-level was seen after sodium diethyl barbiturate. The adrenal catecholamine content after urethane was 63·5 per cent of the control value and 42·5 per cent after reserpine. If it is accepted that the decrease of hypothalamic noradrenaline reflects enhanced central sympathetic activity, then an increased activity in efferent sympathetic neurones should be measurable.

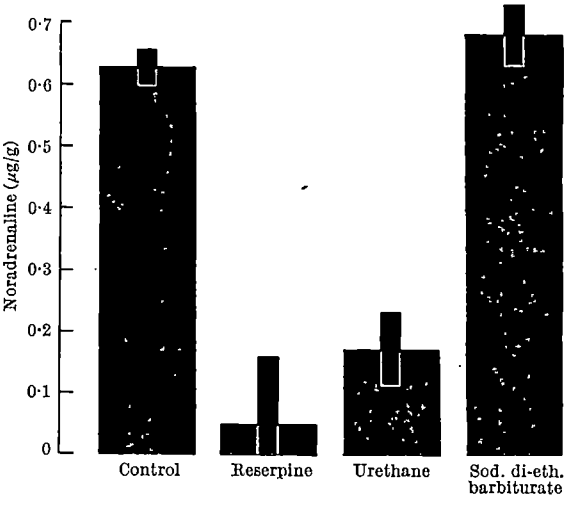

Fig. 4. Hypothalamic noradrenaline-levels (μg/g) of rats 16 h after intraperitoneal injection of saline ($n=20$); 5 mg/kg reserpine ($n=8$); 1·25 g/kg urethane ($n=8$) and 225 mg/kg sodium diethyl barbiturate ($n=8$)

The spontaneous spike discharge in filaments of the preganglionic cervical sympathetic of cats under 'Fluothane', N_2O–O_2 anæsthesia was recorded using Iggo and Vogt's[6] procedure and criteria. In numerous experiments a progressive increase of spike activity was found after 0·2–0·8 g/kg urethane (intravenous). The firing rate of the preganglionic neurones increases immediately after injection and, like the hyperglycæmia, remains raised for several hours (Fig. 5). The intravenous injection of 0·2–0·8 g/kg urethane results in a fall in blood pressure lasting 5–10 min. After this short and initial fall a progressive increase of the blood pressure follows. This is possibly due to continuous recruitment of vasoconstrictor activity through increased central sympathetic discharge. Baroreceptor reflex mechanisms are, therefore, not the cause of the increased preganglionic sympathetic activity. The activation by an initial small dose can be further increased by subsequent injections of the same or larger amounts of urethane.

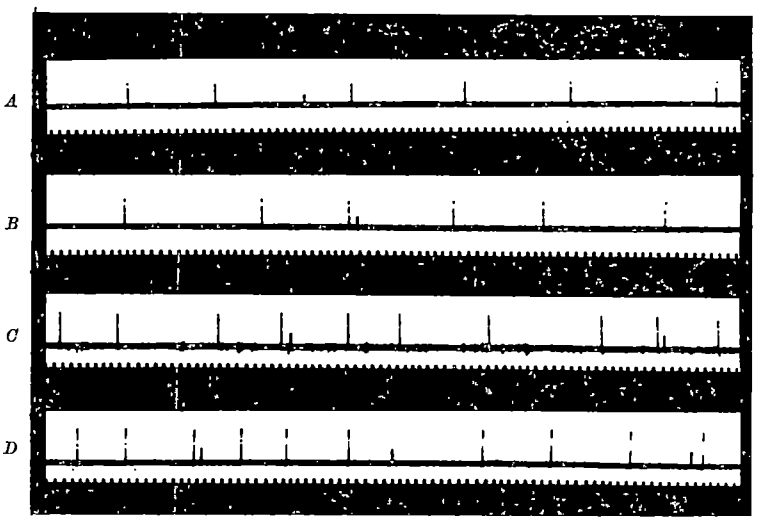

Fig. 5. Cat. 'Fluothane', N_2O/O_2 anæsthesia. Record of spontaneous spike discharge from filament of the cervical sympathetic. *A*, Control period; *B*, 10 min after intravenous injection of 0·2 g/kg urethane; *C*, 30 min later; *D*, 60 min later. Time signal, 100 msec

The hyperglycæmic action of urethane can, therefore, be envisaged as hypothalamic (or general limbic) activation resulting in increased descending sympathetic discharge and enhanced catecholamine secretion from the adrenal medulla. The activating effect of urethane on sympathetic areas in the central nervous system may be relevant for the interpretation of neurophysiological, neuro-endocrine or cardiovascular experiments when this compound is used as a general anæsthetic.

I thank Mr. J. Offerman for the biochemical noradrenaline assays.

Prevention of Cerebral Œdema induced by Triethyltin in Rabbits by Cortico-steroids

PATIENTS receiving cortico-steroid therapy who underwent craniotomy were observed to have a smoother post-operative course than would have been expected[1]. Surgeons were thus led deliberately to administer cortico-steroid preparations before and after craniotomy, in order to ease the patient's course. In particular, patients diagnosed as having cerebral œdema, either from a tumour or more diffuse cause, seemed to benefit[2], and the improvement is explained on the assumption that this treatment reduces the cerebral œdema. The most recent preparation used has been dexamethasone since it is supposed to have minimal water- and sodium-retaining properties.

The assumption that patients improve because the cerebral œdema is reduced is based on analogy with the systemic anti-inflammatory properties of these hormones. Little experimental work exists to verify this hypothesis. One pathological and chemical investigation showed no effect of cortisone acetate on local brain œdema caused by cold injury[3]. Experimental focal œdema due to implantation of *Psyllium* seeds did not respond to steroids[4], nor did the anoxic ischæmic œdema due to carotid ligation[5]. The effects of triethyltin (TET) on the electrolyte content and fine structure of cerebral white matter have been extensively investigated[6,7].

The present experiment is in the nature of a pilot investigation to see whether large doses of cortico-steroid (dexamethasone) could modify the expected diffuse cerebral œdema from injections of triethyltin sulphate.

New Zealand white rabbits weighing between 2·5 and 3·5 kg were used. Six rabbits received TET, 0·5 per cent solution, in a dosage of 1 mg/kg daily for six days by intraperitoneal injection, together with dexamethasone 0·4 per cent solution, 0·75 mg/kg daily by intramuscular injection. This dosage of dexamethasone corresponds to cortisone acetate 25 mg/kg, a maximal dose. Six rabbits received dexamethasone alone during the same period. Also for controls, normal rabbits and rabbits receiving TET alone were examined.

After six days these animals were killed by means of exsanguination. The brains were removed intact, and immediately placed in a high humidity chamber (relative humidity 90 per cent). Four samples of grey matter and four samples of white were dissected under a dissecting microscope. Each was weighed on a microbalance, using weighed aluminium foil planchets, to give the wet weight of the sample. The fragments were then desiccated overnight at 100° C and reweighed to give dry weights. Digestion with conc. HNO_3 preceded flame photometry (with a lithium standard) to estimate Na and K values. The Na/K ratio was then calculated. Samples of serum were withdrawn from each rabbit at death and their electrolyte content and osmolarity were also measured. A Fiske osmometer was used.

The most striking feature was the clinical condition of the animals receiving both TET and steroid. Usually, animals treated with TET are progressively more lethargic, with quadriparesis, and roughening and discoloration of their fur by the fifth day of drug administration. The rabbits in this experiment remained quite lively, with smooth white fur, and two animals showed only very slight weakness. The animals on steroid alone appeared perfectly healthy.

At death, the brains from the rabbits receiving simultaneous steroid and TET appeared slightly œdematous. One brain from an animal on steroid alone appeared quite swollen while the others had normal gross appearance.

The most remarkable changes in brain electrolytes produced by TET intoxication are in the white matter (Table 1). As has been previously reported[6], the water content of the white matter was increased by 109 per cent (dry weight 28·4 per cent in normals and 16·9 per cent in TET animals, converted to g H_2O/100 g dry white matter). In addition, the sodium content of the white matter was increased by 174 per cent (56·3 m.equiv./kg in normals to 91·7 m.equiv./kg in TET animals, converted to m.equiv./100 g dry white matter). The potassium content in the white matter showed only a 14·8 per cent decrease on similar dry weight calculation. The sodium/potassium ratio was changed from 0·685 in normal white matter to 2·21 in TET intoxicated animals. The grey matter showed no significant changes (Table 1).

Table 1. EFFECTS OF GLUCOCORTICOID ON BRAIN ELECTROLYTES IN NORMAL AND TRIETHYLTIN-TREATED RABBITS

	Normal		Steroid treated		TET intoxicated		Simultaneous TET and steroids	
	Grey	White	Grey	White	Grey	White	Grey	White
No. animals/samples	10/23	10/23	5/20	5/20	3/12	3/12	6/24	6/24
Dry/wet × 100	18·7*	28·4	18·2	28·6	18·9	16·9	19·0	24·7
Na m.equiv./kg wet	58·9	56·3	54·4	51·3	47·4	91·7	54·4	71·9
K m.equiv./kg wet	91·0	82·3	86·7	73·0	93·8	41·8	87·1	60·3
Na/K	0·643	0·685	0·629	0·673	0·506	2·21	0·673	1·24

* Mean.

Table 2. RECALCULATION OF ELECTROLYTE DATA WITH DRY WEIGHT REFERENCE

	g H_2O/100 g dry white matter	m.equiv. Na/100 g dry white matter	m.equiv. K/100 g dry white matter
TET intoxicated	491*	54·3	24·7
Simultaneous TET	304	29·1	24·4
Difference	187	25·2	0·3
Per cent change	38·2	46·5	1·2

* Mean.

The administration of dexamethasone alone produced no significant changes in electrolyte content of the brain (Table 1). Simultaneous administration of dexamethasone and TET produced less change in the water and electrolyte content of the white matter than TET alone (Table 1). In comparing the TET-treated rabbits with those receiving simultaneous TET and dexamethasone, there was a 38·2 per cent reduction in water content and 46·5 per cent reduction of sodium content in the white matter (Table 2) calculated on basis of g of water or m.equiv. Na/100 g dry white matter. The potassium showed no significant changes. Again, all the changes were limited to white matter.

Perusal of the results reveals that simultaneous administration of TET and dexamethasone prevents the accumulation of sodium and water in white matter usually seen in TET intoxication. This accumulation provides criteria for describing the resulting brain œdema. Using these criteria, it is permissible to state that the dexamethasone has (partially) prevented the occurrence of cerebral œdema.

The sodium and water are probably retained largely within the intramyelinic vacuoles of white matter[6]. It is

clear that the systemic anti-inflammatory properties of glucocorticoids have not affected their suppression of œdema. Further work is required to find out how the steroid molecule has acted on the neural tissue, or if its action has been on TET excretion.

In conclusion, rabbits were treated with triethyltin sulphate intraperitoneally, concurrently with dexamethasone intramuscularly. A group of rabbits received the dexamethasone solely, as controls.

The clinical condition of the animals receiving both drugs compared very favourably to rabbits intoxicated by TET alone.

The water and sodium content of white matter from simultaneously treated rabbits was considerably less than that in rabbits intoxicated by TET.

Dexamethasone alone caused no significant changes in sodium or water content.

The expected cerebral œdema was partially prevented by the use of dexamethasone.

This work was supported by grant *MS* 303 from the National Multiple Sclerosis Society and grants *CA*–06264 and *NB* 1450 from the National Institutes of Health.

Dipyrrylvinyl Pyridines as Trichuricides

Whipworm infections in man and dog have been, until recent years, quite difficult to eradicate. During the past decade several compounds have been found to have activity against these worms. These compounds are 'Phthalofyne' orally[1] or intravenously[2], dithiazanine iodide[3], stilbazium iodide[4,5], and 'Glycobiarsol'[6]. However, most of these drugs require large doses in mg/kg or a series of doses, or they have undesirable side-effects, or the worm loss is not high enough. Among the numerous modifications of stilbazium iodide[4] which were prepared, a number of members of the dipyrryl vinyl pyridines were found to have activity against the dog whipworm, *Trichuris vulpis*.

The compounds have the following basic structure (I):

I

Numerous variants of the 2,6-*bis* pyrrylvinyl pyridine quaternary ammonium salts, (I), have been made in which R = CH_3—C_5H_{11}, benzyl, etc., and R' = various alkyl, substituted alkyl, aryl, and substituted aryl groups. Details of the syntheses and activities of all these products will be published elsewhere.

In general, the most active members of this type are those in which R is C_2H_5 to C_4H_9–*n* and R' is C_2H_5 or $CH(CH_3)_2$. These compounds, when given in single doses of 15–25 mg/kg, have eliminated whipworms from most of the dogs treated, have been quite active against the mouse pinworm, *Syphacia obvelata*, and the dog ascaris, *Toxocara canis*, but have had little or no activity against three species of dog and cat hookworms.

Four of these compounds are being used extensively in the treatment of dog whipworm and other concomitant infections, for these four proved to be among the most active and least toxic of the series. When compared with the activity of stilbazium iodide against *T. vulpis* infections[6], these require fewer and smaller doses.

Inasmuch as rats tolerate single doses of nearly 2 g/kg and the usual dose for a dog or cat is between 15 and 25 mg/kg, there is a wide margin of safety. The compounds are tasteless, and emetic activity is slight.

HÆMATOLOGY

A Second Example of – – –/– – – Blood or Rh_{null}

The blood of a white female (Mrs. L. M.) was submitted for testing following the birth of her first infant, who was slightly anæmic at the age of 2–3 weeks. The maternal serum contained anti-e. Her red cells failed to react with 5 anti-D, 5 anti-C, 13 anti-E, 14 anti-c, 9 anti-e, 1 anti-f, 2 anti-C^w, 1 anti-C^x, 3 anti-Ce(rh_i), 1 anti-hr^s, and 1 anti-G. The red cells also failed to react with the sera of four immunized –D–/–D– individuals. Her phenotype can be represented as – – –/– – – or as suggested by Ceppellini[1] as "Rh_{null}". The other antigens—A_1, N, s, k, Fy(a + b –), Jk(a –), Le(a – b +)—appeared to be normal.

This blood represents the second example of the phenotype – – –/– – –. The first one was described by Vos, Vos, Kirk and Sanger[2] in an Australian Aborigine who had no living relatives.

Fortunately the propositus is a member of a large family and all bloods were of the probable genotypes R^1R^1 and R^1r. Available members of the family tree are given in Fig. 1, which shows that 12 out of 16 members of both sides of the family exhibited weak reactivity for Rh antigens, D, C, c and e by titration scoring values as compared with appropriate control bloods. The depressed reactivity applied also to the compound antigens ce(f) and Ce(rh_i). Only four of the 16 members gave normal Rh reactivity. These include two paternal uncles II–6, II–8, one maternal uncle II–15, and one sibling (III–1) of the propositus.

For sake of brevity the titration scoring values of the red cells of the parents, their four offspring including the propositus, her husband and their child are presented in summarized form in Table 1. Normal activity is represented by 'N' and suppressed activity by 'w'.

Table 1 shows that only one sibling III–1 and the husband gave normal reactivity. All others, excluding the propositus, exhibit weak reactions. These include the parents, who are not related to each other. The Rh_{null} propositus like her three sibs could be either R^1R^1 or R^1r. Her genotype is represented as [R^1R^1] or [R^1r], the brackets indicating the absence of detectable Rh antigens.

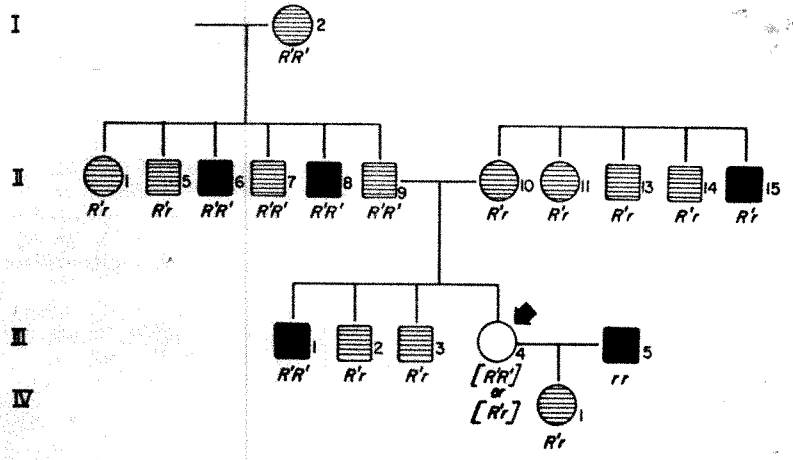

Fig. 1. Selected members of family. Black, normal; hatched, suppressed

Family analysis strongly suggests that the infant's genotype must be R^1r. The R^1 chromosome could be derived only from the Rh_{null} propositus, and r is transmitted by the normal husband. The expression of all Rh antigens was diminished in the infant and this applied especially to antigen C. With some anti-C sera the infant's blood and one maternal aunt (II–11), failed to react, and both bloods were at first mistyped as R^0r.

Since the infant is of the probable genotype R^1r, the Rh_{null} propositus could have produced anti-D, anti-C, anti-G, anti-c and anti-ce (if her underlying genotype is R^1R^1) and anti-e. In fact, the propositus produced only anti-e. In any event, her capacity to produce anti-e would further indicate the complete absence of this antigen. Her failure to produce additional antibodies does not alter the fact that the propositus is, indeed, of the phenotype Rh_{null}.

In order to obtain a more precise measure of the degrees of reactivity of the red cells of the various members of the family, quantitative haemagglutination by probit analysis was carried out by M. E. Gibbs *et al.*[4]. On the whole the results are in agreement with the scoring values in that the same four members had normal activity while the others tested showed varying degrees of suppressed reactivity. These investigations also confirmed that the C antigen was very weak in II–11 and IV–1, and confirmed the observation that chromosome r' was not present in the family.

The propositus as well as the Australian Aborigine were both LW negative while all other members of the large family were LW positive. LW is the name assigned by Levine *et al.*[5] to the blood factor discovered by Landsteiner and Wiener[6].

In their description of the Australian Aborigine blood, Vos, Vos, Kirk and Sanger[2] speculate that the phenotype – – –/– – – "may reflect the absence of a very frequent gene necessary for the production of some Rh precursor substance". It is more than a coincidence that the Rh_{null} Australian blood[3] and the blood of the propositus are LW negative. We believe that both LW and Rh require the same precursor substance to produce their normal phenotypic expression[7]. In the presence of a theoretical and almost universal gene in the homozygous state X^1rX^1r, sufficient precursor substance is available to be acted on by *LW* and *Rh* genes to produce complete expression of their respective antigens. This applies to the four members who showed normal Rh reactions.

Table 1. Summary of Scoring of Titration Experiments

		D	C	c	e
II–9	father R^1R^1	w	w		w
II–10	mother R^1r	w	w	w	w
III–1	sib R^1R^1	N	N		N
III–2	sib* R^1r	w	w	w	w
III–3	sib R^1r	w	w	w	w
III–4	propositus†	0	0	0	0
III–5	husband rr			N	N
IV–1	infant* R^1r	w	w	w	w

*These reactions were not titrated and are based on qualitative tests with several sera. Control bloods showed normal (N) activity.
†$[R^1R^1]$ or $[R^1r]$; phenotype Rh_{null}.

To account for the diminished reactivity of Rh antigens in the 12 members of this family, the data presented suggest the presence of a mutant heterozygote X^1rX^0r, which exerts its effect by producing less precursor substance. In other words, one X^1r gene is replaced by a very rare amorph X^0r. Since all members of the family except the propositus have LW antigen which is apparently not suppressed, it is assumed that *LW* gene successfully competes for precursor substance at the expense of *Rh*. Perhaps *LW* genes have prior claim to precursor substance because they are older from the point of view of evolution as indicated by their wide distribution in monkey bloods[8].

In the homozygous mutant X^0rX^0r—the propositus—genes *Rh* and *LW* are present but no precursor substance is available for production of their respective antigens. Evidence that *Rh* and *LW* genes are present in the propositus is provided by transmission to her infant of R^1 gene complex and probably also *LW*. In short, the genetic explanation for the occurrence of Rh_{null} is analogous to that given for the homozygous suppressor *xx* genes which prevent expression of H, A or B antigens in the Bombay bloods[9]. It differs from the Bombay blood in that *Xx* of the latter cannot be differentiated from the normal *XX* while X^1rX^0r is readily distinguished from the normal X^1rX^1r.

It is difficult, however, to envisage that a mutation at the X^1r locus could explain the rare occurrence of LW negative individuals with apparently normal Rh antigens, some of whom have produced anti-LW[5,10]. The simplest explanation for these cases would seem to be an independent suppressor gene operating at the *LW* locus itself so that only *Rh* genes utilize precursor substance.

In view of the findings reported, the term Rh_{null} for the phenotype of the propositus is preferable to – – –/– – –, which indicates a genotype and implies deletion as underlying the genetic mechanism. The expected genotype can then be represented as usual but characterized by being placed in brackets.

Ultrastructure of Human Leucocytes synthesizing DNA

THE application of autoradiographic techniques in the localization of radioactively labelled compounds in cells by electron microscopy has been developed by a number of workers[1]. The direct coating of ultra-thin sections with photographic emulsion has the disadvantage that long exposure times are required to obtain positive autoradiographs. Furthermore, it is difficult to locate labelled cells in the electron microscope by this method when their frequency is low. In the experiments recorded here the characteristics of the ultrastructure of cells in DNA synthesis were examined by using a 'thick–thin' technique[2]. Two examples of proliferation in atypical lymphocytes were investigated by this method: normal human lymphocytes cultured with phytohæmagglutinin[3–5], and freshly isolated leucocytes from patients suffering from infectious mononucleosis (glandular fever). The cells were incubated with thymidine (^{3}HT) (10 mc./ml., specific activity 1·9 c./mmole) for 30 min and then fixed with osmic acid and embedded in methacrylate. A thick section (about 0·25μ) was cut from a suitable part of the block and mounted on a glass slide. The contiguous ultra-thin section was then cut and mounted on an electron microscope grid. The methacrylate was removed from the thick section with chloroform and the section coated with Ilford *L4* emulsion and stored at 4° C. Three weeks later it was developed in Kodak *D19B* and stained with toluidine blue. A map of the whole section was made from a mosaic of light photomicrographs and the cells with positive autoradiographs noted. This map was used to locate the position of the DNA-synthesizing cells in the ultra-thin section, which were then examined and photographed in the electron microscope.

In general, cells in DNA synthesis (*S* cells) tended to be larger than other transformed cells and their ultrastructure differed in several respects. The nuclear double membrane showed a far greater degree of irregularity in the cells synthesizing DNA. The separation of the two components was variable and resulted in a beaded appearance. In some cases the outer membrane showed evaginations, and in others it was fragmented. It seems likely that this represents a very early stage in the breakdown of the nuclear membrane which is known to precede mitosis. Exceptionally large-diameter nuclear pores were also present in these cells. The chromatin of these nuclei was loosely packed, especially in the central zone of the nucleus; nucleoli were frequently seen and often had a 'bobbined' appearance. The resting transformed cells had more densely packed chromatin and the nuclear membrane was more regular but contained some smaller pores. Nucleoli were less frequently seen in these cells. A few cells with negative autoradiographs were seen to have loose chromatin and highly irregular cell membranes which were breaking down; these were considered to be nuclei in early prophase.

The cytoplasm of the *S* cells had three major features which distinguished it from the organization of the resting transformed cells. The most noticeable was the far higher concentration of free ribosomes and larger number of dense bodies, possibly containing glycogen, scattered in the cytoplasm of the DNA-synthesizing cells. Endoplasmic reticulum was poorly developed in the transformed lymphocytes, but these cells had a more pronounced quantity of smooth endoplasmic reticulum than the resting transformed cells. Among the DNA-synthesizing cells there was considerable evidence of elaboration of mitochondria, especially in the Golgi zone. The other features of the transformed cells—micropinocytosis, the multivesicular bodies, lipid-containing bodies and Gall bodies—were present in the cytoplasm with equal frequency in resting and in DNA-synthesizing cells.

A general ultrastructural description of the characteristic cells of infectious mononucleosis has been given[6,7]. This work suggests that the differences between DNA-synthesizing and resting cells in this cell line were very similar to those described here for phytohæmagglutinin-transformed cells. The chromatin density and nuclear membrane differences were present, but nucleoli were infrequently seen in both resting and DNA-synthesizing cells. The greatly increased cytoplasmic free ribosome concentration in the *S* cells was equally marked, as was the increase in elements of the smooth endoplasmic reticulum. The other cytoplasmic differences, though present, were less marked than in the phytohæmagglutinin-transformed cells.

Allotypes of Hen Serum Proteins

THE allotypic differences in antigenic specificity of rabbit serum proteins were discovered by Oudin[1] in 1956. Oudin's results were confirmed by Dray and Young[2]. Serum groups in rabbits were also described by Dubiski, Dudziak and Skałba[3]. Immunological differences in serum proteins have also been demonstrated in the guinea-pig[4] and the mouse[5].

This paper presents the results of investigations which showed the allotypic specificity of hen serum proteins. The experiments were carried out on four breeds of hen: Rhode Island Red, Sussex, White Leghorn and Greenleg. The isoprecipitins were obtained by immunizing the hens with bacteria mixed with corresponding immune antibacterial hen serum. For the production of antibacterial sera hens were immunized with heat-killed bacterial suspensions of *Proteus vulgaris* (*OXl9*). 0·5 ml. of antibacterial serum was mixed with 0·05 ml. of *Proteus* suspension containing approximately 10^9 cells. The mixture was incubated for 60 min at 37° C and re-suspended in 1 ml. of saline. The inoculum thus prepared was injected intravenously. The injections were made three times a week. During the whole period of immunization (7–10 months) each hen was inoculated with one antibacterial serum only. The birds were bled eight days after the final injection.

The immune sera were tested in 1·5 per cent agar gel by the method of Ouchterlony. The concentration of sodium chloride was 8 per cent in agar gel.

Table 1. DISTRIBUTION OF THE ALLOTYPES GA1, GA2 AND GA3 IN DIFFERENT HEN RACES

Breed	Number of hens	Allotypes GA1	GA2	GA3
Rhode Island Red	112	112	40	41
		1·000	0·357	0·366
Sussex	113	78	65	68
		0·690	0·572	0·602
White Leghorn	120	74	68	48
		0·617	0·567	0·400
Greenleg	117	111	60	37
		0·949	0·513	0·316

Three precipitating antisera were obtained. Three distinct antibodies were identified and the corresponding allotypes of serum proteins. In accordance with the agreed notation for allotypy[6], the allotypic specificities of hen serum proteins were marked GA1, GA2 and GA3.

It is theoretically possible to foresee eight different combinations of the three allotypes, if they were independent.

These eight serum groups could be distinguished in Sussex and White Leghorn hens. Among the sera of Sussex, White Leghorn and Greenleg hens there were some in which no allotypes were detected. The frequency of this allotype formula, GA(1–2–3), was very low in the sera of Sussex and Greenleg hens; it reached 9 per cent in the sera of White Leghorn hens. The sera of Rhode Island Red hens could be divided among four groups only.

IMMUNOLOGY

Techniques for the Measurement *in vitro* of Tissue Sensitization in Immunized Pigs

CYTOPATHIC tests have been used to detect cytophilic antibodies on monocytes and in sera derived from guinea-pigs immunized with *Cl. welchii* toxin[1], and similar tests were made to investigate cytophilic antibodies on leucocytes and in sera from chickens infected with *Salm. gallinarum*[2]. Further experiments have been made to record the development of tissue sensitization in pigs immunized against ovalbumin, and to predict the time at which an additional antigenic stimulation would induce a typical anaphylactic reaction.

Preliminary experiments showed that cultures of *ERK* cells adsorbed antibody from pig sera. They were used in these experiments to provide a constant and homogeneous cell suspension for the detection of serum cytophilic antibody. In addition cytophilic antibody produced by leucocytes was detected by growing washed leucocytes from immunized pigs for five days, and then testing the supernatant growth media for antibodies by absorbing with *ERK* cells. After removal from the culture media, and washing, the *ERK* cells were mixed with albumin, and the cytopathic indices[2] were recorded. Suitable controls were run in parallel with each experiment, using fresh unused growth medium and medium that had been used for growing leucocytes from non-immunized pigs.

Fig. 1 shows cytophilic antibody production in a pig of 25 kg weight, after intravenous inoculation of 1 g ovalbumin. The antibody titre showed a marked decline from the fourth to the seventh day, and the pig was given an intravenous challenge dose of 1 g of ovalbumin on the seventh day. Within 5 min this produced mild symptoms

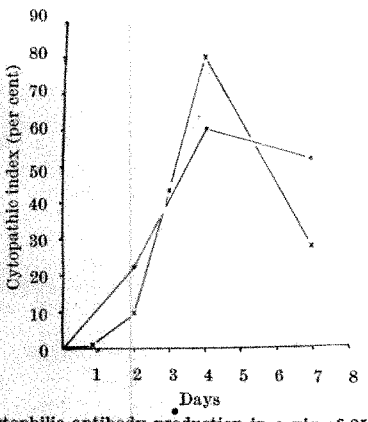

Fig. 1. Cytophilic antibody production in a pig of 25 kg, after i.v. inoculation of 1 g ovalbumin. ×——×, serum, cytophilic antibodies; ●——●, *in vitro* cytophilic antibody production by leucocytes

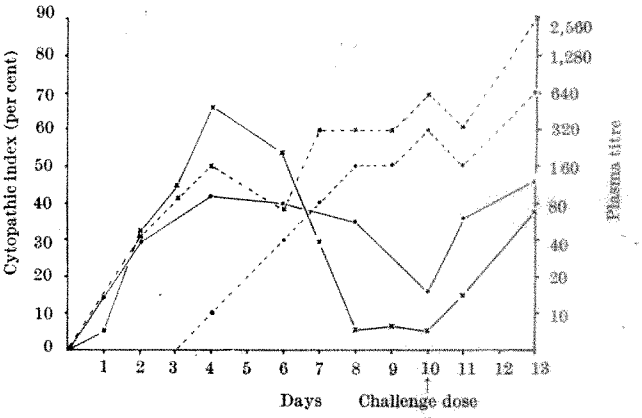

Fig. 2. Cytophilic antibodies and hæmagglutinins in a pig after i.v. inoculation of 1 g ovalbumin, followed by a challenge dose of ovalbumin on day 10. ×——×, serum cytophilic antibodies; ●——●, *in vitro* cytophilic antibody production by leucocytes; × — — — ×, antiglobulin hæmagglutinins; ● — — — ●, hæmagglutinins

of anaphylaxis, lasting for approximately 2 h, similar to those described by Thomlinson and Buxton[3].

The supernatant media from primary cultures of leucocytes were removed after five days' growth and stored at −25° C until all samples had been collected. These were collectively tested and compared with a control medium for the presence of cytophilic antibodies. The results are recorded in Fig. 1 and show that *in vivo* antibody production was continuing despite the decline in the amount of detectable circulating cytophilic antibodies.

A further attempt was made to relate serum antibodies to tissue sensitization and anaphylaxis, by giving an intravenous dose of 1 g of ovalbumin to a pig of approximately 20 kg weight. The concentration of serum cytophilic antibodies reached a peak on the fourth day after immunization and fell steeply until the eighth day (Fig. 2). This decrease would be expected with a cytophilic antibody which was being fixed to tissue cells, particularly when the rate of antibody production by leucocytes had reached a maximum and was also declining. At this state in the immune response it was assumed that extensive sensitization of the pig's tissues had occurred, and that the animal was therefore in a hypersensitive state. For this reason the pig was given a challenge dose of 1 g of ovalbumin intravenously on the tenth day. A moderately severe anaphylactic reaction developed in which congestion of the skin and cyanosis were marked and the respiratory rate was increased; other characteristic symptoms included coughing, muscular tremors, restlessness, straining, vomiting, defæcation and unsteadiness of gait. The pig recovered during the following 18 h, and the serum cytophilic antibody level increased markedly from the tenth to fourteenth day.

Figs. 1 and 2 show that in both cases cytophilic antibodies were being produced by leucocytes and were also detectable in the sera of these animals following the initial inoculation of antigen. During the first four days after inoculation antibody concentrations detectable by both methods increased rapidly. Thereafter the concentration of serum cytophilic antibodies declined more rapidly than antibody production by the leucocytes *in vitro*.

Buxton and Allan[4] have shown that antiglobulin hæmagglutinins in chickens acutely infected with *Salm. gallinarum* were cytophilic. However, Fig. 2 shows that from the sixth day onwards there is a striking divergence in the relative concentration of antiglobulin hæmagglutinins and cytophilic antibodies, and that simultaneously the former follow the same pattern as hæmagglutinins. The antiglobulin hæmagglutination technique does not enable any qualitative distinction to be made between cytophilic antibodies and concentrations of hæmagglutinins which can only be detected by an antiglobulin

system. It is probable that immediately after injection of antigen the antiglobulin hæmagglutination test will detect cytophilic antibodies only, and later the detection of this type of antibody will become masked by the higher titres of hæmagglutinins which are only observed by this antiglobulin method.

New Cellulose Derivatives for the Isolation of Biologically Active Molecules

The search for the relationship between structure and function of antibodies has gone through different phases. Much information has been accumulated concerning the interactions of antibody with antigens, particularly with respect to haptens of related and different structures. These data have given rise to a multitude of speculations concerning the chemical and physical structure of antibodies and the mechanism of antibody reactions. At present, major questions awaiting answers are: (1) Does antibody to a particular antigen have a unique primary structure? (2) Do all antibodies have the same primary structure but they are folded differently? (3) Are the antibody combining sites for a particular antigen the same, but are other parts of the antibody molecule modified for other functions? (4) What is the composition and structure of the active site?

The evidence that antibody produced against protein antigens is heterogeneous, and the possibility that antibody to haptens is heterogeneous makes it mandatory that any investigations concerning antibody structure or interaction be made on all the antibody from a selected quantity of serum, unless it can be shown that a representative sample has been obtained during the isolation process. Conclusions based on comparisons of peptide or amino-acid analyses, and other antibody components are particularly sensitive to fractionation of antibody during its isolation from serum.

For these reasons we have concentrated our present efforts on investigating methods for isolating the maximum possible quantity of antibody from a serum sample, in as pure a form as possible, measured by the fraction precipitable with specific antigen. Available methods have drawbacks which include incomplete separation from antigen, low overall yield, low purity, lack of generality and very involved procedures. The most promising approach is that of chemically coupling the antigen to an insoluble derivative of a polymeric carrier such as an aromatic or aliphatic resin, a protein or a cellulose derivative. In principle, contamination of antibody by antigen should be negligible, and separation from other serum proteins should be complete, if conditions are properly controlled. A review of this and other isolation techniques has recently been published[1].

The most frequently used insoluble antigen is polyaminopolystyrene, which has been diazotized and coupled to protein antigens[2]. This derivative has the disadvantage that recovery of antibody is low, overall yields are low and appreciable amounts of non-specific protein are released with the antibody[1]. In addition, the coupling reaction is limited to substances which will couple to aryldiazonium compounds. To extend the scope and utility of this technique we developed the use of di*cyclo*hexylcarbodiimide as a coupling agent for chemically binding antigenic substances with basic amino groups, to insoluble varieties of carboxymethylcellulose[3]. Water-soluble diimides such as 1-*cyclo*hexyl-3-(2-morpholinyl-(4)-ethyl)-carbodiimide can also be used. Recovery of antibody complexed to the cellulose derivatives was in excess of 88 per cent. Since the original work was done, overall yields exceeding 90 per cent are now being consistently obtained from anti-BSA serum and anti-azophenylarsonate serum, by dissociating the antigen–antibody complex with 1 per cent saline acidified with hydrochloric acid to *p*H 2·3 for the former case, and to *p*H 2·0 for the latter. Human γ-globulins, bovine serum albumin, keyhole limpet hæmocyanin and other proteins can be coupled. Many enzymes couple and still retain activity. In addition, *p*-(*p*′-aminophenylazophenyl)-arsonic acid, ε-DNP-lysine and other organic amines reacted with carboxymethylcellulose and could be used to bind serum antibody. Coupling of the amines to carboxymethylcellulose was more effective at *p*H 3·6–4·0 than near neutral *p*H.

Carboxymethylcellulose coupled to antigens releases about 0·01 mg of non-specific protein per ml. serum/g carboxymethylcellulose. Another cellulose derivative commercially available ('Cellex *PAB*') has been bound to proteins by diazotization and coupling[4]. Any uncoupled diazo groups remaining were blocked by reaction with β-naphthol. While adequate for the isolation of antibody, it is a deep brown substance which is difficult to free of water-soluble material. The coupled 'Cellex *PAB*' retains about 0·1 mg of non-specific protein per ml. serum/g 'Cellex *PAB*'[3].

Coupling through azo links is useful and sometimes advantageous. We have now developed a simple, rapid method of synthesizing a new arylaminocellulose under mild conditions using a slight modification of the method we use for coupling proteins and haptens directly to carboxymethylcellulose (CMC)[3]. The product is a clean, white solid which can be diazotized, or used as it is with di*cyclo*hexylcarbodiimide for coupling to various organic and biological substances.

Benzidine, first suspended in water, was coupled to ten times its weight of carboxymethylcellulose by adding a tetrahydrofuran solution of di*cyclo*hexylcarbodiimide (DCC). The slurry was allowed to stand for 2 days at room temperature, after which the coupled material was washed exhaustively with acetone, dilute acid, base and finally water.

The number of benzidine groups coupled to the cellulose was determined by first reacting the benzidine derivative with a solution of benzenesulphonyl chloride in tetrahydrofuran (in the presence of triethylamine) to form sulphonamides with the free amino groups. After hydrolysing any anhydride that formed, the remaining free carboxyl groups were titrated with sodium hydroxide. Typical data were: 1·0 g carboxymethylcellulose of 0·78 m.equiv. free carboxyl groups per gram was reacted with 0·1 g of benzidine to form a derivative with 0·2 m.equiv. free carboxyl groups/g. By difference, the benzidine coupled amounted to 0·58 m.equiv./g or 0·1 g, signifying that all the benzidine reacted with the cellulose.

An immunoadsorbent was prepared by diazotizing the arylaminocellulose and coupling it to bovine serum albumin. Subsequent treatment with β-naphthol blocked any unreacted diazonium groups. 1 g of this material was poured into a 10-mm glass tube, with a glass wool plug, to make a column several centimetres long.

5 ml. of rabbit anti-bovine serum albumin was passed through the column followed by 1 per cent saline until no protein could be detected using a 1-mm flow-through cell in a spectrophotometer set at 220 mμ. Complexed material was eluted from the column with 1 per cent sodium chloride acidified to *p*H 2·3 with hydrochloric acid. All the specific antibody contained in the serum was picked up and afterwards released. The isolated antibody was not less than 80 per cent precipitable with specific antigen (Table 1).

Similar experiments were performed using a non-specific rabbit serum. In Table 2 the quantity of non-specific

Table 1. Isolation of Antibody from a 1-g Column of Carboxymethylcellulose Benzidine Derivative coupled to Bovine Serum Albumin

Serum added (ml.)	Total antibody passed through column (mg)	Total protein released at *p*H 2·3 (mg)	Precipitable protein (%)
5	10·50	11·25	82·1
5	6·30	6·78	80·5

Table 2. Comparison of Carboxymethylcellulose Benzidine Derivative and *p*-Aminobenzylcellulose Derivative for Release of Non-specific Protein at *p*H 2·3 from 1-g Columns

Column and antigen	Serum added (ml.)	Protein eluted Per ml.	Protein eluted Total (mg)
PAB–BSA	2	0·12	0·24
PAB–BSA	3	0·08	0·24
CMCB–BSA	5	0·18	0·90
CMCB–BSA	5	0·16	0·77

PAB, *p*-Aminobenzylcellulose.
CMCB, Carboxymethylcellulose coupled to benzidine.
BSA, Bovine serum albumin.

protein eluted from an immunoadsorbent made from a carboxymethylcellulose derivative with 0·52 m.equiv./g free amino groups is compared with that eluted from an immunoadsorbent made from a *p*-aminobenzyl derivative with 0·32 m.equiv./g free amino groups.

Under the conditions used, the retention and release of non-specific protein on these immunoadsorbents appear to be dependent on the number of β-naphthyl groups present. Carboxymethylcellulose, which is directly coupled to an antigen through an amide linkage and requires no blocking groups, retains no more than 0·011 mg for each ml. of serum passed through a 1-g column[3]. A *p*-aminobenzyl immunoadsorbent retains about 0·1 mg non-specific protein while the new arylaminocellulose, although still useful as an immunoadsorbent, has about twice the number of reactive groups as the *p*-aminobenzylcellulose and retains about twice the quantity of non-specific protein. By reducing the number of benzidine groups, non-specific protein adsorption should be correspondingly reduced. Such immunoadsorbents are useful because they contain proteins coupled at reactive sites other than those involved in the reaction with di*cyclo*hexylcarbodiimide.

We are now exploring the coupling of this new derivative to other proteins and organic molecules both by diazotization and by amide formation. By chemically coupling inhibitors or other complexing agents to the cellulose derivatives we expect that biologically active molecules and other substances can be concentrated and isolated.

PATHOLOGY

Antigenic Properties of Human Tumours

This communication presents the preliminary findings of investigations on the antigenic properties of human tumours using heterologous antisera. Some attempts have been made to isolate and characterize tumour antigens.

The literature on this subject is voluminous, complex and even contradictory. There is some evidence for the presence of a new antigen or antigens in tumours, and in addition there is also evidence to indicate the loss of antigens.

The possible applications of immunology to the problems of clinical cancer are many and are intriguing. At present, however, they are mainly theoretical and more often purely speculative.

Because of the possible importance of any conclusions concerning the antigenic composition of tumours, it seemed that further investigations were necessary.

Human malignant tumours (predominantly carcinomas) and normal tissues were obtained mainly from surgical operations. A small proportion of the material was obtained from autopsies. The collection of corresponding normal tissues from the same patient was not always possible. Soluble extracts of the various tissues were prepared by a cryostat method[1] using phosphate-buffered saline, *p*H 7·6, as a solvent.

Antisera were prepared from a number of cancerous and normal tissues from different sites, one individual tissue being used to immunize one or more rabbits. The rabbits were injected with the various tissue homogenates and complete Freund's adjuvant. Immunization was continued after one month with tissue homogenates without adjuvant. Antisera were also prepared against protein fractions obtained by chromatographic methods. The antisera obtained were tested for relative potency and specificity.

The antisera were invariably contaminated with antibodies to serum proteins and blood cells. These antibodies were removed by repeated absorptions of the antisera with the corresponding antigens. Anti-tumour antisera were further absorbed with the corresponding normal tissues.

After repeated absorptions several antisera were obtained which reacted exclusively with tumours (Fig. 1). These absorbed antisera were used for the subsequent work.

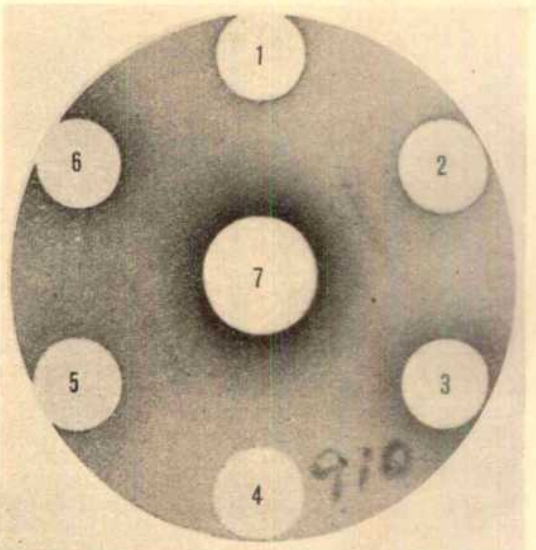

Fig. 1. Ouchterlony plate showing tumour specific reaction. 1, Normal tissue extract; 2 and 5, tumour extracts; 3 and 6, serum; 4, leucocyte extract; 7, anti-tumour antiserum

An antigenic analysis was made of 72 tumours and 31 normal tissue extracts by means of the Ouchterlony agar-gel double diffusion technique.

Tumour-specific reactions were observed with a number of the tumours when reacted with anti-tumour antisera. These positive reactions occurred regardless of whether the tumours were derived from different patients or from different sites. A higher proportion of positive reactions was observed with tumours from the same site as that of the immunizing tumour. Anti-tumour antisera did not react with the normal tissues.

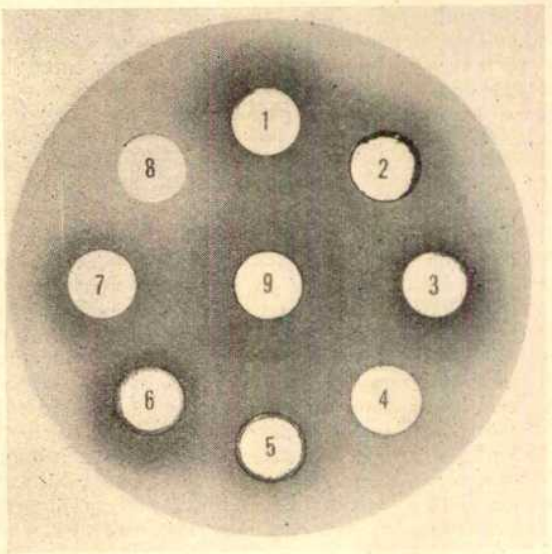

Fig. 2. Ouchterlony plate showing additional antigen in tumours when compared with autologous normal tissues. 1, 3, 5, 7, Different tumour extracts; 2, 4, 6, 8, corresponding normal tissue extracts; 9, anti-tumour antiserum

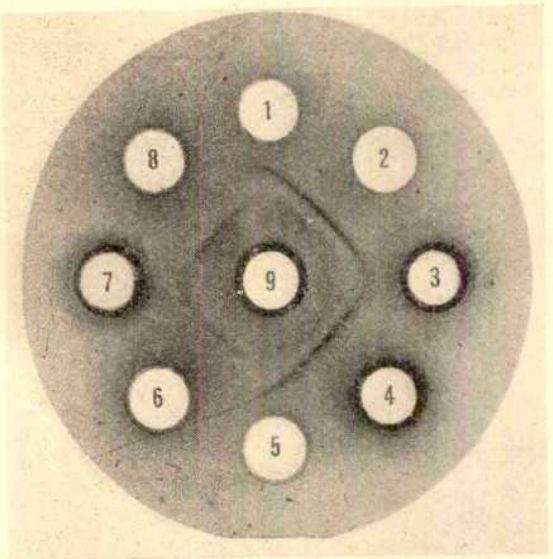

Fig. 3. Ouchterlony plate showing loss of antigens from tumours when compared with autologous normal tissues. 1, 3, 5, 7, Different tumour extracts; 2, 4, 6, 8, corresponding normal tissue extracts; 9, anti-normal tissue antiserum

Positive reactions were observed only with tumour extracts and no reactions were observed with the normal tissues from the same patient (Fig. 2). This confirms that the tumour-specific antigen is not due to iso-antigenic differences between the cells of genetically different individuals.

Loss of antigens was shown in at least a proportion of the tumours when these were reacted against anti-normal tissue antisera (Fig. 3).

No evidence was found for the presence of a soluble antigen present in HeLa cells when an extract was reacted with all the anti-tumour antisera. However, the result may not be conclusive as only HeLa cells from one source have been tested. It was not possible to detect, in extracts of fœtal tissues, antigens serologically identical with the tumour-specific antigen.

Attempts have been made to isolate and characterize these tumour antigens by chromatographic and electrophoretic techniques. The results of these experiments and of further extensions of the antigenic analysis of human tumours will be published in due course.

In summary, we have shown the presence of antigen or antigens in human malignant tumours which were not detectable in normal tissues, and, in addition, we have shown that there was some loss of normal tissue antigen from tumours.

Very recently, McKenna, Sanderson and Blakemore[2] have published results of a similar investigation which largely substantiate our own findings.

Brain Tumours induced in Hamsters inoculated intracerebrally at Birth with Rous Sarcoma Virus

It has been previously shown that new-born hamsters are susceptible to the oncogenic effect of polyoma virus[1] introduced intracerebrally[2]. Likewise, *SV* 40 virus[3] which was shown to be oncogenic when injected subcutaneously into new-born hamsters[4] also proved capable of inducing papillary ependymomas after intracerebral inoculation into the same animals[5]. In recent years a variant of the chicken Rous sarcoma virus (RSV), the Schmidt-Ruppin strain[6], has been shown to be oncogenic in a variety of subcutaneously inoculated rodents, including hamsters[7]. The investigation described here was undertaken to determine the effects of intracerebral inoculation of this virus into new-born hamsters.

The Schmidt-Ruppin strain of virus was prepared by the technique of differential centrifugation[8] from wing's web sarcoma induced in 2–3 weeks old white Leghorn chickens. The virus was suspended in 0·05 M sodium citrate and stored in 0·5-ml. aliquots in sealed ampoules kept at −70°. A pool with a titre of $\log_{10}$ 6·58 plaque-forming units/ml. in chicken chorioallantoic membrane was used throughout the experiments. In order to overcome the toxicity of sodium citrate for the new-born hamster's brain and to further concentrate the virus, 0·5–1 ml. of the virus pool suspension was diluted to 10 ml. with cold phosphate buffer saline, *p*H 7·2 (PBS), and pelletized in a preparative Spinco centrifuge at 30,000*g* for 1 h, a procedure which is known to sediment more than 99·9 per cent of the suspended virus. The pellets were reconstituted in PBS and the titre of the final concentrations used in the inocula are shown in Table 1.

New-born Syrian hamsters (*Cricetus auratus*) were obtained from the Animal Production Unit of the National Institutes of Health, and inoculated when less than 24 h old with 0·02 ml. of viral suspension into the mid-portion of the right cerebral hemisphere.

After a period of time, varying with the titre of the inoculum (Table 1), the animals began to show somnolence and sluggishness followed in a few days by lateral posture of the head and paralysis first of the posterior limbs, then general paralysis leading to death.

At autopsy an increased volume of cerebrospinal fluid was noted in the RSV inoculated hamsters. The brain tissue appeared softer and more friable than normal. Microscopically it showed the presence of multiple, diffuse tumours located within the cerebral hemisphere bilaterally (Fig. 1), with only rare involvement of the meninges.

Table 1. NEW-BORN HAMSTERS INJECTED INTRACEREBRALLY WITH RSV SCHMIDT-RUPPIN STRAIN (POOL *SR* 26) FROM CHICKEN WING'S WEB SARCOMA

Exp. No.	Inoculum titre P.F.U.*/ 0·02 ml.	No. hamsters with neurological symptoms/No. weaned hamsters	Appearance of neurological symptoms (days: average)	Incidence of gliomas No.	%

* Plaques forming units in chicken chorioallantoic membrane.
† Phosphate buffer saline *p*H 7·2 used as diluent.

No extension to the ependymal lining of the ventricles was noted. These tumours consisted of two types of cells: (*a*) large round cells with basophilic cytoplasm and (*b*) bundled fusiform cells interlacing with delicate fibrillar strands. There was no collagen, and very little reticulum. Small amounts of glial fibrils were seen within the tumour. These findings favour a diagnosis of glioma. (We thank Dr. H. L. Stewart, chief of the Laboratory of Pathology of the National Cancer Institute, and Dr. K. Earle, chief of the Neuropathology Section of the Armed Forces Institute of Pathology, for a critical review of the histological sections.)

Further work on the histogenesis of these tumours is in progress. Controls inoculated with the suspending medium (PBS) without virus failed to show evidence of intracranial tumour or noteworthy pathological changes after 3 months of observation. The tumours induced by Schmidt-Ruppin RSV in hamsters differ from those induced in the same species by polyoma virus. The latter resemble human leptomeningeal sarcoma[9] and are mesenchymal type tumours arising from the arachnoid and from the adventitia of the meningeal and cerebral vasculature. They are located at the meningeal surfaces and only at a late stage infiltrate the deeper portions of the cerebrum. In these tumours, collagen and reticulum are easily demonstrated[2].

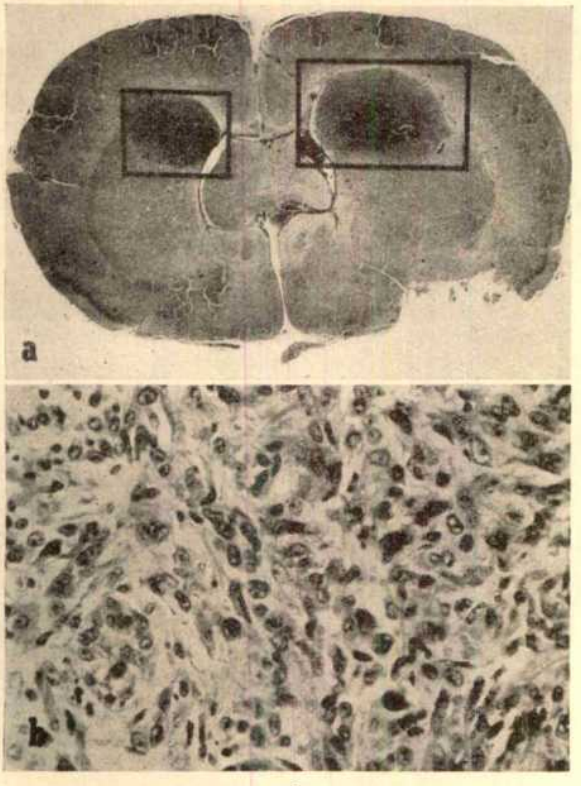

Fig. 1. Brain of hamster inoculated at birth with Schmidt-Ruppin RSV. (*a*) Bilateral tumours (squares) (phosphotungstic acid hæmatoxylin: × *c.* 20); (*b*) area of glioma cells (hæmatoxylin and eosin: × *c.* 390)

Unlike the tumours induced in hamsters with *SV* 40 virus[5], no involvement of the ependyma was found in the RSV-induced tumours. It is also noteworthy that the intracranial tumours induced in hamsters by the Schmidt-Ruppin strain of RSV differ from those induced in the chicken brain by the Bryan's strain of RSV. These latter are myxomatous lesions arising in the pial-arachnoid spaces[10–12].

Both mesenchymal type brain tumours and gliomas have been induced in mice with carcinogenic hydrocarbons[13]. It would appear, therefore, that viral oncogenesis may be more selective in that different types of brain tumours are induced in hamsters by different viruses, namely, leptomeningeal sarcomas with polyoma virus ependymomas with *SV* 40 and gliomas with RSV Schmidt-Ruppin strain.

The implications of these findings may prove of interest in the investigation of pathogenesis of human brain tumours.

Two main points pertaining to the biology of neoplasms induced by RSV in mammals remain to be clarified: (*a*) the incapability of recovering the virus from the tumours induced in mammals by the Schmidt-Ruppin strain; (*b*) the incapability of the Bryan's strain to induce such neoplasms.

RADIOBIOLOGY

Prevention of Plutonium Deposition by Desferrioxamine-B

IN selecting chelating agents to test their ability to remove internally deposited metals, the magnitude of the stability constant of the complex is an obvious criterion. Schubert[1] rightly points out that a more practical guide is the ratio of the stability constant of the chelate, K_{ML}, to that for omnipresent calcium, K_{CaL}. This situation is illustrated in Table 1 for Fe (III) and Ca (II).

Table 1. STABILITY CONSTANTS $K_{ML} = \log_{10} \frac{[ML]}{[M]\,[L]}$

Where M = metal, L = chelating agent (ref. 2)

L	'Common' chemical name of L	K_{FeL}	K_{CaL}	K_{FeL}/K_{CaL}	Ref.
EDTA	Ethylenediaminetetraacetic acid	25·1	10·7	14·4	2
DTPA	Diethylenetriaminepentaacetic acid	28·6	10·1	18·5	2
DFAB	Desferrioxamine B	30·6	2·6	28·0	3

From these results one would predict the efficacy of decorporation of iron to run DFAB > DTPA > EDTA, and this is the case[4]. Similarly, Catsch assigns the superiority of DTPA over EDTA in the removal of certain elements to the greater ratio of the stability constants for DTPA with these elements and calcium[5]. Since DTPA is the

present agent of choice for the removal of certain internally deposited heavy metals, for example, plutonium[6], cerium[7], ruthenium[8], it was of interest to compare the effect of DFAB in this respect. Only the results for decorporation of plutonium will be reported here.

Eight-month-old female Sprague–Dawley rats were intravenously injected with 2·0 μc. $^{239}Pu^{4+}$ in 0·2 ml. of *p*H 5·0 citrate buffer. 1, 5 and 24 h later they were treated with 0·5 m.mol/kg of the agents (total treatment dose, 1·5 m.mol/kg). To prevent tetany, 0·4 m.mol of calcium as calcium gluconate–calcium glucoheptonate (Abbott Laboratories) was mixed with the DTPA just prior to injection. This was unnecessary with the DFAB solution, which was made up just before use and contained 0·1 m.mol of the methane sulphonate salt (CIBA compound No. 33112, 'Desferral') per 0·5 ml. Urine and fæces were collected daily from each group of ten rats. Five days after injection of plutonium the animals were killed and tissues analysed for plutonium by conventional methods.

To obtain homogeneity of group variances, resulting from the large differences between control and treated values, the results were transformed using the arcsine of the square root. The one-way analysis of variance technique was used to analyse the transformed data and Tukey's *T*-method of multiple comparison was used to compare the means.

The statistically summarized results of the non-transformed data are shown in Table 2. Two results of practical importance are apparent: (1) treatment with DFAB decreased bone deposition of plutonium to about one-half the value obtained with DTPA; (2) the two agents given together produced a partially additive effect. This latter observation was not expected, since usually two chelating agents merely compete with one another for the available metal, the sum of their actions being the same as the effect of the stronger agent by itself. The enhanced effect of DFAB is probably due to its different *in vivo* distribution and the consequent tapping of plutonium pools not available to DTPA. This is further suggested by the consistently lower bone deposition and higher fæcal output of plutonium in the DFAB-treated animals.

Table 2. Effects of Treatments on Plutonium Content of Tissues and Excreta Five Days after Administration

Treatment and route of administration	Per cent of ^{239}Pu dose: Liver $\bar{X} \pm S_{\bar{X}}$†	Kidneys $\bar{X} \pm S_{\bar{X}}$†	Femur $\bar{X} \pm S_{\bar{X}}$†	Accumulated excreta*: Urine	Fæces
DFAB, i.p.	1·3 ±0·1	2·1 ±0·2	0·14±0·01	62	20
DTPA, i.p.	0·58±0·07	0·24±0·01	0·28±0·02	67	17
DFAB, i.m.	1·3 ±0·1	1·5 ±0·1	0·16±0·01	66	23
DFAB, i.m. + DTPA, i.p.	0·39±0·04	0·54±0·04	0·13±0·01	73	21
No treatment	20·0 ±1	1·4 ±0·2	3·0 ±0·2	2·5	6·5

* Being pooled results, these data were not statistically analysed.

† Mean ± *S.E.*

Note: all treatments lowered the spleen content 5–7-fold below the control value of 0·35 per cent.

The poor removal of plutonium from the liver and the build-up in the kidneys when DFAB is used alone may be due to lability of the chelating agent[9]. The organic moiety of the Pu-DFAB complex may be destroyed, surrendering its plutonium to the tissue where DTPA, in the combined treatment, can pick it up and complete the removal.

While the measurement of the stability constants of the plutonium chelates of DFAB and DTPA are not yet completed, they are of similar magnitude. On the basis of the likely ratios of the stability constants of the two agents for plutonium and calcium, one would have expected DFAB to show even greater superiority than these results indicate. As this ratio becomes reasonably large, it seems likely that the relative ability of two agents to remove metal is more dependent on such factors as the tissue distribution, relative strength compared to tissue ligands, and stability and excretability of the sequestering complex. Still other factors are no doubt involved, as may be illustrated by the effect of DTPA in removing plutonium from the liver. DTPA is significantly more effective than other polyaminocarboxylic acids of comparable chelating ability and presumably similar distribution[10,11].

In view of its clinical use in the treatment of pathological iron deposition[12], DFAB might well be considered for human use in removal of plutonium. However, the combined use of two chelating agents should be approached with caution, since in our limited experience the DTPA–DFAB combination appeared to be more toxic than either agent alone.

I thank L. C. Gray for his assistance; R. L. Bushbom for the statistical treatment of the data; and Dr. H. Bickel and associates, and CIBA, Ltd., Basle, for donating the DFAB used in these experiments.

This work was carried out under contract *AT*(45–1)–1350 between the Atomic Energy Commission and the General Electric Co.

BIOLOGY

A New Molluscicide 1-(*p*-Nitrophenyl)-2-amidineurea Hydrochloride (*T* 72)

Molluscicide Bayer 73 or 5,2-dichlor-4′-nitrosalicylanilide, better known as 'Bayluscid^R', has been shown to be a potent molluscicide[1]. The chemical similarity of *T* 72 to Bayer 73 (ref. 2) led us to investigate its possible molluscicide property. *T* 72 is known to be active against malaria[3–6] and against several intestinal infestations[7]. It has the following structural formula:

Our experiments were carried out with snails and fish. The snail *Melanopsis costata* (Ferrusac) was obtained from the estuary of the River Jordan; *Melanopsis praemorsa* (Linne) from the Baalbeck stream in Lebanon; *Radix peregra* (Müller) from Lake Yammoune in Lebanon; fish from the River Barada in Damascus.

A total of 135 specimens of *Melanopsis costata* were divided into nine groups and 160 *Melanopsis praemorsa* were divided into eight groups. They were placed in separate solutions of *T* 72 and Bayer 73 for 24 h and afterwards washed in tap water for a further 24 h. In accordance with Kärber's method, the *LC* 50 was estimated 48 h after the start of the experiments, but *Radix peregra* failed to survive in the 0·05 p.p.m. solution. The *LC* 50 values of the other species for *T* 72 and that of the fish for both preparations are shown in Table 1. The

Table 1. Toxic Concentrations of *T* 72 and Bayer 73

Preparation	Animal	Number of animals per group	*LC* 50 in p.p.m.
T 72	*M. costata*	15	22
T 72	*M. praemorsa*	20	17·8
T 72	Fish	11	78·7
Bayer 73	Fish	11	0·33

molluscicide concentrations of Bayer 73 established by us are in agreement with those recorded in the literature[1].

In order to determine whether the molluscicide action of *T* 72 is selective for snails we experimented with fish (88 for *T* 72 and 66 for Bayer 73) and found that they tolerated *T* 72 in molluscicide concentration. This is indicated in Table 1. Extreme motor activity seemed to be the main feature before death of those fish treated with Bayer 73. Concentrations of 0·5 p.p.m. and 0·6 p.p.m. killed the fish in 8 h and 1 h, respectively. Fish treated with *T* 72 remained prostrate but with re-inforced gill movements. A concentration of 90 p.p.m. killed four of the fish in 8 h and the remaining seven in the next 16 h. A concentration of 80 p.p.m. killed seven fish in 24 h. However, fish survived in a 70 p.p.m. solution over a period of 24 h. It should be noted that concentrations of 0·6 p.p.m. and 80 p.p.m. represented twice the *LC* 100 for snails as found in our experiments for Bayer 73 and *T* 72, respectively.

In view of the tolerance of *T* 72 by man and its low toxic effect in the rat under prolonged administration[3,4], water containing *T* 72 in molluscicidal concentration may be safely used for drinking purposes in restricted areas for a limited period. Moreover, *T* 72 can be viewed as a molluscicide belonging to a potentially new group of agents which, unlike Bayer 73, does not contain the salicylanilide structure. This observation does not support the idea that the salicylanilide structure is essential for molluscicide activity[1]. Since halogenation of *T* 72 might give rise to higher activity of the compound, we are proceeding with a study of several halogenated and aromatic derivatives.

We thank Dr. A. Zilch for help in identifying the snail species.

Occurrence and Dispersal of *Verticillium* Conidia in Xylem Sap of the Hop (*Humulus lupulus* L.)

During investigations on the rate of colonization of wilt-sensitive and wilt-tolerant hop varieties by mild and virulent hop isolates of *Verticillium albo-atrum* Reinke and Berthold, conidia were found to be abundant in the xylem vessels of stems, and appeared to play an important part in the migration of the fungus in the hop plant.

The soil of potted plants was inoculated with *Verticillium*-infested hop-stem fragments, and at weekly intervals thereafter the stems of selected plants were cut about 5 cm above soil-level and a specimen tube, held in position by a cotton wool collar, was fixed over the cut end of each stump. The plants were then inverted so that sap expressed by root pressure during the next 4 h collected in the tubes. The number of conidia in the sap was estimated by spreading 0·5 ml. aliquots over the surface of nutrient agar plates and counting the colonies which developed. At the same time, transverse sections were cut from the stem, near the base and at various heights above the soil, and plated on to nutrient agar to isolate the fungus; similar sections were examined microscopically for the presence of hyphæ in the vessels.

Conidia were first detected in expressed sap three weeks after inoculation. The numbers in subsequent samples varied from 0 to 6,870/ml. sap and were unrelated to the time from inoculation. There might be abundant conidia in some aliquots of sap, and none in others, from the same plant. Stem-section isolations and observations showed that: (1) *Verticillium* was invariably present before mycelium could be observed microscopically in the vessels; (2) the fungus often occurred at considerable distances above soil level simultaneously with its first-recorded presence in the stem; (3) the distribution of the fungus was occasionally discontinuous; (4) the rate of spread of the fungus was greatly in excess (about ten times) of the maximum mycelial growth rate *in vivo*. Germinated and ungerminated conidia were observed in stained, centrifuged sap, but rarely in transverse sections of stems.

Estimations of vessel length by Greenidge's method[1] indicated that continuous open vessels extended three-quarters of the length of 4-week-old stems (that is, about 150 cm), and that by early summer open vessels were present virtually throughout the length of field-grown bines. Conidia injected directly into the xylem by a cone-frustrum method[2] or with a hypodermic needle were not, however, immediately transported throughout the stem. After 24 h *V. albo-atrum* was isolated only 20 cm above the injection point at about 100–150 cm, 7 days later, and after 2 weeks fungus was generally present in all parts of the stem except the finer extremities and leaf petioles. Colonization of the latter was slow and there was evidence that this might be associated with the absence of continuous open-vessel systems comparable to those in the stem.

The rapid dispersal of *V. albo-atrum* in the hop plant thus seems to be due to the transport of conidia in xylem sap; this movement is occasionally arrested and then followed by conidial germination and renewed sporulation. The dispersal system probably resembles that described for *Fusarium oxysporum* f. *cubense* in banana[3–6], although gel vascular occlusions may not occur in hop[7,8].

The marked time difference observed between wilting of hop plants after root inoculation and the rapid dispersal of the pathogen within mature xylem vessels is thought to reflect the time taken by the pathogen to colonize, by slow mycelial growth, the extravascular tissues of the root and also the closed xylem systems of the root tip[9] and leaf petiole.

Direct injection has demonstrated that the stems of wilt-tolerant hop varieties are slightly more resistant than those of wilt-sensitive ones and that virulent strains of *V. albo-atrum* are slightly more pathogenic to hop stems than mild ones, but these differences are insufficient to account for the contrast in behaviour of these hosts and pathogens following natural root infection. The root thus appears to be a determinative factor in the hop-wilt syndrome, as has previously been suggested by investigations of intervarietal graft-complexes of hop[10].

We thank Dr. A. G. P. Brown for his co-operation during part of this work.

Asparagopsis in Europe

The spread of *Asparagopsis* in Europe has rightly attracted considerable attention, but the excitement with which each new record has been greeted has tended to obscure certain unanswered questions regarding two species at present accepted, *A. armata* Harv. and *A. taxiformis* (Delile) Trev.

Montagne[1] based the original treatment of the genus on *Fucus taxiformis* Delile[2], although changing the epithet to the illegitimate *delilei*; the combination *Asparagopsis taxiformis*, usually credited to Collins and Hervey[3], was, in fact, used by Trevisan[4] and afterwards overlooked. *A. taxiformis* has been reported widely from the tropical waters of the Pacific, Indian and Atlantic Oceans, the most northerly records in the latter being from Bermuda, the Canary Islands, and possibly the Azores[5], although the latter report has been questioned[6]. *A. taxiformis* has also been reported from the Mediterranean, where it is said to be restricted to the eastern region. Apart from some observations by Schiffner[7], which have been disputed, there appears to be only one record, from Algeria, of the occurrence of *A. taxiformis* as such in the western Mediterranean, and that is based on a drift specimen thought to have originated in the eastern region[8]. However, it should be noted that the type locality for *Falkenbergia hillebrandii*, the alternate phase in the life-history of *Asparagopsis taxiformis*, is the Island of Elba, and there are other early reports[9] of the occurrence of this entity in the western Mediterranean. *Asparagopsis armata* was first described from Australia during the last century and specimens referred to this species were first identified in Europe some forty years ago. Further reports of its occurrence in various localities in north-west Europe and North Africa have been made over the years, but there is still a marked disjunction in tropical waters between the European and Australian areas of distribution.

The first question to be answered concerns the relationship between *A. armata* and *A. taxiformis*. From the literature[6,10] it would appear that the only difference between the two algae is the occurrence of branches bearing spines in the former. The type material of *A. armata* is now preserved in the herbarium of Trinity College, Dublin, and, although the present location of Delile's type specimens is unknown[11], part at least of Delile's original collection of *A. taxiformis* has been found in the Lamouroux Herbarium during a visit to the Institut Botanique, Caen. Examination of these type materials and of other collections confirms that the presence or absence of spine-bearing branches is the only criterion by which the two entities can be distinguished. *A. taxiformis* and *A. armata* have been accepted as distinct species by all authors except Schiffner[7], who considered them merely as growth forms of a single species.

Schiffner's observations have been ignored or dismissed as the erroneous interpretation of badly prepared specimens[10], but some recent personal observations indicate that further investigation of the production of spine-bearing branches in this genus is necessary. During the past few years, several specimens of *Asparagopsis* in which the spine-bearing branches characteristic of *A. armata* were very reduced in size and number have been collected at various localities on the south and west coasts of Britain and Ireland, while in a single collection from the Isles of Scilly no trace of the spine-bearing branches could be found so that the fronds were otherwise indistinguishable from those referred to *A. taxiformis*. In connexion with this problem, it should be noted also that there are no apparent morphological differences between *Falkenbergia rufolanosa* and *F. hillebrandii*, the alternate phases in the life-histories of *A. armata* and *A. taxiformis* respectively.

The second question relates to the origin of the European material referred to *A. armata*. It has been accepted universally that the European material was initially of Australian origin but, in view of the doubts as to the relationship between *A. taxiformis* and *A. armata*, a reconsideration of the origin of the European material is warranted. Whether this can now be undertaken depends very largely on the extent to which the taxonomic problem can be elucidated.

The third question concerns the life-history of the entity in the British Isles. Tetrasporangia have never been detected in the *Falkenbergia* phase in Britain or Ireland, while plants of the *Asparagopsis* phase with carpospores appear to be diminishing in frequency[12]. The barbed branches of the *Asparagopsis* phase facilitate vegetative propagation and the floating 'balls' of the *Falkenbergia* phase, which occur so abundantly on occasions in British waters, have been observed to re-attach with ease[13]. The new attachment is relatively weak and the 'ball' is readily detached so that it may well be moved on many times during its life. These observations suggest that independent propagation of both the *Asparagopsis* and *Falkenbergia* phases is occurring and that the actual life-history of the entity in British waters may not be the functional sequence of sexual, carposporic and tetrasporic phases demonstrated in other areas[14]. It is probable that this independent vegetative propagation is a likely explanation for the small differences in geographical distribution of the two phases which have become increasingly marked during recent years and which have been attributed by various authors[15,16] to differences in ecological requirements.

These three questions demonstrate the deficiencies in our knowledge of *Asparagopsis*, which is by no means as complete as is often assumed. By directing attention to the crucial problem of the relationship between *A. taxiformis* and *A. armata* it is hoped that further investigations will provide the answers to this, and the related problems. In this connexion, reports of the occurrence of spineless specimens of *Asparagopsis* in Britain will be particularly valuable.

Mechanism for Nitrogen-increased Shoot/Root Ratios

Aberg's review[1] cites Söding (*Die Wuchstofflehre*, Georg Thieme Verlag, Stuttgart, Germany, 1952) as suggesting that the generally recognized increased shoot/root ratios resulting from nitrogen fertilization are caused by nitrogen-increased growth hormone content which, in turn, inhibits root growth and promotes shoot growth in the intact plant. This suggestion appears reasonable and was supported by Bosemark[2], who compared the growth of roots in high nitrogen solution with that of roots growing in solutions containing growth hormones.

Strong experimental support for this hypothesis was obtained from two experiments conducted in this Labora-

tory to evaluate the influence of nitrogen and phosphorus fertilization on the extractable growth hormone content of soy-bean roots (*Glycine max* L.).

The first experiment consisted of the addition of minus phosphorus, minus nitrogen, minus nitrogen and phosphorus, and complete Hoagland's solution 2 to autoclaved, calcareous sand at regular intervals. Total plants were gathered at 11, 16 and 21 days after seedling emergence. The second investigation involved a factorial of three levels of nitrogen and three levels of phosphorus mixed throughout similar autoclaved calcareous sand. A tenth treatment consisting of twice the highest level of nitrogen and phosphorus in the factorial was also included. All other essential plant nutrients were supplied in optimum amounts. These plants were gathered 24 days after emergence.

The soybean roots were not nodulated. Root systems were not washed, and the loosely adhering sand particles were shaken free before the determination of fresh weight. The plant tissues were frozen immediately and stored at −29° C until extraction. Total roots per treatment (entire root system) were macerated with a mortar and pestle, and extracted with absolute methanol for 48–50 h at −12° C. The macerated roots and extract were washed and filtered under suction at room temperatures 22°–24° C. Filtered extracts were reduced in volume by vacuum evaporation at temperatures of less than 40° C. Aliquots of this extract were chromatogrammed by the descending technique using an isopropyl alcohol–water mixture (8 : 2) as the solvent. The developed chromatogram was air-dried and divided into 10 equal strips numbered from one to ten starting at the origin. Each strip was subjected to the oat coleoptile straight-growth test to evaluate its growth activity. Concurrent with the bioassays, longitudinal strips of the same chromatogram, or small aliquots of the extract under study, were applied to separate chromatograms and developed. These chromatograms were sprayed with a 2 per cent solution of *p*-dimethylaminobenzaldehyde in 1·2 N hydrochloric acid (Ehrlich reagent). Colour reactions with this reagent were used to attempt identification of substances in those strips of the chromatogram showing growth activity in the bioassay.

Growth activity in the bioassays was confined to chromatogram strip numbers 3, 4 and 5. Planimeter measurements of the area of Ehrlich-positive spots in strips 3, 4 and 5 were recorded as quantitative estimates of the relative amounts of growth-promoting substances on the chromatogram (R_F region of about 0·25–0·55 by colour reaction).

Tryptophan and an unidentified substance were found to be associated with the growth promotion in the oat coleoptile straight-growth test. Indolyl-3-acetic acid was not found in any of the root extracts. The unknown substance gave a yellow colour reaction with Ehrlich reagent, and occurred at slightly higher R_Fs than tryptophan on the chromatogram. It appeared to be differentially produced by soybean roots at higher nitrogen-levels in the root medium. This was supported by consistently greater growth activity in the bioassay at higher R_Fs on chromatograms of nitrogen-fertilized root extracts[3]. The regression equations and correlations reported are based on area measurements of chromatogrammed 100λ aliquots of the extract of the total root system per treatment. This area was divided by the total root weight to provide an estimate of the concentration of indicated growth hormone per gram fresh weight of root.

Fig. 1 shows the statistically significant inverse relationship between Ehrlich area (indicated growth hormone) per gram of root and the fresh weight of roots produced at each of the three harvests (exp. 1). The trend toward decreasing amounts of indicated growth substances per gram of root with increasing age was reduced by nitrogen fertilization[3].

The positive correlation between shoot–root ratios and the amount of indicated growth substances, where the

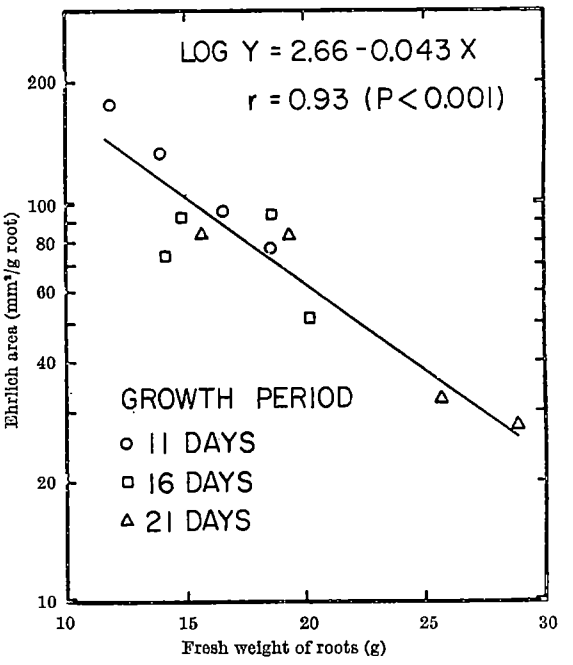

Fig. 1. An inverse relationship is found between the fresh weight of the roots and the logarithm of the Ehrlich area per gram of roots extracted

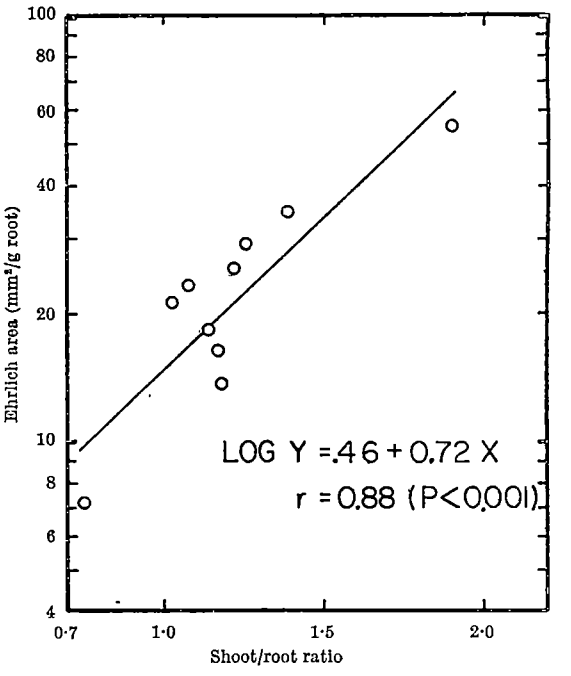

Fig. 2. The logarithm of the Ehrlich area increases with an increase in the shoot/root ratio of plants of the same chronological age. (Exp. 2)

roots were all the same chronological age, is illustrated in Fig. 2. The Ehrlich-positive area in chromatogram strips 3, 4 and 5 was also proportional to the level of nitrogen in the root medium as were the shoot/root ratios. The average Ehrlich-positive area per gram fresh weight of roots was 16 mm², 30 mm² and 55 mm² at the one, four and eight levels of nitrogen, respectively, while the average shoot–root ratios were 1·16, 1·32 and 1·90 at the one, four and eight levels of nitrogen, respectively.

Phosphorus had no consistent effect on shoot/root ratios, or indicated growth hormone content above deficiency levels[3].

A correlation coefficient of −0·72 ($P < 0·05$) between Ehrlich area per gram of root and total fresh weight of

roots per treatment was also obtained from the data of the second experiment. The regression equation for this experiment was log $Y = 1{\cdot}87 - 0{\cdot}013\,X$, where Y equals predicted mm² Ehrlich area per gram of root, and X equals the fresh weight of the roots (g).

The positive correlation between shoot/root ratios and indicated growth substance content, and negative correlation between indicated growth substance content and root growth (fresh weight), was considered to be direct evidence in support of Söding's suggestion that high levels of endogenous hormones in roots may inhibit root growth. The average root lengths in Exp. 2 were 51, 42 and 34 for the one, four and eight levels of nitrogen, respectively: thereby showing general agreement with Bosemark[2] that root length also was reduced by higher levels of nitrogen fertilization.

Determination of Cell Numbers in Dried Leaf Material

The method of maceration in chromic acid followed by counting, using a hæmocytometer, has been widely used in the estimation of cell numbers in fresh leaf material[1–3]. A new method has been developed by means of which cell numbers can be estimated for leaf material which has been oven-dried. The method has the following advantages: direct estimates of cell number can be obtained using dried material from growth-analysis investigations without the necessity of providing separate plants for sampling; this may be especially advantageous for work in glasshouse or constant environment rooms where space is often limited, average cell dry-weight is obtainable directly without the use of a separate sample, and dried material can be stored indefinitely without deterioration and macerated when opportunity arises. The procedure using dried material takes somewhat longer and the estimate of cell number obtained is sometimes slightly lower than that using comparable fresh leaves.

The method has been applied to leaves and leaf disks of French bean and *Canna edulis*, which have been oven-dried at 80° for 24 h and then weighed and stored. The first treatment consists of soaking the dried material in 50 per cent ethanol for 16–24 h. The alcohol is then drained off and the material soaked for a further 6–12 h in two changes of distilled water. The leaves or disks are then carefully blotted to remove the surface liquid and macerated overnight for 14 h in 5 per cent chromic acid (2 ml. per cm² was found to be sufficient for the materials investigated). The cells are then separated by tapping with a glass rod and the resulting suspension is passed rapidly through a fine pipette, made up to a suitable volume and counted using a hæmocytometer. Results comparing this method with that for fresh material are given in Table 1.

The new method gave estimates that were 1–17 per cent lower than the conventional method. As part of this difference could be due to genuine differences between similar leaves, a further comparison was made using disks punched from the same leaves and macerated either fresh or after drying. Here the number of cells per disk ($\times 10^{-6}$) was $2{\cdot}046 \pm 0{\cdot}175$ for fresh material and $1{\cdot}876 \pm 0{\cdot}138$ for dried disks. This difference of 9 per cent was statistically significant ($t = 2{\cdot}86$, $n = 22$). However, a lower value is not always obtained. A comparison for disks taken for the same leaves of *Canna edulis* gave the following values of cell number ($\times 10^{-6}$): for fresh disks $3{\cdot}962 \pm 0{\cdot}580$, and for dried disks $4{\cdot}008 \pm 0{\cdot}424$, the difference not being significant.

Table 1. Comparison of Cell Numbers in the First Pair of Leaves of French Bean Plants, One Leaf macerated after Drying, the other macerated Fresh

Plant	'Fresh' estimate ($\times 10^{-6}$)	'Dried' estimate ($\times 10^{-6}$)	Difference (%)
1	30·28	28·36	6·8
2	36·11	35·61	1·4
3	43·57	40·33	8·0
4	45·32	39·28	15·4
5	52·76	47·86	10·2
6	23·99	20·47	17·2
7	26·02	24·09	8·0

Where differences occur in the values obtained using the two methods it seems likely that they originate in the drastic disruption of the cell wall during the drying process, with the result that a certain number of cells are 'lost' since broken cells are not counted. In the case of *Canna*, disintegration does not appear to occur at all extensively, so that maceration after drying gives an accurate assessment of cell number. The differences can probably be disregarded for most purposes since variation in cell number in comparable leaves can be of the order of 15–25 per cent.

ENTOMOLOGY

Spinning Apparatus of the Caterpillar of *Leucinodes orbonalis*

The spinning apparatus which has so far been investigated in Noctuidae, Saturnidae and Sphingidae becomes more specialized in the case of *Leucinodes orbonalis* (Pyralidae) with respect to its musculature and the structure of the silk press.

The silk glands are elongated tubular structures occupying a great part of the body cavity and lying below the alimentary canal. The accessory acinous glands described in noctuid and saturnid caterpillars[1] are absent in *Leucinodes orbonalis*. The ducts of these glands open at the base of the silk press, which has muscular walls and is completely enclosed within the hypopharyngeal-premental lobe. The hypopharynx is completely united with

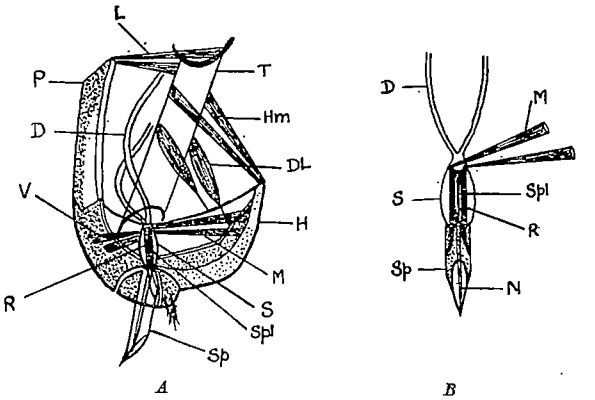

Fig. 1. *A*, Lateral view of the hypopharyngeal-premental lobe of *Leucinodes orbonalis*. *B*, Dorsal view of the silk press. *D*, duct of silk gland; *DL*, dorsal labial muscles; *H*, hypopharynx; *Hm*, hypopharyngeal muscles; *L*, ventral labial muscles; *M*, muscles of the sclerotic plate; *N*, terminal duct; *P*, prementum; *R*, sclerotic bar; *S*, silk press; *Sp*, spinneret; *Spl*, sclerotic plate; *T*, tentorial arm

the prementum, as has been reported in other silk-producing caterpillars[2], but the morphology of the spinneret indicates that it is a component part of the prementum. In the caterpillars of Noctuidae[3], Saturnidae and Sphingidae[4] the dorsal wall of the silk press is invaginated into the lumen and it contains a median sclerotic bar over which two or three pairs of dilator muscles are inserted. Histological investigations of the spinning apparatus of the caterpillar of *L. orbonalis* indicate that the dorsal wall of the press is not at all invaginated and the muscular layer is thicker. The dorsal wall is covered by a thin sclerotic plate formed by the fusion of two sclerotic bars which originate from within the side walls of the spinneret. This sclerotic plate remains opposed to the dorsal wall of the press and is operated by a pair of muscles which take origin from the hypopharyngeal-premental lobe and are inserted on the distal ends of the sclerotic plate. The sclerotic plate is thus movable and quite separate from the wall of the press. The contraction of the muscles withdraws the plate and the pressure so far exerted by it is released, resulting in the extension of the lumen of the press. At the same time the change in the position of the sclerotic plate makes the two bars straighten the spinneret slightly anteriorly, causing a temporary break in the flow of the fluid silk through the terminal duct of the silk press, which opens on the tip of the spinneret. A second pair of ventral muscles, which constitute the dilator of the lumen of the press, arises from the premental part of the hypopharyngeal-premental lobe and insert on the ventral wall of the press.

Up-and-down movements of the hypopharyngeal-premental lobe are brought about by three pairs of muscles. The hypopharyngeal muscles, which are the elevators, take origin from the upper region of the tentorial arms, and are inserted at the base of the hypopharyngeal part of the lobe. Their action is co-ordinated by the dorsal labial muscles, which arise from the middle of the tentorial arms and are inserted on the dorso-lateral margins of the premental part of the lobe. The ventral labial muscles are inserted at the base of the premental portion and originate from the region of the tentorial arms where they join the internal ridge of the frons and act as depressors. The sideways movement of the hypopharyngeal-premental lobe is effected by the elaborate arrangement of muscles of the head and prothorax.

Role of Insects as Vectors of Red Ring Disease

SEVERAL insect species associated with the coconut palm have been suggested as be vectors of red ring disease (Table 1).

Table 1

Order	Family	Species	References
Coleoptera	Curculionidae	*Rhynchophorus palmarum* (L).	1-8, 10-12
		Rhina barbirostris L.	3,6,7,11
		Homalinotus coriaceus Gyll.	3,6,7
	Scolytidae	*Xyleborus* sp.	11
Hymenoptera	Formicidae	(?)	2,11
Isoptera	Rhinotermitidae	*Coptotermes niger* Snyder	13
	Termitidae	*Nasutitermes ephratae* Holmg.	13

Cobb[4], Martyn[10], Fenwick[5], and Hagley[8] have stated that the causal organism, *Rhadinaphelenchus cocophilus* (Cobb), was recovered from the body surfaces of adult palm weevils, *R. palmarum*, and Hagley[9] has discussed the importance of these insects as vectors of the disease.

In recent studies conducted in the eastern and north-eastern regions of Trinidad adults of several other species collected from 188 diseased palms between 2 yr. and 7 yr. of age were examined by the methods previously described for *R. palmarum*[9]. *R. cocophilus* was recovered from four species of Coleoptera (Table 2).

Metamasius hemipterus, observed on 56·5 per cent of the palms examined, was most frequently taken under the external fibres surrounding the internodal stem region and in the upper leaf axils of the palm. At these sites the insects were normally not exposed to direct contact with diseased tissue. Although some individuals were recovered in the tunnels excavated by larvæ of *R. palmarum* in the internal diseased stem tissues, only 2·8 per cent of the total number examined were carrying nematodes.

R. barbirostris which was observed in localized areas was present on 10·7 per cent of the palms examined. The preferred sites of the insects were in the axils of the lower and older petioles and at the base of the stem. Adults were not observed in the internal stem tissues. Nematodes recovered from a single individual were all dead.

The histerid, *Hololepta* sp., was taken most frequently in palms showing severe palm weevil infestation. The tissues of these palms were in an advanced state of decay and 80 per cent of those examined did not contain living nematodes. The insect was recovered from 53·5 per cent of the palms examined and the nematodes recovered from six individuals were all dead.

Nematodes were also recovered from one individual of the dynastid, *Hemiphileurus* sp., which was found in the lower leaf axils of only four palms.

The small numbers of those insects which carried *R. cocophilus*, and the relatively low frequency with which

GENETICS

Genetic Variation of Alcohol Dehydrogenase in *Drosophila melanogaster*

A growing number of biochemical variations are at present being described in many organisms. When variations in proteins can be demonstrated to be under genetic control the interest and importance they hold are, to some degree, based on the background of genetic knowledge in the experimental organism. *Drosophila melanogaster* has recently provided knowledge of several inherited biochemical variations. The protein variations of Pantelouris and Duke[1] and the variations in the esterases[2,3], alkaline phosphatase[4,5], leucine aminopeptidase[6,7] and glucose-6-phosphate dehydrogenase[8] are among the latest to be discovered.

The basis for the observation of these variations is differential mobility, which is exhibited when different molecular forms of protein are subjected to the sieving action of starch-gel electrophoresis[9]. The method separates proteins according to both molecular size and charge; slight variations in either can be detected in the starch gel by a change in mobility. Quite often such variations can be demonstrated to be under genetic control. After electrophoresis various staining techniques[10,11] are used to localize enzyme activity in the gel.

When genetic electrophoretic differences are discovered between *Drosophila* individuals it is most common to find both parental proteins in the hybrids. In one case, however, in addition to the parental protein bands, a third band of intermediate mobility was found. The third or hybrid zone was found in the larval alkaline phosphatase enzyme[4,5] and represented one of the first hybrid enzyme molecules to be found in *Drosophila*. This communication reports the finding of a second hybrid molecule in the enzyme alcohol dehydrogenase.

Starch-gel electrophoresis was carried out using the discontinuous system of buffers by Poulik[12]. Single *Drosophila* individuals (larvæ, pupæ or adults) were homogenized separately in a small drop of distilled water. The resulting liquid was absorbed into a 4 mm × 6 mm piece of filter paper and inserted into a vertical slot in the starch gel. The samples were electrophoresed for about 2 h at a voltage gradient of 6–8 V/cm at room temperature. After electrophoresis the gels were sliced horizontally and stained for alcohol dehydrogenase activity in the following solution: 100 ml. *tris*hydroxymethylaminomethane-hydrochloride buffer, *p*H 8·5, 0·1 M 5 ml. 95 per cent ethyl alcohol; 25 mg diphosphopyridine nucleotide; 25 mg *p*-nitroblue tetrazolium; 7 drops 0·5 per cent methylene blue. Staining was complete in about 4 h and the gel was preserved in a water–methanol–acetic acid (5 : 5 : 1) solution. The *Drosophila* stocks used in this investigation were maintained on standard yeast corn-meal molasses culture medium.

Most of the *Drosophila* laboratory cultures which have been examined for alcohol dehydrogenase show a deeply staining (fast) band approximately midway between the start and the slow larval alkaline phosphatase variant. A second band, much fainter in staining intensity, migrates at nearly twice the rate of the main strong band. However, in one stock, Canton-*S*, the strong fast alcohol dehydrogenase was absent from the usual position and had instead a band (slow) migrating in the opposite direction, toward the cathode. A faint band was also present in this strain which coincides with the position of the fast strong alcohol dehydrogenase band (Fig. 1). All developmental stages, larvæ through adults, show the same alcohol dehydrogenase zones.

Alcohol dehydrogenase-slow flies of the Canton-*S* strain were mated with alcohol dehydrogenase-fast flies from some of the other stocks. The resulting hybrids possessed the parental alcohol dehydrogenase bands and, in addition, zones of intermediate mobility. Not only was there an intermediate or hybrid zone between the strong alcohol dehydrogenase zones but also between the faint bands (Figs. 1 and 2). A tentative explanation which appears satisfactory at the present preliminary stages is that the fast strong alcohol dehydrogenase band present in most stocks is due to homozygosity for one allele at an autosomal locus and that the slow alcohol dehydrogenase band is due to an alternative allele. The hybrid substance is probably the result of combination of unlike molecular sub-units in the heterozygote. Similar reasoning follows for the faint alcohol dehydrogenase bands. Whether or not it represents an independent system has not been determined.

The presence of sub-units in alcohol dehydrogenase has been indicated from other investigations. Alcohol dehydrogenase from yeast has been found to have a molecular weight of 151,000 and to contain four zinc atoms and bind four molecules DPN per molecule of enzyme. Liver alcohol dehydrogenase has two zinc atoms and binds two molecules of DPN with a molecular weight of 84,000. Treatment of the enzymes with zinc-complexing agents removes the zinc atoms and causes inactivation and dissociation into sub-units (cf. Malcolm and Webb[13]) of molecular weight 36,000.

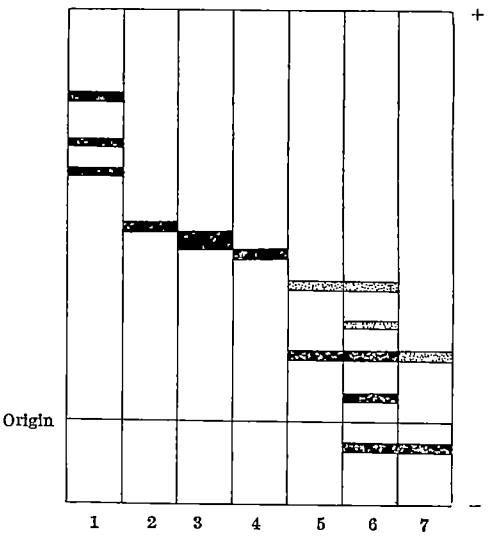

Fig. 1. Schematic comparison of protein patterns of larval alkaline phosphatase and alcohol dehydrogenase in starch-gel electrophoresis of single *Drosophila*. Sample 1 indicates the three main protein bands, samples 2–3 show the fast, heterozygous and slow alkaline phosphatase patterns and samples 5–7 show the fast, heterozygous and slow alcohol dehydrogenase patterns. The faint alcohol dehydrogenase bands are stippled

Fig. 2. Photograph of starch gel showing fast (*FF*), heterozygous (*FS*), and slow (*SS*) alcohol dehydrogenase

Although methanol will not serve as substrate, several other alcohols can be substituted for ethanol in the staining solution. Isopropanol is at least equally effective as a substrate as ethanol. Other alcohols produce less dense patterns.

Mixture experiments with fast and slow variants homogenized together failed to produce the hybrid band. A similar finding resulted from an identical experiment with fast and slow alkaline phosphatases[4,5].

Hæmoglobin *H* Disease in Thailand: a Genetical Study

IN Thailand in 1952 Virginia Minnich and her colleagues first discovered inclusion bodies in the red cells of patients with thalassæmia-like syndrome[1]. This disease became known here as inclusion-body anæmia, but was later identified as thalassæmia-Hgb *H* disease, first reported by Rigas *et al.*[2]. Its genetical peculiarity was immediately recognized. In the majority of cases the abnormal pigment is not detected in either parent, or in the progeny. Thalassæmia stigmata are always present in one of the parents and in the patients themselves, and in some of the sibs and progeny. The associated thalassæmia is of the normal Hgb A_2 or alpha type.

Because of its horizontal distribution, it was suggested that the gene for Hgb *H* was recessive. Motulsky[3] in 1956 proposed that the apparently normal parent might harbour an *H* gene which could manifest only when present together with thalassæmia. In 1959 Jones *et al.*[4] identified the chemical nature of Hgb *H* as β_4. It was then suggested that there might be imbalances in the α-chain synthesis, leading to accumulation of the β chains which then polymerized to form β_4 or *H*. In the same year Ingram and Stretton[5] suggested that Hgb *H* may be formed in one of the following two ways: either, two mild α-thalassæmia occur together resulting in a reduction of the α-chain synthesis and polymerization of the excessive β chains, or, alternatively, there is a silent β-chain mutation causing excessive production of the β chains which, when present together with the α-thalassæmia gene, polymerize. The second hypothesis was favoured by Ingram and Stretton. Later it was found that in the patients with Hgb *H*, Hgbs γ_4 and δ_4 are also present[6–8]. It therefore appears more likely that reduction in the α-chain synthesis is solely responsible for the development of all three abnormal pigments.

In 1961 Koler and Rigas[9] carefully analysed the genetical data available up to then. They could find eleven sibships with one *H* parent, five of these sibships including one or more children with hæmoglobin *H*. Among 23 children of the *H* patients seven had hæmoglobin *H*. They argued against *H* being due to homozygosity of an α-thalassæmia locus. They explored the many possibilities, including a single mutation at the α locus, the β^H mutation with an α-thalassæmia gene, and the existence of an α-thalassæmia allele producing no demonstrable abnormality when present alone. They decided that evidence was not yet available to choose among these hypotheses.

In Thailand Hgb *H* disease is prevalent, over 140 cases having been investigated by us. The clinical and hæmatological data were recently presented at the Asian and Pacific Congress on Hæmatology in Jerusalem[10]. We have studied over 350 members of 42 unrelated families with this disease. The results are summarized in Tables 1–4.

With regard to the presence of α-thalassæmia gene, Hgb *E* trait (*A*+*E*) and α-thalassæmia-Hgb *E* will be treated as equivalent to normal and α-thalassæmia trait,

Table 1. PARENTS OF Hgb *H* PATIENTS

Normal	23	26	
A+*E*	3		
α-thalassæmia trait	32	35	0·2 > P > 0·1
α-thalassæmia-Hgb *E*	3

Hgb *H*	7	(in 4 sibships)
Total	62	

respectively. The recognition of the α-thalassæmia trait was based on the findings of the abnormal RBC morphology, decreased osmotic fragility, with normal serum iron and normal Hgb A_2 level. While it is fully realized that these criteria are not conclusive, up to now they are the only available ones.

The ratio of *H* individuals among sibs, after correcting for truncate selection, fits well with 1/4 (*a priori* expectation is 66·742 versus the observed 69). This, together with the frequent absence of Hgb *H* in the other generations, suggests that a single gene mutation is not the cause of *H* and indicates double-gene origin of the abnormal pigment, one from each parent.

Of the two abnormal genes harboured by the *H* person, one is generally accepted as an α-thalassæmia. There is much evidence against the idea that homozygosity of the α-thalassæmia locus is the cause of *H*—the persistent absence of thalassæmia stigmata in one of the parents, the lack of this disease among Negroes in spite of the prevalence of α-thalassæmia gene in this race[11,12], and the existence of a prototype for homozygosity at this locus, the hydrops fœtalis with Hgb Bart's[13,14]. Furthermore, if it were due to homozygosity of the α-thalassæmia locus, parent–child transmission might happen only when the *H* person married an individual with α-thalassæmia trait or with Hgb *H*. We have observed parent–child transmissions four times out of nineteen. This would mean that the frequency of α-thalassæmia trait in the population was 4/19 or 0·21. From this the frequency for Hgb *H* persons is expected to be approximately 0·011, which is much too high.

For convenience, let the *H* gene be taken to be the abnormal allele which the *H* person derives from the apparently normal parent. The *H* gene and the α-thalassæmia gene could be independent or allelic or linked.

With regard to them being independent, parent–child transmission must be very frequent and at least 1/4 of the offspring of *H* persons will have Hgb *H*. The observed 7 *H* out of 62 progeny is significantly less than 1/4 ($P < 0·02$). It would therefore appear that the *H* gene is either allelic or linked to the α-thalassæmia locus.

If the two genes are allelic, the *H* individual will never produce *H* progeny, unless he marries a person with an α-thalassæmia trait or with an *H* trait. That would mean that the combined incidence of α-thalassæmia trait and *H* trait is 4/19 or 0·21. The frequency of α-thalassæmia obtained from our survey here is 0·03. Therefore, that of *H* trait would be 0·18. From these an approximate expectation of the frequency of *H* persons is 0·00135. We do not yet know the incidence of *H* obtained directly from a survey investigation, because all our investigations were such that the patients were most likely not included. However, the incidence of *H* in the population is indirectly estimated. The patients with thalassæmia-Hgb *E* disease and those with Hgb *H* disease come to our attention for similar reasons. Lately, after a routine examination for RBC inclusion bodies and hæmoglobin electrophoresis on cellulose acetate strips, which is highly sensitive in detecting Hgb *H*, having been adopted, the number of patients with each of these diseases is similar. The gene frequency[15] for Hgb *E* is 0·069 and the frequency of β-thalassæmia trait from our unpublished study is 0·035. From these the expected frequency of thalassæmia-Hgb *E* is calculated to be 0·0012, which, as mentioned above, is also taken to be the approximate frequency of Hgb *H* disease. Mating between two *H* trait persons, which is frequent (0·0324), most likely does not result in offspring with the disease.

At present it is not possible to differentiate between allelomorphism and close linkage between the *H* and the α-thalassæmia genes.

In the offspring of *H*, if the *H* trait is not manifest, a phenotypic ratio of 1 normal : 1 α-thalassæmia trait is expected. But the ratio of 16 : 38 was observed. In the sibs of *H* the expected ratio is 2 normal : 1 α-thalassæmia trait, but 40 : 45 was observed. It would therefore appear that approximately half the *H* traits in the progeny and sibs of *H* persons do have hæmatological characteristics similar to the α-thalassæmia trait. Furthermore, it would appear that the manifestation of the *H* trait decreases with age.

In conclusion, the *H* gene, which is either allelic or closely linked to the α-thalassæmia locus and which, in the heterozygote state, appears to have, at least at younger ages, similar hæmatological findings to the α-thalassæmia trait, might well be another and milder form of α-thalassæmia.

Finally in view of the findings of Hgb *H* in the individual harbouring genes for α-thalassæmia and Hgb *Q*, which is an α-chain defect[16], in cases of leukæmia[17], in α-thalassæmia trait[12], heterogeneity of the genetic mechanism of its development is obvious, but all stem from various degrees of reduction of the α-chain synthesis.

PSYCHOLOGY

Arousal and Childhood Autism

The clinical features of the syndrome 'early infantile autism' were described by Kanner first in 1943 (ref. 1) and more recently in 1958 (ref. 2). The cardinal symptoms of this syndrome are: (*a*) an inability to form social relationships; (*b*) an 'obsessive insistence on the preservation of sameness'. The latter feature often has the corollary that catastrophic reactions are provoked by the introduction of novelty or the change of an established routine. A catastrophic reaction closely resembles infantile rage, consisting of screaming, weeping, threshing movements of arms and legs and sometimes self-directed aggression such as biting the limbs.

Investigation of a substantial number of children with Kanner's syndrome including systematic observation of their free-field activities has suggested a neurophysiological hypothesis to account for some aspects of their behaviour. The hypothesis is that in these children the non-specific activity of the reticular system is sustained at a chronically high and relatively inflexible level, or in other words, they are in a chronically high state of arousal.

This formulation would account for several features of their disorder.

(1) The resting electroencephalograms (EEGs) of these children are predominantly of two types: (i) records of very low voltage (< 25 μV) irregular activity irrespective of whether the eyes are open or closed, that is, 'flat' or 'desynchronized' EEGs; (ii) α-dominated records with eyes closed, similar to those found in adults, and flat EEGs with eyes open. Records which are consistently desynchronized or of higher frequency than is usually found in children of this age (2–6 years) may be evidence of an unusually high level of electrocortical activation or arousal in the waking state. Sleeping EEGs are generally within normal limits for the age-group.

(2) Two main characteristics of the syndrome are behavioural withdrawal and the continued performance of stereotyped behaviours such as rocking, grimacing, idiosyncratic hand movements. Investigations with animals have shown that both these behaviours are associated with states of high arousal[3,4].

(3) In a recent investigation[5], detailed observations were made on six children, aged 3–6 years, diagnosed as suffering from this syndrome. The waking EEG records made in the laboratory showed desynchronized activity. None of the children had neurological signs or a history of cerebral insult. Observations were made in a situation which, in other children, usually elicited exploratory behaviour[6]. These autistic children, however, showed marked stereotyped movements and very little exploratory behaviour. In fact, stereotypy was their predominant activity. It was found that stereotypy increased with increasing complexity of the environment and was least in evidence when the child was by himself in an unfurnished waiting-room. If stereotypy is a function of level of arousal then increased sensory bombardment (arising from increasing complexity) would result in more stereotyped behaviour. Conversely, this behaviour would be least likely when there was relative sensory deprivation. In fact we found that these children were least 'psychotic' in the empty room. (Adult schizophrenics have also been found to show less disturbed behaviour under conditions of sensory deprivation[7].) In these children stereotypies may be a device to prevent level of arousal exceeding critical limits, by blocking further novel sensory input.

(4) It has been possible to telemeter the EEGs of 2 autistic children while behavioural observations of their free-field activities were simultaneously being recorded. As before, stereotypies occurred least frequently in the unfurnished room, and in this situation the EEG was more synchronized and of higher voltage than in more complex environments. Stereotypies were more frequently accompanied by 'desynchronized' EEG activity than rhythmic activity.

(5) Nearly all autistic children seen by us have been suspected of deafness on referral, yet audiometry (where this has been possible) has seldom revealed any loss of hearing. They also manifest a higher threshold than normal children to painful stimuli. It has been shown that stimulation of the brain-stem reticular formation in cats produces blocking in sensory pathways the receptors of which are simultaneously stimulated[8,9]. It is possible that the chronically high level of arousal in these children similarly produces blocking of sensory pathways, thus accounting for their altered responsiveness to sound and pain.

(6) Autistic children strive to maintain 'sameness': as with complexity, novelty results in activation of the reticular system[10]; if this is already highly activated, either there will be an attempt on the part of the organism to prevent any further excitation by engaging in repetitive activities, or else the organism will succumb to excessive excitation when a catastrophic reaction will result.

It is perhaps relevant that the reticular system has been implicated in the schizophrenic disorders of adults[11,12], which may possibly be related to the present disorder; it has also been shown[13] that social withdrawal in many chronic schizophrenics is associated with increased physiological arousal. Furthermore, chlorpromazine, the action of which is to depress the activity of the reticular system[14], is effective in the treatment of many schizophrenic disorders of adults. Jasper[15] has stated more specifically, on the basis of Rothballer's work, that chlorpromazine has a differential effect on the thalamic and caudal portions of the reticular system, blocking the action of the tonic (caudal) system without affecting the rapid phasic system. If, as seems likely, chlorpromazine proves to be effective also in the treatment of these autistic children, it is possible that at least in some of them the ascending reticular activating system (ARAS) is more specifically involved in the disorder. It is premature, however, to suggest the nature or extent of this involvement, or its ætiology.

Lateralization and One-trial Inter-hemispheric Transfer of Avoidance Conditioning

MANY workers have demonstrated the use of spreading cortical depression to lateralize the effects of conditioning to one cerebral hemisphere. Russell and Ochs[1] have shown that food-reinforced bar-pressing lateralized to one hemisphere could be transferred to the other hemisphere with a single reinforced trial during bilateral cortical function. More recently Russell and Ochs[2] showed that a necessary condition for such one-trial inter-hemispheric transfer of a memory trace was the presence of reinforcement during bilateral function. If animals were allowed to perform the conditioned response in the absence of reinforcement no transfer was found.

Bureš and Burešová[3] have reported lateralization of simple avoidance conditioning to one cortical hemisphere. Animals were trained in a shuttle-box to a criterion of 9 out of 10 successful avoidance responses with one cortical hemisphere depressed. On the following day either 5 or 10 avoidance trials were given with both hemispheres functional. Thirty minutes later spreading depression was produced in the trained hemisphere and the animals trained to criterion. They found that if the animals were given 10 'interdepression' trials with both cortices functional, inter-hemispheric transfer of the memory trace to the untrained hemisphere was seen in terms of a significant

savings score. Further, five 'interdepression' trials were found to be ineffective in producing transfer.

The purpose of the experiment recorded here was to examine whether a single 'interdepression' trial could produce transfer of a lateralized avoidance response comparable to the one-trial transfer effects found for food-reinforced conditioning. Twelve rats were prepared with permanently indwelling cannulæ, one over each tempero-parietal region[4]. Close-fitting mandrins were used to keep the cannulæ patent. Spreading depression was produced by a 25 per cent solution of potassium chloride injected by a microdrive syringe. The volume of each injection was 0·008 c.c., which produced a depression of approximately 90 min duration. The effectiveness of each injection was tested before and after training by loss of the placing reflex in the contralateral forelimb of each animal.

Avoidance conditioning was obtained using a runway, 6 ft. long, with an electrifiable grid floor. Animals were placed in the start box and the door leading to the runway then raised. Simultaneously a buzzer (*CS*) was sounded followed 8 sec later by shock (*UCS*) in both the start box and the runway. On reaching the end of the runway, the rats gained access to the goal box, where they either escaped or avoided the shock. They were trained to a criterion of nine consecutive avoidance responses on each of the five days of training. A successful avoidance response was recorded when the animal reached the goal box before the onset of shock. Fifteen minutes before training, spreading depression was generated by injection in the left hemisphere of the animals on days 1, 2 and 3. On day 4 depression was produced in the right hemisphere. A single trial was given on day 5 with both hemispheres functional for half the animals. Ninety minutes later the right hemisphere was depressed and the rats run to criterion. The remaining animals on day 5 followed the same procedure with the omission of the 'interdepression' trial. The results may be seen in Fig. 1.

Acquisition of the avoidance response can be seen in terms of the successive decrements in trials to criterion over the first three days of training with the left hemisphere depressed. On day 4, when the right hemisphere was depressed, the performance was the same as day 1 for both groups. The effect of previous training was clearly lateralized to the hemisphere functional during the first three days of training. Student's '*t*' test showed no significant differences between days 1 and 4 for each group. Further, no differences were found between groups on any of the four days of training. This lateralization of learning, indicated by the absence of any savings for the untrained hemisphere on day 4, showed there was no spontaneous transfer of the memory trace between training sessions. A single 'interdepression' trial, however, given when both hemispheres were functional on day 5, did produce significant transfer effects on the experimental group compared to the controls (P 0·01). This significant drop in trials to criterion for the experimental group is also seen by comparing the scores for both groups on days 2 and 5. This is critical when it is remembered that day 5 was the second day of training with the right hemisphere depressed and day 2 was the second day of training with the left hemisphere depressed. If there was no transfer of the memory trace one would expect identical scores within groups for both days. Comparing the scores of day 2 with day 5, however, reveals significantly lower scores on day 5 for the experimental group (P 0·001), and no difference for the controls. It is interesting to note that, although one 'interdepression' trial produced positive transfer effects, it did not produce perfect transfer. This can be seen by a comparison of the scores for the experimental group of days 3 and 5, where the scores for day 3 are significantly smaller (P 0·001).

These results give generality to the experiment by Russell and Ochs[2] and differ somewhat from that of Bureš and Burešová[3]. Two points should be made here concerning this discrepancy: (1) Bureš did not use any conditioned stimulus in his avoidance procedure whereas in the present experiment shock was always preceded by a buzzer; (2) Bureš allowed only 30 min between 'interdepression' trials and the initiation of spreading depression whereas a 90-min interval was used in the present experiment. Ross[5], Chamberlain, Halick and Gerard[6], McGaugh, Westbrook and Thompson[7], and many others have pointed out that a period of time after learning is necessary for consolidation of the memory trace. Estimates of the length of this time vary; but it is quite possible that 30 min is not long enough for the trace to consolidate. If this is true then one would not expect to find positive one-trial transfer in such a case.

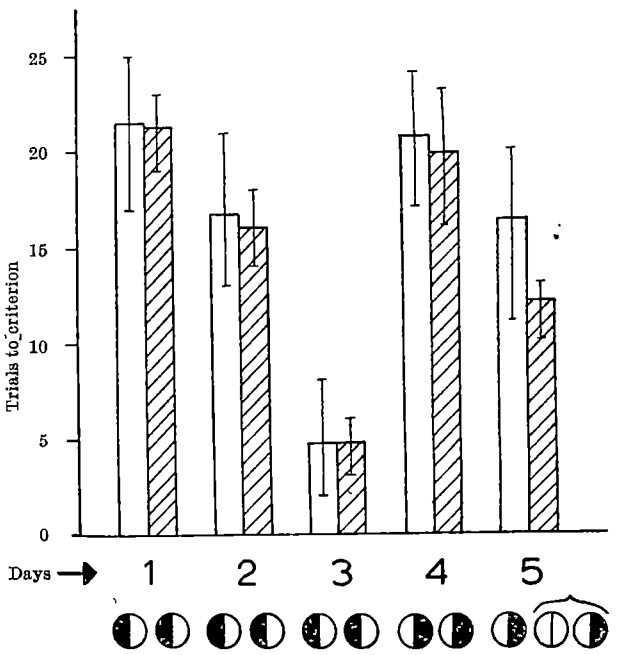

Fig. 1. Average number of trials to criterion are presented for both groups on each of five days of training. The clear histograms represent scores for the control group and shaded histograms the experimental group. The range of scores for each group is indicated by the vertical lines. The hemisphere depressed is indicated by the shading in circles below each histogram

Bureš, however, did find that 10 'interdepression' trials with a 30-min consolidation period were effective for transfer. This suggests the possibility of an interaction effect between the number of reinforcements and the length of the consolidation period. In other words, a single reinforcement might require a longer period to consolidate than would several successive reinforcements. It is clear that spreading depression as well as being a useful tool for lateralizing the effects of learning may further be used to shed light on the perseveration-consolidation theory of learning.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, November 30

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (joint meeting with the I.E.R.E. Medical and Biological Group, at Savoy Place, London, W.C.2), at 2.30 p.m.—Discussion on "Lasers".

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Anniversary Meeting.

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Sir John Lockwood: "Higher Education". (Last of three Cantor Lectures on "A Comparative Study of World Trends in Education".)

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Dr. T. F. Gaskell and Captain G. S. Ritchie, D.S.C., R.N.: "Beneath the North Atlantic".

Tuesday, December 1

UNIVERSITY OF LONDON (at the Institute of Obstetrics and Gynaecology, Hammersmith Hospital, London, W.12), at 2 p.m.—Prof. P. Polani: "Human Chromosomes and Their Abnormalities".

UNIVERSITY OF LONDON (at Westfield College, Kidderpore Avenue, London, N.W.3), at 5.15 p.m.—Sir Edward Bullard, F.R.S.: "The Floor of the Ocean".*

INSTITUTION OF ELECTRICAL ENGINEERS, SCIENCE AND GENERAL DIVISION (joint meeting with the I. Mech. E. Automatic Control Group, at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. H. Nicholson: "Optimal Control of a Boiler".

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, Prince Consort Road, London, S.W.7), at 5.30 p.m.—Dr. P. L. Willmore: "The Contribution of the Tape Recorder to Seismology".*

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. D. J. Bauer: "Antiviral Chemotherapy". (Eleventh of fourteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Richard Wollheim: "On Drawing an Object" (Inaugural Lecture).*

INSTITUTION OF MECHANICAL ENGINEERS, MANIPULATIVE AND MECHANICAL HANDLING MACHINERY GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Bulk Unloading of Solids from Ships—Is It Time for New Methods?"

SOCIETY OF INSTRUMENT TECHNOLOGY (at Manson House, 26 Portland Place, London, W.1), at 6 p.m.—Mr. E. N. Martin and Mr. R. J. Weir: "Process Instrumentation up to 1984".

UNIVERSITY OF LONDON (in the Engineering Theatre, University College, Gower Street, London, W.C.1), at 6 p.m.—Prof. René Tavernier (Ghent): "Genesis and Classification of Brown Earth".*

PLASTICS INSTITUTE, LONDON SECTION (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Mr. B. S. Dyer and Mr. M. R. Day: "Reinforced Thermoplastics".

Wednesday, December 2

COLOUR GROUP (Great Britain) (in the Lamont Room of the National Book League, 7 Albemarle Street, London, W.1), at 3 p.m.—23rd Science Meeting.

SOCIETY FOR ANALYTICAL CHEMISTRY (at the Wellcome Building, Euston Road, London, N.W.1), at 3 p.m.—Meeting on "Solvent Extraction".

INSTITUTION OF MECHANICAL ENGINEERS, APPLIED MECHANICS GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 4 p.m.—Papers on "High-Rate Forming".

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5 p.m.—Prof. J. W. Pratt: "Bayesian Interpretation of Standard Inference Statements".

FAUNA PRESERVATION SOCIETY (at the Offices of the Zoological Society of London, Regent's Park, London, N.W.1), at 5.30 p.m.—Dr. Hugh Lamprey (Principal of the College of Africa Wildlife Management): "The Work of the College".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. H. J. Sketch: "The U.K. 3 Satellite".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, ELECTRO-ACOUSTICS GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Symposium of short papers on "Special Loudspeaker Applications".

SOCIETY OF ENVIRONMENTAL ENGINEERS, PACKAGING GROUP (in the Mechanical Engineering Department, Imperial College of Science and Technology, London, S.W.7), at 6 p.m.—Mr. R. A. C. Ives: "The Fragility of Simple Structures".

Thursday, December 3

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 10.30 a.m.—Discussion Meeting on "Some Aspects of the Stratosphere, Mesosphere and Lower Thermosphere" organized jointly by Prof. D. R. Bates, F.R.S., Prof. P. A. Sheppard, F.R.S., and Dr. R. C. Sutcliffe, F.R.S.

ROYAL INSTITUTION OF NAVAL ARCHITECTS (in the Weir Lecture Hall, 10 Upper Belgrave Street, London, S.W.1), at 4.45 p.m.—Dr. R. L. Townsin: "Boundary Layer Separation from Ship Models—a Note on Its Detection and Suppression with Some Examples"; Mr. R. E. Clements: "The Control of Flow Separation at the Stern of a Ship Model Using Vortex Generators".

INSTITUTION OF CIVIL ENGINEERS, TRANSPORTATION ENGINEERING GROUP at Great George Street, London, S.W.1), at 5.30 p.m.—Informal Discussion on "The Growth of Private Car Ownership and the Redevelopment of Public Transport" introduced by Mr. J. D. C. Churchill.

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. S. Shaldon: "Long-Term Hæmodialysis as a Substitute for Kidney Function". (Twelfth of fourteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

UNIVERSITY OF LONDON (at the Middlesex Hospital Medical School, Cleveland Street, London, W.1), at 5.30 p.m.—Prof. J. G. Mulnard (Université Libre de Bruxelles): "Experimental Approach to Mammalian Development".*

INSTITUTE OF REFRIGERATION (at the National College for Heating, Ventilating, Refrigeration and Fan Engineering, Southwark Bridge Road, London, S.E.1), at 6 p.m.—Mr. G. C. Hatcher and Mr. J. C. F. Payne: "The Application of Computers to Problems Associated with Refrigeration Engineering".

INSTITUTION OF MECHANICAL ENGINEERS, EDUCATION AND TRAINING GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "How to Encourage Schoolboys to Become Chartered Mechanical Engineers".

UNIVERSITY OF LONDON (in the Engineering Theatre, University College, Gower Street, London, W.C.1), at 6 p.m.—Prof. René Tavernier (Ghent): "The Soil Map of Europe".*

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (joint meeting with the Northampton College Chemical Society, at the Northampton College of Advanced Technology, St. John Street, London, E.C.1), at 7 p.m.—Dr. L. J. Bellamy: "Hydrogen Bonds".

Thursday, December 3—Friday, December 4

ROYAL PHOTOGRAPHIC SOCIETY (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2)—Symposium on "Optimum Results from Colour Photography".

Friday, December 4

ROYAL AERONAUTICAL SOCIETY, ROTOCRAFT SECTION (at 4 Hamilton Place, London, W.1), at 2.15 p.m.—Mr. L. M. Hewin: "The General Requirements of the Three U.S. Armed Services for Helicopters and other VTOL Aircraft"; Major-Gen. N. Crookenden: "British Army Unit Light Helicopter Project".

SOCIETY OF CHEMICAL INDUSTRY, FINE CHEMICALS GROUP (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. D. J. Bauer: "Antiviral Chemotherapy".

TELEVISION SOCIETY (in the Conference Suite, I.T.A., 70 Brompton Road, London, S.W.3), at 7 p.m.—Mr. J. Weltman: "Television University".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. C. C. Butler, F.R.S.: "High-Energy Nuclear Physics—Achievements and Future Developments".

Saturday, December 5

BRITISH INTERPLANETARY SOCIETY (at the Northampton College of Advanced Technology, St. John Street, London, E.C.1), from 10 a.m. to 12.30 p.m.—Meeting on "Astronautics Education".

ASSOCIATION OF CLINICAL BIOCHEMISTS, SOUTHERN REGION (at the Wright Fleming Institute, St. Mary's Hospital, Praed Street, London, W.2), at 10.30 a.m.—Meeting on "Forensic Toxicology".

BRITISH MYCOLOGICAL SOCIETY (in the Rooms of the Linnean Society of London, Burlington House, Piccadilly, London, W.1), at 2.15 p.m.—Annual General Meeting, followed by Prof. N. F. Robertson: "The Fungal Hypha" (Presidential Address).

LONDON COUNTY COUNCIL (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Dr. J. G. Sheals: "The British Museum (Natural History) Expedition to East Nepal".*

Monday, December 7

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 10 a.m. and 2.30 p.m.—Colloquium on "Programmed Test Equipment and Techniques".

BRITISH SOCIETY FOR THE PHILOSOPHY OF SCIENCE (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Mr. G. C. Archibald: "Refutation or Comparison?".

INSTITUTION OF ELECTRICAL ENGINEERS, SCIENCE AND GENERAL DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Prof. J. C. West: "Non-Linear Circuit Theory".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"The Bridge" (Geographical Films).

UNIVERSITY OF LONDON (at Birkbeck College, Malet Street, London, W.C.1), at 6 p.m.—Prof. J. Th. Runnenburg (University of Amsterdam): "Some Practical Problems Solved with Simple Tricks from Probability Theory and Analysis".*

SOCIETY FOR ANALYTICAL CHEMISTRY, MICROCHEMICAL METHODS GROUP (at "The Feathers", Tudor Street, London, E.C.4), at 6.30 p.m.—Discussion Meeting on "The Characterization of Organic Compounds" opened by Dr. D. W. Mathieson and Mr. L. C. Cross.

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (joint meeting with the Paper and Textile Chemicals Group, at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. I. F. Hendry and Mr. J. A. S. Newman: "New Developments in Papermaking".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

M.R.C. RESEARCH ASSISTANT IN THE DEPARTMENT OF PHARMACOLOGY for work on amine metabolism in neurological diseases, under the direction of Prof. H. Schnieden—The Registrar, The University, Manchester, 13 (December 5).

Assistant Lecturer in the Department of Medicine, University of Edinburgh—The Professor of Medicine, Department of Medicine, The Royal Infirmary, Edinburgh, 3 (December 7).

Assistant Lecturer in Zoology—The Registrar, The University, Manchester, 13 (December 10).

Lecturer (with an honours degree in geography and teaching experience in schools) in Geography and Education at the Institute of Education—The Registrar, The University, Sheffield (December 12).

Lecturer (man or woman graduate) in Geomorphology in the Department of Geography—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (December 13).

Senior Lecturer or Lecturer in Mechanical Engineering at the University of Natal, Durban—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, December 14).

Chair of Crop Husbandry and Horticulture at the University of Ghana—The Assistant Registrar, University of Ghana Overseas Office, 15 Gordon Square, London, W.C.1; or The Registrar, University of Ghana, P.O. Box 25, Legon, Accra, Ghana (December 15).

Chair of Geology at the University of Ghana—The Assistant Registrar, University of Ghana Overseas Office, 15 Gordon Square, London, W.C.1; or The Registrar, University of Ghana, P.O. Box 25, Legon, Accra, Ghana (December 15).

Research Fellow in Computer Science—The Secretary, University of London Institute of Computer Science, 44 Gordon Square, London, W.C.1 (December 15).

Lecturer or Assistant Lecturer in Statistics—The Secretary, The Queen's University, Belfast, Northern Ireland (December 17).

Lecturer (with a good honours degree in civil or mechanical engineering, professional and/or research experience, and preferably interest in strength of materials) in the Department of Engineering—The Secretary, The University, Aberdeen (December 19).

Lecturer or Assistant Lecturer (Probationary) (man or woman graduate) in Zoology—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (December 20).

Lecturer or Assistant Lecturer in Pure Mathematics; a Lecturer or Assistant Lecturer in Applied Mathematics; and a Lecturer or Assistant Lecturer in Statistics—The Registrar, The University, Leeds, 2 (December 31).

Lecturer (with special interests in the application of physical chemistry to pharmaceutical, medicinal or biochemical problems) in Physical Chemistry in the Department of Pharmacy—The Registrar, The University, Nottingham (December 31).

Senior Lecturer in History and Philosophy of Science at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, December 31).

Senior Lecturer in Mammalian Physiology in the Department of Biological Studies—The Principal, Lanchester College of Technology, Priory Street, Coventry (December 31).

Chair of Theoretical Physics at Queen Mary College—The Academic Registrar, University of London, Senate House, London, W.C.1 (January 1).

Research Assistant (with an honours degree in geology or zoology and preferably postgraduate experience in palæontology or micro-palæontology) in Palæontology, for duties which will involve the preparation, identification and cataloguing of carboniferous fossils—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (January 1).

Lecturer in Immunochemistry in the Department of Pathology—The Registrar, Monash University, P.O. Box 92, Clayton, Victoria, Australia; or The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (January 4).

Research Fellow in Environmental Archæology in the Department of Anthropology and Sociology, Research School of Pacific Studies, Institute of Advanced Studies, Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 20).

Chair of Mathematics at the University of Otago, Dunedin, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or The Registrar, University of Otago (New Zealand and London, January 31).

Assistant Lecturer (with a good honours degree in biology or zoology) in Biology—The Registrar, University of Strathclyde, George Street, Glasgow, C.1.

Entomologist (preferably under 35, with an honours degree in agriculture, horticulture or an appropriate natural science, plus two years postgraduate training or experience) in Hong Kong, to undertake and supervise agricultural research work and to provide appropriate specialist advice and assistance in the field of practical agricultural entomology—The Appointments Officer, Room 301, Ministry of Overseas Development, Eland House, Stag Place, London, S.W.1, quoting Ref. RC213/81/02.

Graduate Research Assistant (preferably with training or previous research experience in exfoliative cytology) for work on cancer cell detection—The Dean, Guy's Hospital Medical School, London Bridge, S.E.1.

Horticulturist (preferably under 35, with a degree in agriculture, horticulture or an appropriate natural science, plus two years' postgraduate training or experience) in Hong Kong, to undertake and supervise agricultural research work, and to provide specialist advice and assistance in the field of horticulture—The Appointments Officer, Room 301, Ministry of Overseas Development, Eland House, Stag Place, London, S.W.1, quoting Ref. RC 213/81/04.

Lecturer or Senior Lecturer (with a first- or second-class honours degree or equivalent, and preferably experience in teaching, industry or the Scientific Civil Service) in the Mathematics Branch—The Registrar, Royal Military College of Science, Shrivenham, Swindon, Wiltshire.

Master to teach Physics throughout the School, with a good share of VI Form work—The Headmaster, King's School, Worcester.

Research Assistants (2) (preferably with a degree in biochemistry or chemistry at a good honours standard, or graduate in a biological science, with suitable experience) in the Department of Applied Microbiology and Biology, to undertake studies related to the mechanisms of sporulation in filamentous fungi—The Registrar, University of Strathclyde, George Street, Glasgow, C.1.

Research Biophysicist in the Department of Pathology, for work concerned with the application and further development of an electron probe microanalyser in the investigation of trace element distributions in human diseases—Dr. A. J. Hale, Department of Pathology, St. Thomas's Hospital Medical School, London, S.E.1.

Technician in the Department of Biochemistry, to assist in research on the biochemical effects of radiation on normal and cancer tissues—The Secretary, The Medical College of St. Bartholomew's Hospital, West Smithfield, London, E.C.1.

REPORTS and other PUBLICATIONS

MAN AND THE SECRET SPRINGS OF NATURE

SIR HAROLD HARTLEY'S Romanes Lecture, "Man and Nature", delivered at the University of Oxford on October 27, has all the sweep and vision that have marked recent reviews of the Carnegie Institution of Washington, with which, in style, it has something in common. Sir Harold's insight is all his own, though he is prompted by the observation of Lucretius with whose modernity he is confessedly amazed. It is indeed from a passage in George Santayana's essay on Lucretius that he derives his initial inspiration: "The man who discovers the secret springs of appearances opens to contemplation a second positive world, the workshop and busy depths of Nature, where a prodigious mechanism is continually supporting our life and making ready for it from afar by the most exquisite adjustments. The march of the mechanism, while it produces life and fosters it, yet as often makes it difficult and condemns it to extinction".

Sir Harold begins his lecture with a review of the way in which, in the half-century since Santayana wrote those words, enquiry into the 'secret springs' of Nature has revealed something of what was then a profound mystery. He quotes also Jowett's forecast almost a century ago, in his introduction to Plato's *Republic*: "The resources of the natural sciences are not half developed as yet; the soil of the Earth, instead of growing more barren, may become many times more fertile than hitherto; the uses of machinery greater, and also more minute than at present. New secrets of physiology may be revealed deeply affecting human nature in its innermost recesses. The standard of health may be raised and the lives of men prolonged by sanitary and medical knowledge . . . The ever-increasing power of locomotion may join the extremes of the earth".

Sir Harold moves easily over the realms in which Jowett's prophecies have been fulfilled and Santayana's perceptive interpretation justified during the past half-century and more. He has the deep understanding and perspective of the historian as well as the intellect of the scientist. The contributions of Pasteur and Ross are related with deep insight, as also are such more recent discoveries as Melvin Calvin's food-producing photosynthetic cycle, Sir Hans Krebs's metabolic cycle, and the discovery of the pattern of the coiled protein molecules in the nucleus of the cell and the physical basis of heredity. All this is set, not against forecasts of half a century or a century ago, but against the astonishing insight of Lucretius two thousand years ago.

Again and again Lucretius used words which fit our present-day knowledge. He recognized the cyclical character of Nature's processes, the life and death of living organisms and their return to the primordia to begin the cycle again, the alternation of the seasons, and of day and night. His reference to *natura gubernans* to keep successive changes in living organisms in proper balance is apposite to what we are just beginning to simulate with the aid of computers in our great chemical factories and oil refineries. Equally appropriate is the simile Lucretius uses to account for the rarity of the substances formed from the primordia, his reference to heredity "by which things can, as they grow, preserve their kind". Even of new views on the origins of life on this planet, Lucretius's words "buffeted by blows from limitless time, by trying movements and unions of every kind" fit the passage of organic compounds through the stage which Mr. N. W. Pirie calls 'biopoiesis', producing at last some primitive organism that could use radiation from the Sun to make food from water and return the oxygen to the air. Newton often quoted Lucretius, and their arguments touching the eternal nature of atoms are identical.

Sir Harold Hartley is not content merely to show how the torch of tradition is handed on through the ages, nor to outline this world of new particles and intricate cycles of living processes. We are beginning to see glimpses of the third stage through which Sir Cyril Hinshelwood, in a presidential address to the Royal Society, suggested that scientific theories may pass in the search for principles and in the conflict between imagination and the austere regard for truth—the new order which succeeds the early gross oversimplification, the distortion of the symmetry of the hypothetical systems and marring of neatness as recalcitrant facts increasingly rebel against uniformity. It was not necessary for Sir Harold in this lecture to refer to the corrective value of the historical perspective. The whole lecture is steeped in that sense, and the scientist at least has reason to be grateful to him for displaying so clearly the rashness of any neglect of the insight or interpretation or experience of the past.

But Sir Harold's own contribution is pregnant with meaning for to-day. In the latter part of his lecture he asks how this deeper understanding has influenced man's relations with Nature and he seeks to apply what lessons he draws to the pressing problems of to-day, particularly at the international level. First, he reminds us that it is misleading to think of a partnership with Nature because the common interest which partnership implies does not exist. We can learn from Nature and co-operate with her, but, although man has now largely mastered the constant threat from his environment under which he lived in the past, he has still to come to terms with the great power that his new understanding of Nature has put into his hands.

Sir Harold looks at the effect of these changes on man's philosophy and on his attitude to social and ethical concepts formulated in different circumstances, and it is in this context that he examines the question of food supply and population—by far the most urgent problem that the world is facing to-day. It is not sufficient to consider the many contributions that new techniques and the new understanding of the living process have made to food production, from improvements in yields and quality of crops, of breeds of animals, control of diseases and pests, and the improvement of soil fertility, for there is no finality. Nature does not take kindly to man's interference with her balance and man has ever to be on his guard and watchful of her reactions. The new science of ecology is dynamic, not static, and has much to teach.

Man has still much to learn, not only about food supply but equally also the use of his raw materials in general. Sir Harold is well aware of the new possibilities in the use of micro-organisms, but what he stresses above all is the constant need for forethought, the choice of means appropriate to the purpose to be served. This is of fundamental importance in designing aid to the developing nations, and its significance can scarcely be over-stressed. As Sir Harold observes, the average yields of crops and the

progressive improvement in those yields are much greater in the developed countries. It is not simply a matter of food surpluses on one hand and food deficiencies on the other; there are wide divergencies in the efficiency of the cultivator and in the resources he can command, as well as wide gaps between the primitive cultivator and the fund of knowledge long available to the developed countries. Progress in the developed countries is based on the fertility of the soil built up by generations of good farming practice, whereas in Africa and Asia the soil has often been depleted of nutrients by erosion and long years of exploitive agriculture. Emergent countries may have to start by making good long periods of neglect and depletion before many of the new techniques can yield results.

Apart from problems still unsolved as to how far existing knowledge regarding, for example, the ability of legumes to fix nitrogen is valid in the tropics, the innate conservatism of man poses social, political and technological problems which each country must solve for itself, with the appropriate means to which education, land tenure, irrigation and other technical factors contribute. Much more is at stake than production alone. More mechanization of agriculture will not provide the answer. In many countries the key factor is raising the efficiency of the individual cultivator and not the introduction of costly equipment which has proved its value under different conditions in the developed countries.

These considerations underline the importance of accurate surveys, such as Sir Harold Hartley has long urged, and which have now been made by the agencies of the United Nations. The problems are now defined, and what Sir Harold emphasizes in this Lecture is that the great challenge to the present generation, which involves the future of humanity and the stability of the world, is only to be met by some sacrifice of personal and national self-interest and by the recognition of the ultimate community of interest of the world in spite of fragmentation. Many difficulties have to be overcome and the greater freedom of world trade, the appropriate choice between various forms of aid, above all the devotion and inspiration of personal service, are not to be achieved by political dogma or formulæ. Each country must choose for itself the appropriate relation between man and machine, the wisest allocation of resources, without blindly following the economic, political, social, educational or technical patterns of other countries where the relation of population to resources is different.

Finally, Sir Harold sees the relation between man and Nature as something deeper than the relief of hunger. It is interesting to contrast this lecture with Lord Brain's presidential address to the British Association in August, in which Lord Brain covered some of the same ground as Sir Harold. The difference, however, is that Lord Brain emphasized how little we know of man himself, whereas Sir Harold emphasizes the vast potentialities of the knowledge we already have—but without dissenting from our need to know more about man himself. When Sir Harold insists that the deeper problem is to find a way of living that will give human satisfaction and hope, he is challenging us to search for that further knowledge of man's nature which will enable us to find the means to redress the imbalance between man and Nature.

That challenge is sharpened in Sir Harold's final words when, quoting a passage from Sir Geoffrey Vickers, he insists that man was not made for leisure, and that he will continue to accept the challenges of Nature as he has done in the past. Sir Harold did not elaborate the point. He was content to leave it in the context of the words of Sir Geoffrey which he quoted: "For each of us, as well as for society and posterity, the need to struggle is the chance to grow. The world is like a dark forge, lighted by the sparks which men strike as they beat the stuff of life into significance on the anvil of circumstance. The light is a function of the effort; we make it bright as day if we hammer hard enough; but we shall never dispense with the need to hammer, or live by the light of sparks struck yesterday".

That passage goes to the roots of Britain's own difficulties to-day, and Sir Harold's comment that man was not made for leisure indicates where its relevance lies. Preoccupation with leisure rather than effort is responsible for much that is amiss in Britain to-day in the whole social and political climate, as well as in her economic and industrial situation. Even advances such as the computer and automation make possible bring their own challenge and the need to come to fresh terms with Nature; challenges that are not simply technical or economic but social and moral as well. In this interdependent world it may well be that the challenge of leisure will be met in part as we respond to the challenge of the underdeveloped countries—framed so clearly in the problem of food and population.

IMAGE OF CHILE

THE scientific advice and financial assistance which the United States has been giving to the Central and South American countries is now well known. This has applied especially to the development of agriculture, but now such assistance is converging into scientific collaboration—much to the credit of the United States, having profound scientific knowledge and the policy to give advice and financial help, and also to the wisdom of the other American countries concerned.

The most recent evidence of this desirable scientific collaboration was presented by a conference on "Science and Development in Chile", held in Washington, D.C., under the joint auspices of the Embassy of the Republic of Chile and the U.S. National Academy of Sciences, during October 5–9.

The President of the United States sent the following message to members of the conference:

"In this third year of the Alliance for Progress, it is gratifying to see scientists of Chile and the United States sharing the fruits of their research in the Image of Chile Science and Development in Chile program, jointly sponsored by the Embassy of Chile and the National Academy of Sciences of the United States of America.

"The pressing need to apply the benefits of science and technology for the well-being of humanity makes it particularly appropriate that the scientists of our two countries work together in the spirit of hemispheric co-operation.

"To the distinguished scientists from Chile and to my fellow Americans who share our hopes and aspirations for the advancement of human welfare in all of the Americas, I bid a warm welcome and wish you every success."

Space will not allow a report of the symposium held, and the papers read, at the conference; but the closing remarks made by Mr. Dean Rusk, U.S. Secretary of State, and by the Ambassador of Chile to the United States are a source of inspiration to all countries, and therefore the substance of each speech is reported as follows.

SCIENCE AND DEVELOPMENT IN CHILE

By The Hon. DEAN RUSK
U.S. Secretary of State

When the United States pledged its commitment to the Alliance for Progress in 1961, it recognized the central part science and technology must play in the economic and social transformation envisaged under the Alliance. The experience of the first years of the Alliance has not lowered our assessment of the importance of science in this development process. But it has refined thinking on how science can most usefully spur economic growth.

In Latin America generally, scientific talent is limited in quantity—indeed only 2·3 per cent of the population is classified as professional or technical in any field. It has been necessary to establish priorities. This has led to extensive discussions between scientists and technologists, on one hand, and those responsible for allocating national resources on the other; and, as a rule, the result has been the sound conclusion that short-range scientific and technical projects, however interesting in and of themselves, are less urgent than research and teaching institutions capable of promoting science and technology. Much has been done, and is being done, in improving curricula, strengthening faculties, equipping laboratories with the most modern and sophisticated research devices, and providing interchanges between the United States and Latin American scientists.

There is general agreement, I believe, that most of the Latin American countries need to put more emphasis on improving their agriculture and on making their rural areas a more active market and stimulus for manufacturing. Indeed, this is true of most of the developing areas of the world. As I have recently pointed out, agricultural production in the developing areas, particularly in Asia and Latin America, is growing less rapidly than population —and if current trends continue, the point will not be too far off when world food stocks will simply not be enough to meet minimum needs in the deficit areas.

Although Chile has a rich agricultural potential, it has been a net importer of food for some years and now imports about 20 per cent, or 125 million dollars, of its food needs. Every dollar of increased food production has the potential of freeing a dollar of valuable foreign exchange to buy goods and services needed for Chilean development.

The Agricultural Development Project now being initiated in Chile is a good example of how applied science contributes to a total development strategy. This project seeks to increase farm production through research activity and improved rural education institutions. Closely correlated activities seek to stimulate food output and exports through changes in the agricultural credit and marketing systems and in overall national agricultural policy.

Another effective application of science to Chile's economic priorities is the Maule River Project, so reminiscent of the Tennessee Valley Authority development in the United States. By late 1967 a comprehensive regional development plan will be created for the Maule River Basin, to include an integrated and co-ordinated construction and financial schedule for individual projects. The multi-purpose water resource plan will include uses for agriculture, industry, power, recreation, flood control and conservation. Related projects will cover agrarian reform, transportation, marketing, education and training, housing, urban growth, community development and public health.

The Manpower and Educational Planning Project is a key to assuring that, in the future, human resources will make their optimum contribution to Chile's economic and social goals.

I believe these three projects, among the other technical assistance activities with which the United States is concerned in Chile, are excellent examples of the co-operative endeavour the States share under the Alliance. They are being implemented by Chilean institutions in collaboration with the Chile–California Programme and the U.S. A.I.D. Mission in Santiago, with funds provided both by the Government of Chile and A.I.D., and they are utilizing more fully than ever before the scientific capability of Chile and the United States in the service of the former's economic and social development under the Alliance for Progress.

Co-operation between Chile and the United States extends over a wide range of scientific subjects, including the sleep–wakefulness mechanisms. This has a somewhat special appeal to me. I have been told that science may make it possible for us to get on with less sleep at night. As I remarked on another occasion, I know some government officials who, of necessity, have already made considerable progress in that direction.

I turn now to the second main discipline of these seminars—earth sciences.

The same force which caused so much destruction in Chile during 1960 manifested itself in Alaska only last year. This awesome power of Nature disdains international boundaries. Investigations carried out in Chile on earthquake-resistant construction can have universal application. Development of techniques and instrumentation which can sense the early on-rush of earthquakes is as important in the eastern hemisphere as in the western.

New techniques to determine the location and extent of as yet unfound ore deposits are of great significance in the economic development of a country such as Chile, which has potentially such a great mineral wealth. I understand that investigations of this type are being actively pursued by the Institute of Geologic Research.

Investigations in physical oceanography offer many potential benefits, such as harnessing the tides and ocean currents for power. Exploitation of the plant and animal resources of the sea promises, I think, even more rewarding benefits. In a world where much of the population goes to bed at night hungry, where protein deficiency is widespread, the potential benefits from harvesting the sources in the sea are spectacular. The successful conclusion of experiments now under way in Chile producing fish protein concentrate on a pilot-plant scale could be of far-reaching benefit to mankind. We need more research in methods of influencing the biological cycle of the sea and in techniques leading to farming fish rather than hunting them. Such programmes might pose a challenge for scientists in the Fish Development Institute in Chile.

Progress in any of these scientific fields depends not so much on dollars as on manpower. The necessity for the development of trained manpower, including scientists, is an essential component of Chile's goals. It will continue to receive close attention by Chilean authorities and the U.S. A.I.D. Mission.

Because of the particular importance of science and engineering in economic development, a special committee of the Pan-American Union has been set up to investigate the science and engineering education programmes in Latin America. Investigations have already been carried out in several countries, and for Chile they have now been completed.

Let a meeting of scientists from Chile and the United States, gathered within the spirit of hemispheric co-operation, be interpreted by all as a certain sign that we stand together, ready to attack any and all to overcome any scientific or technological obstacles in the path of the economic and social progress of the peoples of the New World.

SCIENCE, FOREIGN RELATIONS AND GOVERNMENT IN DEVELOPING NATIONS

By HIS EXCELLENCY THE AMBASSADOR OF CHILE TO THE UNITED STATES

(Sergio Gutiérrez-Olivos)

Perhaps it may be surprising that a diplomatic mission should engage in a venture not normally associated with diplomatic duties and activities. This surprise would be justified if these symposia were purely and simply a scientific expression. As science and technology more and more saturate every fibre of our lives as individuals and communities, it becomes progressively more difficult for us to ignore the decisive part they play in all events in which we, as laymen, are daily called on to play a responsible part.

I am reminded of what the celebrated French General Lyautey said when he was assigned to an African garrison early in his brilliant military career. "What is your speciality, lieutenant?" his commander asked him. Lyautey replied: "I am a specialist, Sir, in general ideas". Permit me, then, to invoke my status as a non-scientist in developing some general ideas on the importance of the sciences in certain contemporary activities that are not *per se* scientific, such as foreign affairs and government.

A general belief exists in developing countries that only the foreign policies of the great powers are influenced by science and technology. There is some justification for this belief, because the inter-relationship of science, foreign policy and government in those powers is tangible and clear to the man in the street every time he opens his newspaper. Even though the developing nations do not face problems requiring foreign policy alternatives fixed at a given moment by the balance of space and/or nuclear progress; even though the day is still remote when such countries must resort to high theories of a mathematical content and to electronic computers to try to interpret and predict the course of international relations, there is ample evidence—as even a rapid survey reveals—that the inter-relationship of science, foreign policy and government has a concrete and decisive effect on the theory and practice of foreign relations of even minor powers.

The 'eclipse of distance' produced by advances in transportation and communication has, among other things, made the masses all over the world familiar with the way of life of the wealthier nations, and has fired the imagination and ambitions of vast sectors in such a manner that to-day the configuration of world politics is determined, at least in part, by tensions—national and international—that did not exist when each region was circumscribed by its local horizons and surrendered to its individual fate.

Progress toward development requires that Foreign Offices have access to—and that they examine, classify and file for ready use in case of need—a vast compendium of political, economic and scientific knowledge which grows by the minute. Unless they do so, the general lines of foreign policy, or a specific decision in a specific situation, can fall into serious and even irrevocable error.

Foreign policy to-day is made only in part in the cabinets of the Foreign Ministers. For the rest, it evolves at international meetings of varied political, economic, social—and, of course, scientific—hues, and frequently at meetings of a mixed type, such as that which produced the Antarctic Treaty. Let us remember that in the area of science and technology alone there were more than 300 international organizations in 1962, and that 50 of them were of an inter-governmental type.

Just as the conquest of underdevelopment calls for a planned strategy in utilizing internal resources, so does it call for a planned strategy in utilizing international resources, including those of a scientific nature.

The influence of science on the foreign policy of a developing country can assume a more subtle aspect, curiously akin to that of the major powers. In effect, their superior scientific development serves these powers to strengthen and increase their international prestige, attract domestic and foreign capital, and involve them in executing or taking part in technical assistance programmes elsewhere in the world.

With due and prudent regard for distances, these benefits and functions are not beyond the reach of certain developing nations. I have said that this 'Image of Chile' sought to show the United States public the state of certain specific areas of Chilean science and thereby promote the image of my country and the interest of the United States public in it. With all frankness, and without false pride or false modesty, I can say that Chile has made, and will continue to make, a valuable contribution to the development of other countries for which our technical and scientific resources are of interest.

Willy-nilly, the developing nations are being called on properly to understand and resolve, individually or collectively, certain questions of a very sophisticated scientific or technical nature: Will the right of 'innocent passage' apply or not to space? The assignment of frequencies for transmissions from satellites is already in sight. What kind of international law will govern 'occupation' of the Moon?

For Melba Phillips, "The truly central problem in economic development, and perhaps the most difficult of all, is education". I need not enlarge on the degree to which the answer to this problem depends on adopting a foreign policy geared to maximum utilization of available international resources and programmes, to attracting human talent from without, to a planned policy of immigration, to the recovery of scientists and technicians who have abandoned their own country for another, etc.

The process of regional integration is often thought of as being limited to economic and political considerations. It would not be amiss to emphasize that this process also has a high scientific and technological coefficient, which begins with the measurement of the physical and human potential of a region, continues along the difficult path of proper or improper utilization by each country of the opportunities that integration open to it, and so on.

Even though, as I have pointed out, the developing countries are removed from military decisions having an immediate and conclusive impact on world affairs, this does not mean that science and technology are irrelevant to the decisions they must make in their own interest or in their regional interest. Far from it. Which is the modern military hardware the country really needs and can efficiently operate? What is the optimum measure of 'self-protection' in relation to the optimum measure of development? What type of contribution can and must a country make to regional defence without prejudice to availabilities for internal security or local emergencies? To what extent can the scientific and technological education of the armed forces be a complementary factor in national development?

The so-called population explosion in Asia, Africa and Latin America poses difficult questions which are linked to moral and religious matters, but linked no less to the

advance of science. The dialogue on these problems involves the churches, most of them international in scope; scientific assemblies which are equally international in scope; and the conduct of each country, considered individually. It is now impossible to evade this dialogue, and the attitudes to be adopted, whatever they may be, must stem from a profound understanding of the economic, political, moral and scientific issues involved.

These are but some of the modern questions of a high scientific or technological content which developing nations must face. In short, within the framework of their responsibilities, within the framework of their obligations and opportunities, the developing nations must recognize an interdependence among science, technology and foreign policy that, on an appropriate scale, is comparable to that which is customarily attributed to the foreign policy of the great powers. Expressing it in another way, we have here something that was set forth by a task force of the United States Department of State, acting in accordance with certain recommendations of the Hoover Committee, as follows: "The Department is dealing on the one hand with foreign policy matters which have a great effect on United States scientific policy, and on the other hand with international scientific activities which have an impact on foreign policy".

James R. Killian, jun., recalls that Thomas Jefferson once observed that nothing had been heard from their Ambassador to Spain for more than two years, and that, if he did not hear from him in another year, he proposed to send him a letter. From one point of view, at least, those were enviable and happy times. The relationship between the national and the international to-day is immediate, imperative and inescapable.

Governments traditionally have recognized the interdependence between science and public administration in those agencies clearly concerned with such activities as agriculture, transportation and public health—to cite a few.

As I have noted, to-day science and technology are all-pervasive. Harrison Brown has told us that: "Just as the people in agrarian civilizations became dependent upon agriculture for their survival, so we to-day become dependent on our science and our technology". The time is past when it could be said that "the least government is the best government". That does not mean, of course, that the best government is necessarily the biggest. Far from it. But it should be recognized that the size of government tends to grow, even in countries that protest a doctrinaire distaste for this phenomenon.

This fact is reflected in what is happening to scientific research. According to the U.S. National Science Foundation, Federal funds for basic research constituted 45 per cent of the total national basic research expenditure from all sources during 1953–54. By 1957–58 this amount had grown to 51 per cent, and for 1960–61 it reached 60 per cent. This has been accompanied by a relative decline in the contributions from other sources. Industry's proportion fell from approximately 35 per cent in 1953–54 to 30 per cent in 1957–58, and 22 per cent in 1960–61. College and university contributions declined from roughly 18 per cent to 12 per cent over this period. Other non-profit institutions made up the remainder, and their contributions declined from not quite 10 per cent to approximately 6 per cent.

Is this invasion of government of a sphere that was almost immune to it a few short years ago a peculiar application of Parkinson's Law on bureaucracy? That might be true up to a point, but the real motivation is that scientific and technological progress has become a matter of prime national interest and, therefore, a matter of governmental responsibility.

We can verify this with readily accessible data. Profs. Harbison and Myers have established a correlation between the national income of certain countries and the development of their human resources. The results are surprising. If we compare the number of persons per 1,000 of population possessing at least 12 years of education with the *per capita* income, converted to dollars, we arrive at the following results:

	Persons per 1,000 of population with at least 12 years of education	*Per capita* income (U.S. dollars)
Nigeria	0·8	64
Egypt	10·7	116
Italy	31·4	594
U.S.S.R.	112·6	721
United States	288·0	2,800

The great task, then, that the governments of the developing countries now face—assuredly with the desirable, necessary and maximum co-operation of private institutions—is to devise a logical strategy of high-level manpower development and relate it to the broader objectives of economic growth. This is a difficult matter, which involves many purely political problems. In effect, natural pressure in the developing countries is exerted on broadening the base of primary and secondary education. The formation of a scientific and technological *élite* and, what is apt to be just as difficult, retaining this *élite* in the face of attractions offered by emigration to more developed countries, also requires a well-defined and vigorous national policy.

Finally, assuming that countries of intermediate development, as are some in Latin America at present, succeed in forming an intermediate *élite* of technicians and engineers, they still must face the problem of forming the contingent of truly original outstanding talent essential to the full development of their potential. Otherwise, their role in the world will be necessarily and indefinitely subordinated to the fresh and original progress of other areas of the world. It is true that the emergence of such talent answers no physical law—"the spirit blows where it will", say the Scriptures—but to some extent its appearance depends on a degree of probability linked to the dimensions of the educated sector of the population. Here is where we encounter anew a very necessary aspect, albeit somewhat ignored up to now, of the integration of the Latin American nations, which imperatively requires us to follow the example of Europe in basic modern research.

Thus, the development of science and technology is not merely a question of science and technology. In essence, it is a political question which affects all society. The United States has understood this, and that is why in recent years it has created a variety of scientific advisory agencies at all levels of Government, including the Presidency of the Republic and the Department of State.

We are not concerned alone with a matter which relates to the material progress of our communities, essential as that may be.

Lord Snow has intimated that professors and scientists should be entrusted with the world because they are a little better than other people. Robert M. Hutchins, from the Centre for the Study of Democratic Institutions, good-humouredly quarrels with this notion: "My view, based on long and painful observation", he says, "is that professors are somewhat worse than other people, and that scientists are somewhat worse than other professors".

I do not intend to take sides in this highly debatable issue. But let me express my honest conviction that the decision-making responsibility in a democratic government must repose in the hands of accountable political leaders (it does not matter if they are *also* scientists), accountable leaders responsible to the people.

In a world which is progressively more scientific and technological and in a society that seeks to preserve its democratic way of life, the diffusion of the pertinent basic knowledge among the greatest number is an essential in maintaining the national dialogue inherent in every democracy. Otherwise, weighty decisions relating to science and technology at best would slip from the control of the electorate and its representatives. A tiny group, which we assume to be competent and well intentioned,

would decide on fundamental questions at its own and exclusive discretion. By definition, this could constitute a very dangerous situation. "Democratic government cannot survive if the most important issues of public policy are inexplicable to citizens and their constitutional officers. Deliberation . . . is impossible if communication among experts and between them and citizens is not feasible."

Perhaps these observations on the inter-relationship of science, foreign policy and government, and its necessary impact on the democratic way of life that we are determined to defend and advance, might well be summed up in the words of the late President John F. Kennedy, when he spoke in October 1963 at the centennial of the founding of the U.S. National Academy of Sciences:

"I think", he said, "that never in the . . . history of science has the time been brighter, the need been greater, for the co-operation between those of us who work in government, and those of you who may work . . . in laboratories."

STRUCTURE OF GLYCERALDEHYDE-3-PHOSPHATE DEHYDROGENASE

STRUCTURAL SYMMETRY WITHIN THE MOLECULE

By Dr. H. C. WATSON and Dr. L. J. BANASZAK

Medical Research Council Laboratory of Molecular Biology, University Postgraduate Medical School, Cambridge

GLYCERALDEHYDE - 3 - phosphate dehydrogenase (GPDH) is an important enzyme in intermediary metabolism where its function is to catalyse the oxidation and subsequent phosphorylation of aldehyde substrates to the corresponding acyl phosphates[1].

$$R - CHO + NAD^+ + HPO_4^{2-} \rightleftharpoons R - CO - OPO_3^{2-} + NADH + H^+$$

This enzyme has now been prepared in pure crystalline form from yeast[2] and skeletal muscle[3] with molecular weights reported to vary from 118,000 to 150,000[1]. Recent chemical work has shown that enzymatically active GPDH is composed of four chemically similar if not identical sub-units of molecular weight about 35,000[4]. Each sub-unit binds up to one molecule of the coenzyme nicotinamide adenine dinucleotide (NAD^+)[5] and contains four free sulphydryl groups one of which is highly reactive and participates in the enzymatic reaction[6]. These chemical and physical properties suggest that this enzyme might be amenable to detailed crystallographic analysis.

So far crystals of pig, rabbit, lobster and yeast GPDH have been prepared, but only the lobster GPDH crystals have been found suitable for extensive X-ray diffraction work. Crystals of the enzyme inhibited with *para*-chloromercuric-benzoate (PCMB)[7] are isomorphous with the native enzyme, but crystals grown from a solution containing inhibited enzyme in the presence of excess PCMB are quite different. The molecular arrangement in this new crystal form requires that the molecules lie on dyad axes. The molecule therefore has two structurally identical halves each related to the other by a two-fold symmetry axis.

Separation and Purification of Lobster GPDH

The procedure adopted for the separation and purification of lobster GPDH is similar to that described by Allison and Kaplan[8]. The tails are taken from the live lobsters and frozen. The shells are removed from the tails and the muscle washed, minced and extracted with a solution of 0·001 M versene, 0·001 M β-mercaptoethanol. The soluble protein extract is separated from the mixture by centrifugation. Solid ammonium sulphate is added to the supernatant until the salt concentration reaches 50 per cent saturation. The precipitate is discarded and the supernatant saturated with ammonium sulphate. The precipitate containing GPDH is removed by filtration, dissolved and dialysed against 0·001 M versene, 0·001 M β-mercaptoethanol and recrystallized at least three times from 75 per cent saturated ammonium sulphate solution.

The activity of the enzyme is measured by observing the change in absorption at 340 mμ due to the conversion of NAD^+ to NADH in the presence of a substrate of mixed triosephosphate esters and arsenate.

This preparative procedure yields approximately one gram of pure crystalline GPDH for each kilogram of wet lobster muscle.

Crystals of the Native Enzyme

Crystals of GPDH grown at room temperature from a 3·0 M ammonium sulphate, 0·001 M versene, 0·001 mercaptoethanol solution (*p*H 5·5) are shown in Fig. 1. The crystals are optically biaxial and invariably grow with the {100} faces well developed.

X-ray diffraction photographs recorded using copper $K\alpha$ radiation show that the crystals are orthorhombic with space group $P2_12_12_1$. The $0kl$ and $hk0$ sections of

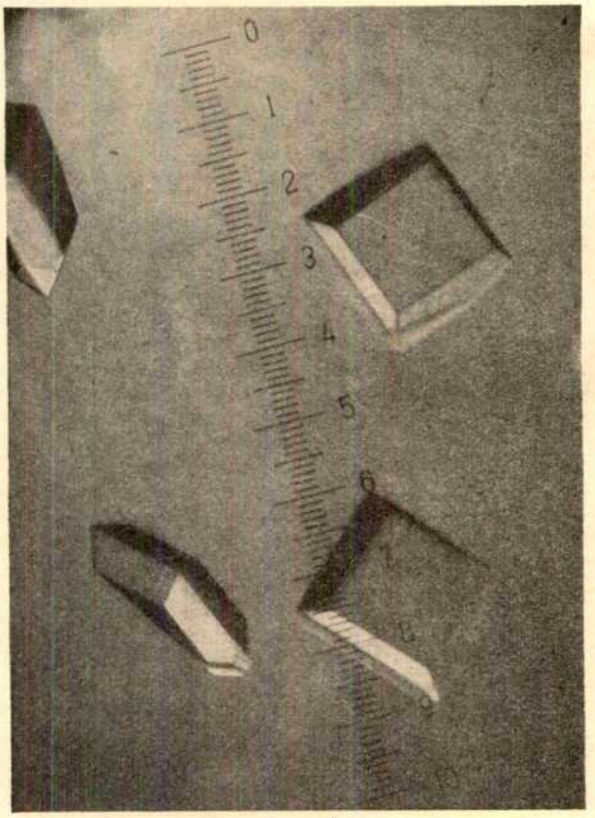

Fig. 1. Photomicrograph of crystals of native lobster GPDH. Each numbered scale division corresponds to 0·25 mm

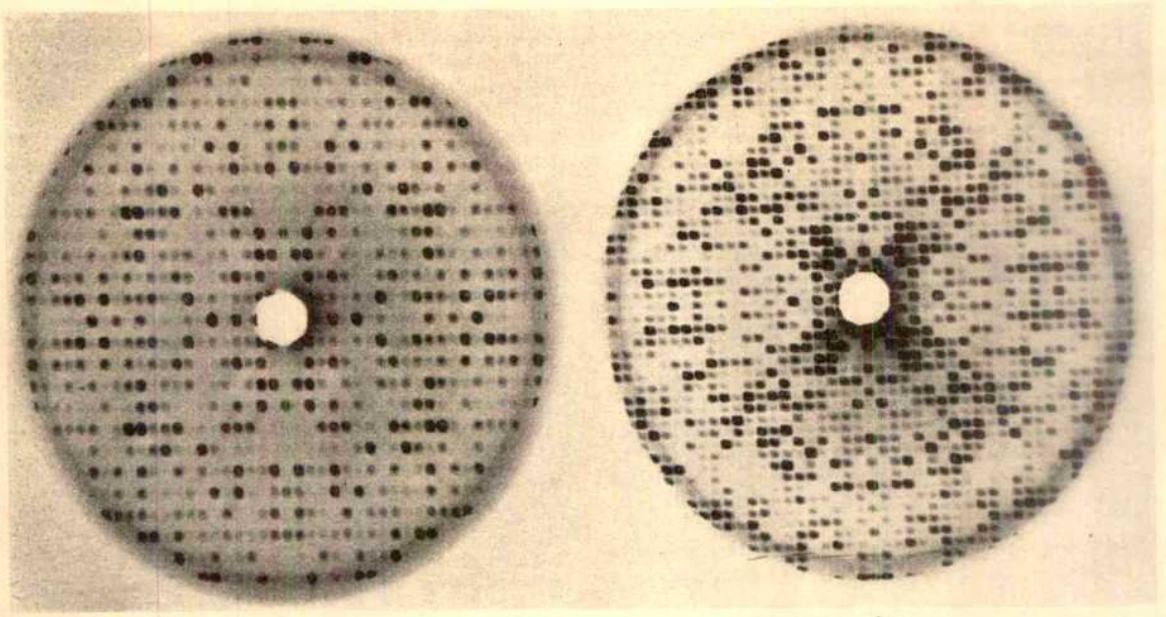

Fig. 2. Two X-ray diffraction photographs of native lobster GPDH. (*a*) the 0*kl* reciprocal lattice section; (*b*) the *hk*0 reciprocal lattice section. Both photographs are orientated with the b^* axis horizontal and contain reflexions to spacings which correspond to 6·3 Å resolution

the diffraction pattern shown in Fig. 2 indicate, at low resolution, the presence of a pseudo four-fold screw axis parallel to [001].

The unit cell dimensions are:

$a = 149 \pm 1$ $b = 140 \pm 1$ $c = 80{\cdot}5 \pm 0{\cdot}5$ Å

The volume of unit cell is: $1{\cdot}68 \times 10^6 \pm 5 \times 10^4$ Å^3

The diffraction pattern extends to spacings corresponding to a resolution of approximately 2 Å. The crystalline enzyme therefore has a defined structure extending to interatomic distances.

The density of the wet crystals as measured by flotation in a bromobenzene–xylene mixture is $1{\cdot}243 \pm 0{\cdot}002$ g/c.c., while the mother liquor is $1{\cdot}192 \pm 0{\cdot}001$ g/c.c. If a value of 0·75 c.c./g is assumed for the partial specific volume[9] and a molecular weight of 140,000[4] is used, the number of molecules in the unit cell is calculated to be 3·49. Since molecules in the space group $P2_12_12_1$ cannot be placed in special positions, the number of molecules in each unit cell must be a multiple of four. The crystals of native lobster GPDH therefore contain four molecules of approximately 140,000 molecular weight per unit cell.

The pseudo-space group $P4_12_12$ or $P4_32_12$ has eight non-equivalent positions[10] and therefore requires the four molecules in the unit cell to be placed on the space group's dyad axes. This restriction implies that, to within the limits of the pseudo symmetry, the molecules of GPDH have at least two structurally similar units and that these units are related by a two-fold symmetry axis.

Crystals of the PCMB-inhibited Enzyme

When four moles of PCMB per mole of protein are added to a versene, β-mercaptoethanol-free solution of lobster GPDH the enzymatic activity of the protein is reduced to less than one-hundredth of its former value. Crystals of the inhibited enzyme grow from a 3·0 M ammonium sulphate solution under conditions similar to those used for growing the native crystals. X-ray diffraction photographs show that these crystals are isomorphous with the enzymatically active GPDH crystals.

Crystals of lobster GPDH grown in the presence of thirty-two moles of PCMB per mole of protein are quite different from the native enzyme crystals. They are optically biaxial, rhombohedral plates with the {001} faces well developed. The crystals invariably appear with a dividing crack perpendicular to [001]. X-ray diffraction photographs show that these crystals are orthorhombic with space group $C222_1$.

The unit cell dimensions are:

$a = 94 \pm 1$ $b = 130 \pm 2$ $c = 137 \pm 2$Å

The volume of unit cell is: $1{\cdot}67 \times 10^6 \pm 6 \times 10^4$ Å^3

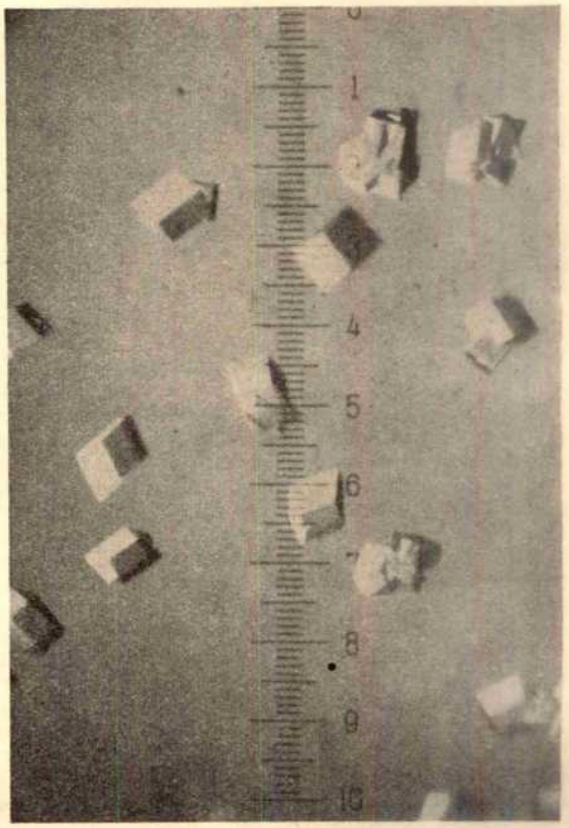

Fig. 3. Photomicrograph of crystals of the PCMB loaded GPDH. Each numbered scale division corresponds to 0·25 mm

Native GPDH crystals rapidly deteriorate when soaked in a large excess of PCMB, and small rhombohedral plate crystals are eventually formed.

The density of the wet rhombohedral plate crystals, as measured by flotation, is $1{\cdot}250 \pm 0{\cdot}003$ g/c.c. and the density of the mother liquor $1{\cdot}201 \pm 0{\cdot}002$ g/c.c. If values of 0·75 c.c./g and 140,000 are again used for the partial specific volume and molecular weight respectively, the number of molecules in each unit cell is found by calculation to be 3·50. Since the space group $C222_1$ has eight non-equivalent positions[10], the unit cell of the PCMB 'loaded' crystals must contain four molecules and these molecules must be placed on the space group's dyad axes.

Discussion

Chemical studies have shown that molecules of enzymatically active rabbit GPDH are composed of four similar if not identical sub-units[4]. Comparative investigations of rabbit, pig, yeast[11] and lobster[12] GPDH's indicate that these enzymes have similar sub-unit structures.

The crystallographical data presented in this communication indicate that the lobster GPDH molecule possesses at least one two-fold symmetry axis. The combined chemical and crystallographical results suggests that the lobster GPDH and, by inference, other glyceraldehyde-3-phosphate dehydrogenase molecules contain two pairs of chemically and structurally equivalent sub-units.

The sub-unit structure of GPDH is therefore analogous to that found for hæmoglobin[13] where two identical pairs of sub-units are related to one another by a two-fold symmetry axis. If, however, the sub-units of GPDH are identical, as the chemical evidence suggests[4,14], then the existence of the molecular dyad axis may represent only a partial expression of the full symmetry of a regular tetrahedral arrangement of sub-units.

Further crystallographical work on this enzyme is in progress. It is hoped that the active centre labelled PCMB derivative and an NAD^+ heavy atom analogue will be of use as isomorphous heavy atom derivatives.

We thank Dr. I. Harris for directing to our attention the GPDH enzyme and Dr. W. Allison for technical information concerning the preparation of the lobster enzyme. One of us (L. J. B.) thanks the U.S. National Institutes of Health for a post-doctoral fellowship.

IMPERIAL CHEMICAL INDUSTRIES, LTD.

PETROCHEMICAL AND POLYMER LABORATORY

IT is now some two years since Imperial Chemical Industries, Ltd., announced the formation of a central research laboratory to supplement the research already being carried out by the manufacturing divisions of the Company, particularly the longer range research in the two fields of petrochemicals and polymers, both of which are obvious growth areas for the chemical industry. The establishment of the Laboratory is now well advanced and its pattern is therefore beginning to emerge. Before describing this pattern, however, it will be useful to fill in the background by summarizing the reasons for the decision to set up the Laboratory, and the plans which were made once that decision was taken.

The total research effort of the divisions of Imperial Chemical Industries, Ltd., is, of course, extremely substantial, and has already resulted in many inventions and developments. Moreover, each division carries out in the fields of interest to it a complete range of research from the long-term, such as might be carried out in any good university department, to the short-term investigations required for its day-to-day business. It may well be asked, therefore, why a central research laboratory was needed in addition to the massive forces already deployed. The answer is two-fold. First, as every research manager knows, when long- and short-term research are going on side by side in the same department, the long-range research always tends to be eroded by the pressures of shorter-term work or other urgent problems. Secondly, without a central research laboratory, there was no easy mechanism for Imperial Chemical Industries, Ltd., to start research in a completely new area outside the existing interests of any of the component divisions. These reasons led to the concept of the Petrochemical and Polymer Laboratory as a source of research effort comparatively free from short-term pressures, able to supplement divisional research effort at points of particular need, to look outside the existing interests of the Company, and also to tackle problems running across division boundaries.

The Petrochemical and Polymer Laboratory is not intended to be in any sense an academic institution; it is very much part of Imperial Chemical Industries, Ltd., and good communications between it and the rest of the Company are as important to it as good science and technology. This in fact is one of the reasons why the chosen site was Runcorn Heath, alongside the Research Department and Headquarters of the Mond Division, one of the biggest and most active of the Company (Fig. 1). Here the staff of the Laboratory has the advantage of daily contact with their colleagues in the Mond Division Research Department, and they are also within a hundred miles of five other divisions of Imperial Chemical Industries, Ltd.

Turning now to staff, the aim was to acquire about 100 graduates, about twice that number of junior supporting staff, and about 10 managers (plus administrative staff). Studies of the balance between disciplines indicated that the 100 research workers would be made up roughly of 55 chemists, 33 physicists, and 12 engineers; in fact the Laboratory is now more than half-way to this target, and may well be at nearly full strength by the end of this year. The staff is divided between five groups of varying sizes, known respectively as the New Chemistry, New Polymers, Materials Science, Molecular Structure, and Engineering Groups. These titles indicate clearly and correctly that a considerable proportion of the effort of the Laboratory will be spent on work other than chemical research. Much of this other work will be

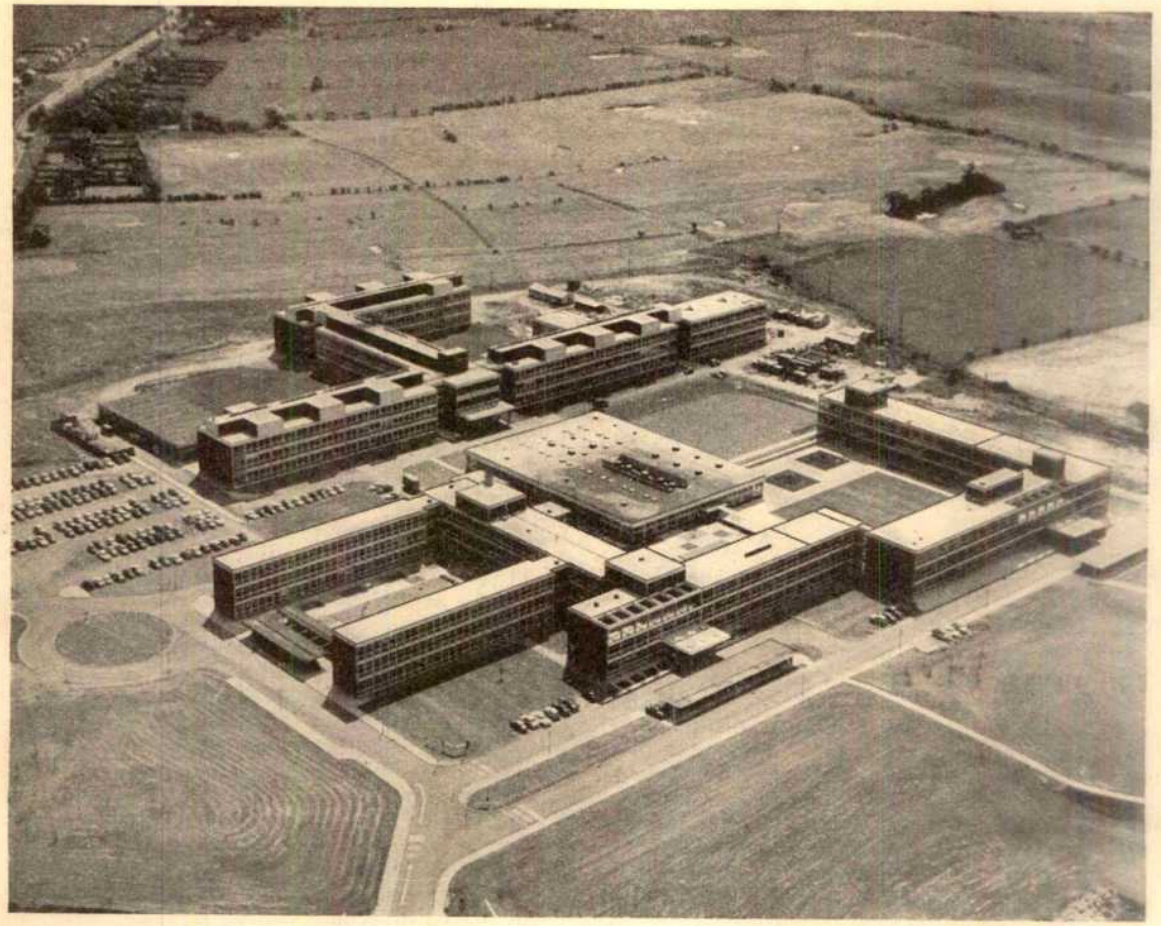

Fig. 1. Imperial Chemical Industries, Ltd., Runcorn Heath, with the research complex in the background

physical in nature, but physics applied in several very different fields. First there will be the use of physical techniques of all sorts for the investigation of molecular structure and for quantitative analysis (Molecular Structure Group); then there will be work on polymer physics and on the physical properties of solids in general (Materials Science Group); and the third field will be that of polymer application research, in other words of research into new methods of using or fabricating polymers, either new or existing ones (Engineering Group). Success in this field could be just as rewarding as a chemical invention; indeed, in the case of a polymer with valuable properties but incapable of being used by existing processes, the chemical invention might be sterile without the accompanying invention of a method of fabricating it. It is therefore considered vital for the chemists doing long-term speculative research to have alongside them people skilled on the application side, who will be constantly on the look-out for potentially valuable results, and who, from their knowledge of a wide range of technologies, could spot commercially promising developments at a very early stage. In fact, there should be a continuous interaction between these people and the chemists right from the initial choice of research topics, for while narrowly targeted research is not the Laboratory's function, equally it cannot afford to undertake all its research without ever considering possible end uses. The Laboratory must also ensure patent protection for its results by having its own patents section.

So far as equipment is concerned, one or two points are worth making. First, it is obvious now that infra-red spectrometers and gas liquid chromatography columns are as much standard tools for organic chemists as melting-point apparatuses used to be, and provision for such pieces of equipment has been made accordingly. Secondly, so far as physical equipment for the investigation of molecular structure is concerned, the Laboratory either has, or has access to on the site, a very complete range. It is, incidentally, the intention that the specialists working with these elaborate physical techniques such as nuclear magnetic resonance, electron-spin resonance, mass spectrometry, etc., will not only use their existing equipment to solve problems brought to them by the chemists, but will also carry on their own research into their particular fields with the view of extending the power and usefulness of those techniques.

The overall planning of the Runcorn Heath site was the responsibility of Frederick Gibberd and Partners; but the internal planning of the Mond Division and Petrochemical and Polymer Laboratories was based on experience within Imperial Chemical Industries, Ltd. The complete research complex consists of six buildings—three belonging to the Mond Division and three to the Petrochemical and Polymer Laboratory—all being linked at all levels to ensure close day-to-day contact between both the various disciplines and the two research organizations.

The three buildings of the Petrochemical and Polymer Laboratory consist of a chemistry block housing some 50 graduates, a physics block for 25, and an engineering or application block for 10–12 graduate research workers. The chemistry building, which was completed and occupied in early 1964, has three floors with a total floor area of some 30,000 sq. ft. A corridor runs the length of the building on each floor, the offices being on one side and laboratories on the other. These laboratories are of fairly normal design; each is intended for four graduates and their associated junior staff, having four large island benches with a number of side benches and generous provision of fume cupboards. There is a positive supply

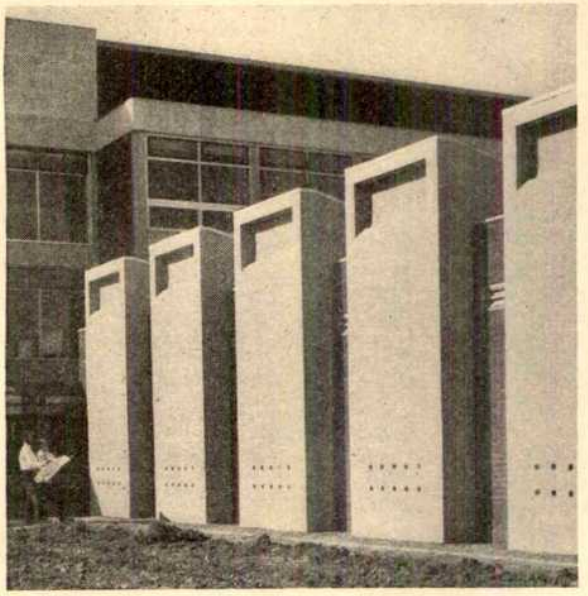

Fig. 2. Autoclave annexe showing reinforced concrete cubicles

of heated replacement air which is sufficient to allow the construction of further fume hoods. At one end of the chemistry building there is a 'tall apparatus area'. This is a 36-ft. high space occupied by a staircase with two landings, the floors of the landings being readily removable so that the full height of the building can be used if required.

The physics building, recently completed, is of the same height as the chemistry building but initially of only half its length. Since there is no longer the same need for plentiful fume cupboards and service provision, the internal layout is rather different, being designed to cater for the larger space and greater power requirements of the physicist. The unit laboratory, of which there are four per floor, is a 2-graduate unit some 38 ft. × 24 ft. overlooked by offices for the technical staff. There is no corridor as such, but a notional 5 ft. outside the offices is reserved for traffic.

The engineering building, also recently completed, is a single storey one basically designed to give a large interior space without obstruction and an 18-ft. high roof, in which can be placed or built any engineering apparatus which is necessary. This open space is overlooked by a double tier of offices at one end and is capable of extension by doubling its length. Outside the building, and along one of its sides, has been built the autoclave annexe. This contains eleven cubicles, six of steel and five of reinforced concrete, in which moderate pressure experiments can be carried out with maximum safety (Fig. 2). There is provision for remote control of the experiments and for the release of any pressure or fume generated in the cubicles. Nevertheless, the autoclave annexe is not intended for very hazardous or very high-pressure work; other more suitable sites are available, for example the Winnington Laboratories of the Mond Division some twelve miles away, where there is a wealth of experience of, and very good facilities for, work at really high pressures.

So far as the real purpose of establishing the Imperial Chemical Industries, Ltd., Petrochemical and Polymer Laboratory is concerned, it will of course be obvious from what has been said here that so far only the foundations have been laid. The laboratory is now entering on the period when the plans by which it has been shaped, both in terms of buildings and staff, will be really tested by the stern criterion of success or failure in inventing new products and processes for Imperial Chemical Industries, Ltd. Unfortunately, all those engaged in speculative research know only too well that no amount of planning can guarantee success; chance must play a part. However, one can at least attempt to reduce to a minimum the part played by chance in bringing about success, and this has been the aim throughout in planning and establishing the Petrochemical and Polymer Laboratory.

NEWS and VIEWS

The Advisory Council on Technology

The following have been appointed members of the Advisory Council on Technology under the chairmanship of Mr. Frank Cousins, Minister of Technology: Sir Leon Bagrit, chairman and managing director of Elliott-Automation, Ltd.; Mr. W. B. D. Brown, chairman of the Glacier Metal Co., Ltd.; Sir William Carron, president of the Amalgamated Engineering Union; Mr. C. F. Carter, vice-chancellor of the University of Lancaster; Dr. S. C. Curran, principal and vice-chancellor of the University of Strathclyde; Sir Arnold Hall, managing director and vice-chairman of the Hawker Siddeley Group and vice-chairman of Bristol Siddeley Engines; Mr. C. F. Kearton, chairman of Courtaulds, Ltd.; Prof. M. J. Lighthill, Royal Society research professor at the Imperial College of Science and Technology, and formerly director of the Royal Aircraft Establishment, Farnborough; Lord Nelson of Stafford, chairman and chief executive of the English Electric Co., Ltd.; and Mr. H. C. Tett, chairman of Esso Petroleum Co., Ltd. Prof. P. M. S. Blackett, professor of physics in the Imperial College of Science and Technology, is deputy chairman.

The 1964 Nobel Prize for Chemistry : Prof. Dorothy Crowfoot Hodgkin, F.R.S.

The work for which Prof. Dorothy Crowfoot Hodgkin was awarded the 1964 Nobel Prize for Chemistry consists of a remarkably coherent and well-planned series of investigations covering the whole field of organic structures of medical and biological importance. In 1932, when she started her work in Cambridge, all that X-rays could do was to confirm or correct formulæ arrived at by essentially organic chemical methods. Prof. Hodgkin's achievements lay in her transcending these limitations and making the X-ray method one of the major tools for the complete analysis down to accurate atomic positions. All the way through, her work was characterized by a consciously evolved strategy of analysis which showed itself both in the choice of the crystals to be examined and the crystallographic methods successively evolved to study them. She began with the sterols and combined extensive, comparative method with intensive, accurate structural investigations of selected crystals, notably those of calciferol and lumisterol. The structure of cholesterol iodide, which she carried out with Dr. C. H. Carlisle, was, in fact, the first complex organic structure without molecular symmetry to be analysed completely by X-rays. She was also at the very beginning of the X-ray analysis of proteins, and was the first to show that the insulin molecule, and, by extension, those of all proteins, possessed a rigid inner structure independent of the state of hydration.

On her return to Oxford she continued with a more definite bias towards molecules of physiological and medical importance. Her first great triumph was the elucidation with Bunn and others of the structure of penicillin, with 17 atoms in the molecule, in advance of

the chemical evidence. The next important molecule she attempted was to lead to her greatest triumph, the structure of vitamin B_{12}, the anti-pernicious anæmia factor. It was here that she was able to show how a knowledge of, and, better still, a feeling for, chemistry could be combined with the most refined physical analytical techniques. Her series of papers on this structure will always be a model of a tactical approach to a formidable problem. Her step-by-step advance, beginning with the recognition of the planar porphyrinoid ground around the cobalt atom, continued atom by atom until it included the whole closed loop, through the propanolamine and nucleotide group, which linked it ultimately with the cobalt atom itself. The completion of this work included the precise location of more than ninety atoms and is the present 'high-water mark' of crystallographic analysis. In establishing it, Prof. Hodgkin's work has set a new standard in X-ray analysis methods and has shown the way by which successively more difficult structures can be attacked.

The 1964 Nobel Prize for Physics

THE 1964 Nobel Prize for Physics is shared: one half has been awarded to Prof. Charles H. Townes, provost of the Massachusetts Institute of Technology, and the other half jointly to Prof. Nikolai G. Basov and Prof. Aleksandr M. Prokhorov, of the U.S.S.R. Academy of Sciences Lebedev Institute of Physics. The prize is awarded for work in the field of quantum electronics which led to the development of the micro-wave maser, and later to the laser.

Prof. Charles H. Townes

Prof. Charles H. Townes, who is forty-nine, obtained his bachelor's degrees at Furman University, South Carolina, and his M.A. at Duke University, North Carolina. He worked for his Ph.D. at the California Institute of Technology, and in 1939 joined the Bell Telephone Laboratories, where he remained until he was appointed professor of physics at Columbia University in 1947. Here he directed his attention to the problem of generating coherent radiation by using transitions between the energy-levels of molecules. The method, used in 1953 in the first maser, was based on the stimulated emission of radiation from excited ammonia molecules at a wave-length close to 1·25 cm. This maser was novel in two respects: its very low noise when used as an amplifier, and its high-frequency stability as an oscillator.

Prof. Nikolai G. Basov and Prof. Aleksandr M. Prokhorov

Profs. Nikolai G. Basov and Aleksandr M. Prokhorov developed independently an almost identical maser at the Lebedev Institute. Prof. Basov is a graduate of the Moscow Engineering and Physics Institute. He is forty-two and is at present deputy director of the Lebedev Institute. Prof. Prokhorov was born in Australia in 1916. After attending Leningrad State University he served in the Soviet Army during the Second World War and then joined the Lebedev Institute, where he became chief of the Oscillation Laboratory in 1954. He was awarded the Lenin Prize in 1959. Profs. Basov and Prokhorov are both corresponding members of the U.S.S.R. Academy of Sciences.

The operation of the first micro-wave masers evoked widespread interest in the application of the maser principle, and led to the development of the optical maser, or laser. This device was first discussed in detail in a paper published by Townes and Schawlow in 1958, and a little later Basov was among the first to suggest the use of stimulated emission in semiconductors as a means of generating coherent radiation.

Ministry of Aviation Chief Scientist : Dr. W. Cawood, C.B.E.

DR. W. CAWOOD has been appointed chief scientist of the Ministry of Aviation in succession to Sir Robert Cockburn, who has been appointed director of the Royal Aircraft Establishment, Farnborough (*Nature*, 204, 127; 1964). Dr. Cawood has been chief scientist of the Ministry of Defence (Army Department) since September 1960. He was born at Leeds in 1907 and educated at Archbishop Holgate's School, York, and the University of Leeds. During the period 1928–38, while engaged on research work, he produced many scientific papers on the physical properties of aerosols, the theory of coagulation, etc. In 1937 he was a member of the League of Nations International Atomic Weights Committee. He entered the Scientific Civil Service in 1938 and served for some eight years in the Headquarters Armament and Instrument Research and Development Branches of the Air Ministry and Ministry of Aircraft Production, becoming deputy director of armament research in 1945. He was promoted to chief scientific officer in April 1947, and served as deputy director of the Royal Aircraft Establishment until February 1953, when he was appointed principal director of scientific research (defence) of the Ministry of Supply. Some two years later he became principal director of scientific research (air) (later director-general of scientific research (air)); and in March 1958 he was appointed deputy controller of aircraft research and development. Two and a half years later he was transferred to the post of chief scientist of the War Office (now Ministry of Defence (Army Department)). His new appointment took effect as from November 30.

Head of Agricultural Bacteriology Division of the Ministry of Agriculture: Dr. J. G. Murray

DR. J. G. MURRAY has been appointed head of the Agricultural Bacteriology Division of the Ministry of Agriculture, and took up his new duties on November 1. Dr. Murray, who was born in Derrytrasna, Lurgan, was educated at Lurgan College and Greenmount Agricultral College, before entering Queen's University, Belfast, in 1934. After graduation, he joined the Ministry of Agriculture as an advisory officer, working mainly with the Milk Section. Since 1943 he has been a member of the research staff of the Ministry's Agricultural Bacteriology Division. He now also becomes head of the Agricultural Bacteriology Department at Queen's University. Dr. Murray is a member of the Council of the Society of Dairy Technology, a committee member of the Society of Applied Bacteriology and a member of two committees of the British Standards Institute. His particular research interest is the bacteriology of processed foods—especially milk and dairy products.

Meeting of Panel on WMO Development Fund

THE Panel of the Executive Committee of the World Meteorological Organization, established to approve projects for implementation in 1965 under the new WMO Development Fund, held a meeting at the Headquarters of WMO in Geneva, in November. The new Meteorological Development Fund of U.S. dollars 1,500,000 was established by the Fourth World Meteorological Congress in 1963 in order to enable significant and prompt assistance to be rendered to members during the period 1965–67. Its general purpose is that full advantage be derived from the opportunities which now present themselves for the improvement of man's basic understanding of the atmospheric processes. A plan for the operation of the new fund was approved by member governments earlier in the year, and assistance is to be made available in the following fields: (*a*) telecommunications facilities; (*b*) observational facilities (including those relating not only to conventional observations but also to APT and other satellite installations, automatic weather stations, ocean

weather ships and upper-air observations from merchant ships); (*c*) meteorological data processing, including electronic computers; (*d*) education and training; (*e*) any other activities related to the planning, establishment and operation of world, regional and national centres under the World Weather Watch not covered by the preceding items.

Wellcome Trust Grant for Research in Chemotherapy

THE Wellcome Trust is to make a grant of £30,000 to the Sir William Dunn School of Pathology at the University of Oxford. This will meet part of the cost of a new building and provide space for the work of Prof. E. P. Abraham on naturally occurring substances of biological and medical interest. In recent years Prof. Abraham's group has succeeded in isolating cephalosporin *C*, in determining its structure and in showing that a family of compounds of varying biological activity can be obtained from its nucleus. Members of this family promise to be of value in the treatment of penicillin-resistant staphylococcal infections and infections by bacteria from the intestinal tract. The grant will meet part of the cost of constructing an additional floor especially for the use of Prof. Abraham. The building will also house a new Medical Research Council Cellular Immunology Research Unit under the direction of Prof. J. L. Gowans, Henry Dale professor of the Royal Society.

The South African Institute for Medical Research

THE annual report of the South African Institute for Medical Research for the year 1962 records in impressive detail the very wide range of research being done by its staff all over South Africa (Johannesburg: South African Institute for Medical Research, 1964). Directed by Dr. J. H. S. Gear, the Institute not only conducts detailed research into many fields of medical investigation, but also provides a medical laboratory service for provincial hospitals in every part of South Africa and co-operates with such organizations as the World Health Organization and the U.S. Public Health Service. The report discusses this immense range of beneficent work under six main headings. The first of these is devoted to administration. The second and longest section deals with the work of the Research and Routine Division and covers almost every important field of medical research. The third section deals with the work of the Serum and Vaccine Division on diphtheria, typhoid, *Staphylococcus*, tetanus, gas gangrene, venoms and anti-venoms. The fourth section discusses the regional medical laboratory service, the fifth deals with research on pneumoconiosis, and the sixth the work of the Poliomyelitis Research Foundation. Like other publications of this kind, the report indicates, to those who read between the lines, not only the incalculable human suffering caused by disease, but also the devotion and industry of the many workers who are dedicating their lives to the alleviation and prevention of this suffering.

The Corrosion and Protection Association

A CORROSION and Protection Association has been established as an independent and comprehensive organization to embrace all aspects of corrosion and protection science and practice. It is intended that the Association shall serve the interests of all who are engaged in corrosion or protection work, and will not seek to rival existing groups, but rather to supplement them. It will especially strive to bring the latest advances before practising engineers, and its official journal will be *Corrosion Science*, which, in its new enlarged form, appearing monthly, will include sections devoted to research papers, present and future practice, and general information. Special terms for subscriptions to the journal will be available to members of the Corrosion and Protection Association. The inaugural meeting of the Association will be held at 2 p.m. on December 30 at the Sir John Cass College, Jewry Street, London, E.C.3. The business will be to adopt a constitution and to elect a Council and officers. Membership (£1 per annum) is open to all persons with scientific, technological, practical or commercial interests in corrosion and protection, and further information and forms of application for membership can be obtained from Dr. T. P. Hoar, Department of Metallurgy, Pembroke Street, Cambridge; Prof. T. K. Ross, Manchester College of Science and Technology; or Dr. L. L. Shreir, Sir John Cass College, Jewry Street, London, E.C.3.

Market Research

THE latest Library Association *Special Subject List* (No. 44) is *Market Research*, by D. C. Fanning (London: The Library Association, 1964. 5*s*.). A foreword by Viscount Chandos, president of the Market Research Society, shows how capital expenditure on industrial plant and building is generally decided by the results of market research: such factors as high rates of money at a given date are often over-stressed. Since a new plant frequently takes more than three years to bring into production, it is the size and nature of the market three years hence that are the primary considerations, and market research is the examination of these two subjects, projected three years ahead. The book list indicates directories and bibliographies as well as specific books on market research, motivation research, industrial market research, media research, techniques and methods, general text-books and periodicals. It will be useful to all concerned with market research in any of its many forms.

Wild-life Conservation

Oryx, the journal of the Fauna Preservation Society, continues to improve under its new editor. Conservation news from all parts of the world is well presented in Vol. VII, No. 5, August 1964, and a number of articles deal with special aspects of the subject. The most important is one by Dr. Fraser Darling on the ethical and technical problems of wild-life conservation, in which he emphasizes that animals and plants exist in an environment which is not merely physical or climatic but biotic and social. He gives a reasoned argument on the necessity for the management of wild-life in a world largely claimed by man for his own immediate needs, and shows the importance of controlling the numbers of wild animals in certain circumstances so that they shall not destroy their own environment. He does not, however, point out the obvious conclusion that man himself must control his numbers and bring himself into an ecological balance with his environment.

Clonal Selection Theory of Immunity

SIR MACFARLANE BURNET of the Walter and Eliza Hall Institute of Medical Research, Melbourne, writing in the *Australian Journal of Science* (vol. 27, July 1964), has described a Darwinian modification to the clonal selection theory of immunity. In the seven years since the clonal selection theory of immunity was first outlined a great deal of research has been concerned with testing its implications. The results can be summarized as being incompatible with the rather rigid form of the theory which postulates that all immunological patterns are normally present at the time of birth. On the other hand, there has been a striking swing away from the classical 'instructive' theories of antibody production to an acceptance of the central point of the clonal selection approach, that the pattern of antibody and of cell reactivity is determined wholly by genetic processes. The work of Gowans, in particular, has resulted in the establishment of the small lymphocyte as the commonest immunologically competent cell, and there appears now to be no controversy as to the importance of specific stimulation of immunologically

competent cells by antigen, or antigen derivatives, in inducing the change of small lymphocyte to pyrininophil stem cells, and the initiation of germinal centres or of plasma cell clones producing antibody. Present points of difficulty are related to the generation of the essentially unlimited range of immunological patterns by genetic (or somatic-genetic) processes; the range of potential immune reactivity of a lymphoid stem cell, and the possibility of transfor of genetic (immunological) information from one cell line to another. The essential modification of the original theory accepts the existence of frequent somatic mutation in all body cell lines at all periods of life and underlines the great significance of minor genetic change, possibly involving no more than the substitution of one amino-acid for another, in relation to the modern picture of γ-globulin structure. Equally we must accept as before the continuance of selective processes throughout life, both negative selection involving destruction or inhibition of physiologically immature cells reacting with antigen in relatively high concentration and positive selection for proliferation and antibody production following contact with antigen under other circumstances.

Woolgorong Stony Meteorite

NUMEROUS fragments of a stony meteorite were recovered from Woolgorong Station, north-east of Wullewa, in Western Australia, approximately 300 miles north of Perth, in 1961. This find almost certainly represents a possible fall noted in this locality in December 1960. A double report was heard at the time, but G. J. H. McCall and P. M. Jeffrey, writing in the *Journal of the Royal Society of Western Australia* (Vol. 47), consider that this does not necessarily imply a multiple fall, since phenomena of this kind are generally attributed to compression wave effects in the atmosphere. The meteorite is a veined and brecciated, grey hypersthene-olivine chondrite, Prior's class III, and shows evidence of pronounced recrystallization. Recovery of fragments from shallow burial in the soil, and from the surface, has allowed a confident reconstruction to be made. There is evidence that it had an aerodynamically stable form under conditions of atmospheric entry, since surface patterns and the distribution of thickened and thinned fusion-crust reveal a distinct orientation. Such orientation supports the idea that this was a single fall, complicated only by fragmentation at or near the point of impact.

Microscopic investigation has revealed considerable structural variation, some areas revealing well-formed, though recrystallized, chondrules. Others show almost complete recrystallization to a granular aggregate of polysomatic and larger fractured grains. In these areas of recrystallization the chondrular structure is only vaguely defined. Chemical tests, etch-tests, X-ray diffraction examinations and two full chemical analyses have been carried out, and the minerals determined include kamacite, iron sulphide (troilite ?), olivine (chrysolite-hyalosiderite), orthopyroxene, oligoclase, and possibly a calcium silicate (rankinite ?).

University News :

Aberdeen

THE following appointments to lectureships have been announced: Dr. W. Welsh (geology); Dr. M. N. Court (soil science).

Leeds

THE following appointments to lectureships have been announced: C. R. Abbott (pathology, with special reference to hæmatology); Dr. J. W. Taylor (gas engineering and general fuel science).

London

DR. JOHN ANDERSON, reader in medicine at King's College Hospital Medical School, has been appointed to the chair of medicine tenable at that school. Dr. P. N. Rowe, principal scientific officer in Chemical Engineering Division, Atomic Energy Research Establishment, Harwell, has been appointed to the Ramsay Memorial chair of chemical engineering tenable at University College from October 1. Dr. Kenneth Smith, of the Argonne Laboratory, has been appointed to the readership in mathematics tenable at Royal Holloway College.

Sussex

THE prospectus for 1964–65 of the University of Sussex gives particulars of the introduction of majors in philosophy in the School of African and Asian Studies; experimental psychology in the School of Biological Sciences; and social psychology in the School of Social Studies. Decisions regarding all three were taken too late for inclusion in the *Handbook of the Universities Central Council on Admissions*.

Eclipse of the Moon, December 19

THERE will be a total eclipse of the Moon on December 19, visible at Greenwich. The circumstances are:

Moon enters penumbra	Dec. 19d 00h 01m U.T.
Moon enters umbra	19d 00h 59m
Total eclipse begins	19d 02h 07m
Mid-eclipse	19d 02h 37m
Total eclipse ends	19d 03h 07m
Moon leaves umbra	19d 04h 15m
Moon leaves penumbra	19d 05h 14m
Magnitude of eclipse	1·18

Announcements

DR. E. J. DENTON, senior principal scientific officer at the Laboratory of the Marine Biological Association at Plymouth, has been appointed to a Royal Society research professorship at the University of Bristol. Dr. Denton, who took up his appointment as from October 1, 1964, will be attached to the University of Bristol but will continue to carry out most of his research work at the Plymouth Laboratory. Dr. Denton is distinguished for his contributions to the physiology of marine animals, in particular of their visual processes and maintenance of buoyancy.

THE Association of Commonwealth Universities has published, under the title *United Kingdom Postgraduate Awards, 1964–66*, information on such awards in a form suitable for quick reference. It does not include awards open to graduates of only one university, or those restricted to the academic staff of a single institution. A short list of awards tenable outside the United Kingdom by graduates of the United Kingdom is also included, and there are subject indexes to both lists, as well as an index to names.

A SYMPOSIUM on "Crustacea", under the auspices of the Marine Biological Association of India, will be held at Cochin during the second week of January. Further information can be obtained from the Convener of the symposium, Marine Biological Association of India, Marine Fisheries P.O., Mandapam Camp.

A SYMPOSIUM on "Morphogenesis and Differentiation in Relation to Cellular Fine Structure", arranged by the British Biophysical Society, will be held at the Imperial College of Science and Technology, London, during January 8–9. Further information can be obtained from Prof. R. E. Burge, Physics Department, Queen Elizabeth College, Campden Hill Road, London, W.8.

A JOINT meeting of the Biochemical Society and the Association of Clinical Biochemists will be held in Leeds during January 7–8. Colloquia on "Vitamin B_6 in Metabolism" and "Some Aspects of the Biochemistry of Protein and Peptide Hormones" will be held during the meeting. Further information can be obtained from the Meetings Secretary, Biochemical Society, 20 Park Crescent, London, W.1.

SCIENCE AND GOVERNMENT REORGANIZATION IN BRITAIN

A SENTENCE in The Queen's Speech at the opening of Parliament on November 3 stated that Britain's industries would be helped to gain the full benefits of advances in scientific research and applied technology. The Speech also announced that central and regional plans were being prepared to promote economic development, with special reference to the needs of the underemployed areas of the country. New arrangements (including the appointment of a Secretary of State for Wales, with a seat in the Cabinet, and a Minister of State, Welsh Office) would ensure that proper attention would be directed to the needs of Wales, and legislation would be introduced to provide for the appointment of a Highland Development Authority. Some light was thrown on these and other changes in the structure of the Government in the subsequent debate on the address to the Throne, although early in the debate Sir Alec Douglas-Home was critical of certain changes, particularly the fragmentation of the Treasury and some Ministries, such as the Ministry of Education and Science. He believed that to take the Ministry of Technology out of the latter Ministry was a real mistake.

Mr. R. Maxwell, in a maiden speech, however, welcomed the new Ministry of Technology, and also supported the proposal to review the *Concord* project. He referred to the backwardness of much of British industry in making use of science and technology as an aid to increased productivity, and suggested that one of the major obstacles was ineffective communication at various levels—between scientist and technologist and management, between industry and Government, between universities, colleges of technology and research associations. Like Lord Thomson of Fleet, Lord Melchett and Lord Boothby, in the corresponding debate in the House of Lords on November 5, he also emphasized the special importance of management. Lord Melchett, while agreeing as to the importance of efficient management and the structure of labour and management relations, questioned whether the establishment of a Department of Economic Affairs and a Ministry of Technology would do more than shift the emphasis and priorities within a system incapable of satisfactory rates of sustained growth. Nor did he think that the proposals for economic planning, the stimulation of science and technology, and the correction of assumed errors in past policies went to the roots of the matter. Mr. Maxwell, however, urged that the strength of our science depended on the initiative, imagination and intelligence of individual scientists and engineers, and thought that the Government's arrangements for organizing science and technology would meet the need.

Speaking in the debate on November 4, the Secretary of State for Economic Affairs, Mr. G. Brown, recognized the value of the work of the National Economic Development Council and said that it was the intention of the Department of Economic Affairs to take up the work of that Council, expand and develop it, and produce, in consultation with both sides of industry, through the Council, a plan for the next five years to guide the development of the economy and all the economic activities of the Government. Under the new policy the responsibility must be with the Government and in future this planning would be carried out in the Department of Economic Affairs, in close co-operation with the Treasury and other Departments concerned. Part of the staff of the Council's office had already joined his Department for this purpose, but there was a continuing need for an outside body. It was proposed to reconstitute the Council on much the same lines as it was based before with a membership of about twenty from Government, management and Trade Unions, with some independent members. Sir Robert Shone had been invited to continue as director-general. He thought that the regional councils would grow in importance and he was proposing that they should work in closer association with the Department of Economic Affairs and other Departments.

Mr. Brown then stated that the Government's regional economic plans would take their place within a coherent national framework, and effective means for consultation would be set up in the regions. The first major task was to fashion the national framework into which the detailed work of the regional investigations would fit, and this was one reason why the Government had started to modernize Whitehall. It was also intended that the regional plans should reflect regional needs, views and experience, and advisory regional councils would be set up with membership drawn from industry, local authorities, the universities, commerce and others concerned with strengthening and improving the fabric of regional life. These councils, to which the Government would look for considered and informed advice on regional problems, would participate in the examination and analysis which should precede sensible planning decisions and would work with regional planning boards consisting of representatives of the main social and economic departments. The chairmen of these boards would be appointed by the Secretary of State for Economic Affairs and each regional headquarters would have staff from that Department. The Secretary of State for Scotland would set up a Scottish planning council with similar functions and membership and the Scottish Development Group would be strengthened and constituted as a Scottish planning board. Similar arrangements would be made for Wales.

The resumed debate in the House of Commons on November 5 was concerned with technology. In opening the debate, Mr. Q. Hogg criticized particularly the decision to separate industrial and academic science as seen in the establishment of a Ministry of Technology and the Secretary of State for Education and Science. Mr. M. Stewart, who followed, pointed out that the previous Government had itself proposed to place the National Research Development Corporation with the Board of Trade, and went on to outline the new structure of the Department of Education and Science. This Department would include the Medical, the Agricultural and the new Science Research Councils. Some of the functions of the Department of Scientific and Industrial Research would be transferred to the new Science Research Council, which would also have responsibilities relating to the European Space Research Organization. A new National Environment Research Council would be established to bring together the activities of the Nature Conservancy, the Geological Survey and other groups of study including oceanography. There would also be the Advisory Council for Sciontific Policy, responsible, *inter alia*, for advising the Secretary of State on the allocation of resources between different fields of research.

The Ministry of Technology would assume the responsibility for the Atomic Energy Authority, the industrial side of the Department of Industrial and Scientific Research and the work now being done by the National Research Development Corporation. On the dissolution of the Department of Scientific and Industrial Research, Mr. Stewart pointed out that this was part of the previous Government's proposals, and although he did not refer to the Trend Report, as did Mr. E. Lubbock later in the debate, he did refer to the wide consultations between the late Government and all concerned with the proposed reorganization. He referred to the criticisms voiced by the Institution of Professional Civil Servants, though he did not point out as he might well have done, in view

of the extent to which the present proposals follow those of the Trend Report, that the demand for fresh consultation is largely specious. A government must take its own decisions once it is satisfied it has ascertained the facts and the views of those concerned. As to the status of members of the Institution under the new arrangements, he readily agreed as to the desirability of full consultation

In reply to specific questions, Mr. Stewart said that no decision had yet been taken regarding the National Physical Laboratory or as to whether there would be any change in the organization of the Atomic Energy Authority. He would not say yet whether the Committee on Scientific Manpower would continue as at present or whether separate committees would deal with technological and with scientific manpower. This was a matter which the Department of Education and Science and the Ministry of Technology would have to consider jointly. The Ministry of Technology would also be concerned with the development in the civilian field of the kind of research and development contract familiar in the field of defence. There would also be an Advisory Council on Technology with the Minister as chairman and Prof. P. M. S. Blackett as deputy chairman (see also p. 922 of this issue of *Nature*). Finally, there was a need to take a broader view of the educational process. It was necessary not only to provide a sufficient amount of skilled manpower but also to achieve in the population as a whole a general understanding of what a technological civilization meant.

This explanation of the Government's proposals was welcomed in a particularly well-informed speech by Mr. E. Lubbock, who asked what would be the role of the new Council of Engineering Institutions and whether they would be represented on the new Advisory Council: he thought it might well be a valuable source of advice. Otherwise there was little constructive comment in the debate, the main other topic being the future of the *Concord* project. This was raised by Mr. Lubbock and other speakers in relation to its effect on Britain's technology generally, and although it was originally raised by Mr. Q. Hogg, who also asked about Britain's support of the European Launcher Development Organization and the European Space Research Organization, Mr. Stewart left it to the Minister of Aviation, Mr. R. Jenkins, to reply in winding up the debate.

Sir Lionel Heald, who stressed the importance of the aircraft industry in Britain's technology, quoted Sir George Edwards's opinion that *Concord* represented the first full collaboration in such a venture by two great European powers and that it might be the first step to a world rationalization of the civil aviation effort. He was concerned as to the effect of discontinuing the *Concord* project on the other collaborative projects. Mr. N. Marten, like Mr. A. Neave and many others, was concerned about the future of the design teams and other workers in the industry if the project was discontinued. Mr. E. S. Bishop's concern that public expenditure on research and development should be well spent and not wasted was also generally shared.

Dr. J. Bray questioned whether discontinuance of the *Concord* project would, in fact, lead to a considerable loss of skilled manpower to the United States, and pointed out that the maximum number of workers who might be redundant by the end of 1965 was 6,000. Strong support for the project came from Mr. Angus Maude, who was convinced that supersonic transport was bound to come, but very reasonable answers were given to his specific questions by Mr. R. Jenkins in his reply on the debate. Mr. Jenkins reiterated that the only decision taken so far was to ask for an urgent review of the project, and he had personally explained to the French Minister of Transport in Paris Britain's doubts about the project. He had also had talks with the French Minister of Defence and the Minister of Science, who had French responsibility for the European Launcher Development Organization; a meeting had been arranged for January at the request of the French and Italian Governments, when the rising costs of this project and their allocation would be discussed.

As regards *Concord*, Mr. Jenkins said that neither Britain nor France had as yet spent or committed large sums, and up to the present time only about 3,000 people were involved, mostly in Bristol with about 400 in Coventry. The point had been reached where costs and the amount of labour involved would begin to rise fairly sharply. Besides these short-term reasons for desiring to review, there were long-term reasons. All should be satisfied that the counterbalancing technological and social considerations were commensurate with the costs. Whatever view was eventually taken of the *Concord* project, he was convinced that in the interests of both the French and the British aircraft industries, the two countries should work as closely as possible alongside each other. Collaboration so far had been happy and our doubts were entirely about the *Concord* project, not the collaboration. If the Government was convinced that the project was in the best interests of both countries it would wish it to go ahead, and even if there was an area of legitimate doubt a solution might still be found which would retain the possibility of developing a supersonic airliner which would be economic. But it could not be assumed that Britain's scarce resources permitted her to develop every existing possibility.

SCIENTIFIC RESEARCH IN SCHOOLS

THE president of the Royal Society, Sir Howard Florey, presided at a meeting in the Society's apartments at Burlington House, London, W.1, on September 30, to hear an account of some of the researches which have been carried out by practising teachers assisted by funds administered by the society's Research in Schools Committee.

The president, in his introductory remarks to an audience of more than 140 comprising school science teachers, their research advisers and officials of the Association for Science Education, said that the Council and Fellows take a great pride in the work done in schools, with the help of the committee, and it is crucial to Britain's benefit for this kind of work to be undertaken in schools. In addition, it gives teachers an insight into the frustration and disappointment which often go hand in hand with research.

After the president's remarks two papers were read, followed by a discussion and an interval for tea. Then two further papers were read and a further discussion was held. A brief summary of the four papers is given here.

Studies of Sympatric Evolution in the Butterfly, Maniola jurtina. By W. H. Dowdeswell, Winchester College.

The number of spots on the underside of the hind-wings of the meadow brown butterfly (*Maniola jurtina*) was a characteristic well known to be subject to the action of natural selection. Among the females, a typical South European spot-distribution with a high mode at 0 spots changed abruptly to a bimodal distribution (at 0 and 2 spots) in the vicinity of the Devon–Cornwall border where no physical barriers exist which might restrict the flight of the insect. There was evidence that the braconid *Apanteles tetricus* may be one of the agents tending to reduce spotting, while the bacterium *Pseudomonas fluorescens* may have the opposite effect. We might have a situation here comparable with that controlling sickle-cell anæmia in man.

The Lower Carboniferous Flora of the Tweed Basin. By A. G. Long, Berwickshire High School.

Primitive pteridosperm ovules from Berwickshire suggested that the integument evolved by fusion of separate sterile lobes around a megasporangium.

Two species of ovules occurred within cupules also composed of sterile cylindrical processes. Such cupules showed features comparable to angiosperm carpels and suggested that the pteridosperm cupule was the precursor of the angiosperm carpel.

Three *Lepidodendron* specimens showed the transition anatomy between stem and root without a stigmaria.

The nearest comparable flora was that of the Saalfeld beds in Central Europe.

The Stowe Radio Telescope. By J. M. Osborne, Westminster School, London.

A brief outline of the Stowe radio telescope was given. The original concept was described and the discussion with slides included the results obtained. Their significance in the field of amateur radio astronomy was mentioned.

The Szilard–Chalmers Reaction in Iodobenzene. By T. A. H. Peacocke, St. John's School, Leatherhead.

The original theory of the Szilard–Chalmers reaction explains the retention of iodine-128 in the parent molecule in terms of the recoil energy of the active atom. The recoil energy is about 200 eV and would result in the production of 5–7 free phenyl radicals. An alternative theory recently emphasized by C. N. Walton[1] considers the total energy release in terms of the electron excitation produced by the γ-rays emitted following the absorption of the neutron. This energy is greater than the recoil energy by several orders of magnitude and would produce many more free radicals than the 5–7 predicted by the original theory.

To test the rival theories iodobenzene has been irradiated with neutrons in the presence of scavenger iodine labelled with iodine-131, using the *Lido* reactor at the Atomic Energy Research Establishment. The accompanying γ-flux produces considerable radiolysis. To differentiate this from the effect of slow neutrons, some tubes were surrounded with cadmium. The observed retention of iodine-131 was measured in the absence of cadmium (R_1) and in the presence of cadmium (R_2). At neutron fluxes of the order of 10^8 n cm^{-2} sec^{-1}, R_2 is less than R_1; as the flux is increased the differences become smaller and at high neutron fluxes become negative. This could be explained in terms of the increased γ-flux inside the cadmium box as measured with the ferrous sulphate dosimeter. Approximate calculations indicate that 10^5 atoms of scavenger iodine are captured per Szilard event. This indicates the production of at least this number of free radicals, which would give strong support to the electronic excitation theory. The conclusions so far drawn must be tentative and further work is in progress.

Dr. F. P. Bowden, the chairman of the Committee for Scientific Research in Schools, in his closing remarks, said:

"This is the first occasion in the history of the society that scientific research carried out in schools has been presented in a formal discussion before it, which emphasizes the importance, at this moment of time, of science teaching in schools and it shows clearly the high level of ability with which some of our schools are manned on the scientific side. A wide increase of such research is without doubt one of our greatest needs in this country. Only a few days ago I was discussing with a research director of a major industry the implementation of his company's programme for the next five years. It was a highly imaginative programme and of great interest. Its successful prosecution, and that of similar companies, is vital to the economy of this country.

"It was clear that the programme could not be fully implemented because sufficient scientific and technical men were not available to carry out the work. There are many things we must do to cope with this situation and to breed more of them. It is clear that the cradle and source of them all is science in schools, and it is there that we must take urgent and effective action. This is one reason why we are grateful to the masters and the schools who are taking part in this scheme. There is no better way of showing schoolboys that science is an exciting activity than by doing creative work in it under their noses, and frequently with their participation. This is a fairly new scheme and it has developed quite rapidly—about 100 projects are in progress at the present time—but we would like to see it much more widely extended and we would be glad if you would tell your colleagues in other schools throughout the country about it.

"The other reason for our gratitude is a more usual one. One of the main functions and pleasures of the Royal Society is to hear of new scientific work and discoveries and to discuss them on their own merits. This has been an essential function of this meeting and it is very impressive to see the remarkably high scientific quality of the work which has been put before us. Of course, we have heard only a few papers; but it is typical of much of the work which is being carried out.

"We wish to express our thanks to the contributors and to the speakers for the very interesting afternoon they have given us, and to the president for presiding and taking part in the meeting. His presence here is a visible sign of the effective action which he, the Council and the officers of the society have taken throughout in supporting our committee and the scheme." R. H. Dyball

HYDROXYCINNAMIC ACIDS AND RELATED COMPOUNDS

THE Plant Phenolics Group recently changed its name to the Phytochemical Group with the object of broadening the scope of its discussions into the whole field of plant products; but for its first meeting under the new title, held in the Department of Chemistry of the University of Sheffield during September 21–23, it appropriately returned to the topic of plant phenols and in particular to hydroxycinnamic acids. Investigations of the structure and properties of natural products and in particular plant polyphenols have figured prominently in the researches carried out in Sheffield under a founder member of the group, Prof. R. D. Haworth, and these problems continue to interest his recently appointed successor, Prof. W. D. Ollis.

The meeting opened on September 22 under the chairmanship of Prof. Ollis, who welcomed the group to Sheffield. The first speaker, Dr. J. B. Harborne (John Innes Institute, Hertford), revealed the general background to the meeting in a paper entitled "The Occurrence, Distribution and Function of Hydroxycinnamic Acids in Plants", in which particular emphasis was laid on the taxonomic interest which these acids and their combined forms possess. They also play a central part in the biosynthesis of many of the more complex plant phenols, and in this context Dr. Harborne made brief mention of the problem of the complete absence in plant tissues of 3,4,5-trihydroxycinnamic acid suggesting that, for example, it may be replaced by gallic acid.

The four speakers who followed dealt with the problems associated with the determination of the structures of compounds recently discovered and found to contain one or more of the known hydroxycinnamic acids.

Prof. L. Birkofer (University of Cologne) unfolded the story behind the isolation, characterization and structure

determination of the acylated anthocyanins, pigments from *Petunia, Salvia, Raphanus* and *Matthiola* hybrids.

Dr. L. M. Scarpati (University of Rome) discussed in detail the problem of the isomers of chlorogenic acid, showing the caffeoyl ester group to be located at the 5 position of quinic acid in neochlorogenic acid and at the 4 position in 'band 510'. Isochlorogenic acid, a component of coffee beans and for a long time considered to be an isomer of chlorogenic acid, was revealed as a mixture of three di-*O*-caffeoyl quinic acids in which the 3,5 isomer predominates.

Dr. D. G. H. Daniels (Cereals Research Station, St. Albans) and Mr. M. O. Naumann (University of Sheffield) in two short communications announced the isolation and characterization of two new types of hydroxycinnamoyl esters, respectively, esters with a long-chain aliphatic ω diol found in oats and the 2-*O*-caffeoyl ester of the phenolic glucoside arbutin found in *Vaccinium vitis idaea*.

The session concluded under the chairmanship of Prof. J. W. Fairbairn and concerned the metabolism of hydroxycinnamic acids in higher plants. Miss J. J. Corner (Low Temperature Research Station, Cambridge) read a paper in which the distribution and formation of the *O*-glucosides and glucose esters of the hydroxycinnamic acids were critically evaluated. Dr. M. H. Zenk (University of Munich) discussed the experimental evidence underlying the important $C_6C_3 \rightarrow C_6C_1$ pathway for the formation of plant phenols and proposed a biochemical mechanism for this reaction.

The metabolism of the hydroxycinnamic acids was again considered in the final session on the morning of September 23 when Prof. R. D. Haworth took the chair. Prof. R. A. Thomson (University of Aberdeen) and Prof. E. E. Conn (University of California) discussed the question of the biosynthesis of coumarin from respectively the chemical and biochemical points of view. The pathway of coumarin metabolism was elegantly traced by Prof. Conn, and Prof. Thomson directed attention from a purely chemical point of view to the important step of *ortho*-hydroxylation, indicating the possible ways in which this transformation might be achieved.

Prof. W. D. Ollis (University of Sheffield) followed with a review of the biogenetic relationships among C_{15} compounds derived from cinnamyl precursors; in particular he detailed the possible ways in which the dalbergiones and 4-arylcoumarins might be formed and propounded a theory of oxidative biogenesis to explain the production of the associated benzophenones.

The final paper in the meeting was read by Dr. M. Zucker (Agricultural Experimental Station, Connecticut) and concerned an investigation of the biogenesis of chlorogenic acid showing that this is believed to involve a transformation of phenylalanine → cinnamic acid → 3-*O*-cinnamoylquinic acid → 3-*O*-p-coumaroylquinic acid → chlorogenic acid.

The meeting was well attended, and the lively formal and informal discussions which followed many of the lectures indicated the interest in phytochemical problems which it is the Group's policy to discuss.

POP-OUTS ON CONCRETE SURFACES

THE term 'pop-out' is technically applied to a particular type of disruption or disintegration of concrete surfaces, in serious cases only shortly after casting, with rather special significance. The subject has recently been discussed in a paper by G. M. Idorn (Concrete Research Laboratory, Karlstrup, Denmark) entitled "A Concrete Jetty with Frost Damage" (*Magazine of Concrete Research*, Cement and Concrete Association, 16, No. 47; 1964).

Mr. Idorn finds that pop-outs on concrete surfaces usually result from exposure to freezing and thawing, involving swelling pressure from ice in certain types of coarse aggregate occurring in Danish gravels. "Pure and silicified limestones and opaline and chalcedonic porous cherts in Danish aggregates are liable to give such pop-outs. These rocks account for about 20–40 per cent in ordinary gravel aggregates (considerably less in the sands). . . . There is always the possibility that a pop-out has developed because of the swelling pressure from alkali-silica gel in a porous rock particle when it contains or consists of opaline or chalcedonic silica. . . . The development of alkali-silica gel in a reactive rock particle can also bring about alteration in the interior pore-structure, so that any inherent tendency to be affected by freezing and thawing will increase." This raises again, but in a somewhat different form, the much-debated problem of alkali-reactive aggregate constituents as contributors to disruption of concrete, for example, the mineral chlorophaeite in some dolerites (*Nature*, 196, 943; 1962).

Whereas chlorophaeite and certain volcanic rock-types as pebbles have been suspect in causing damage to concrete by virtue of their chemical vulnerability and without the assistance of frost, it is now clear that the incidence of frost may considerably enhance the rate at which disruption of the concrete concerned can happen. Pop-outs produce unsightly 'pock-marks', rather like burst blisters, on concrete surfaces where these physico-chemical mechanisms are at work; they lead to extensive scaling. Four general types are recognized by Mr. Idorn: (*a*) capillary water in porous pebbles freezing to generate pressure on covering mortar; (*b*) alkali-aggregate reaction in porous cherts, etc., causing fracturing along a 'reaction rim'; (*c*) in rocks of very low permeability and negligible capillary water, ice may form on the surface of the pebble, destroying the bond, causing covering mortar or laitance to fall off; (*d*) growth of microscopic ice lenses in the thin layer of mortar or laitance over the pebble, a variation of type (*c*).

Pop-outs may not, however, fit all cases of surface deterioration of concrete, especially in circumstances where the potential causes of disintegration and exfoliation of mortar, as outlined above, are not in evidence. Mr. Idorn describes his inspection of a jetty in a Baltic harbour where a thick mass-concrete superstructure has suffered severe deterioration due to exfoliation of the mortar, resulting in pools of water where this disruption has occurred. In this case the aggregates used are said to be of excellent quality, ". . . strong, impermeable and chemically inert, and . . . no reason to question the quality of the cement". The concrete had been exposed to severe frost action involving numerous cycles of freezing and thawing during several winters. Of the type of deterioration, he says: "The aggregate pebbles show no sign of disruption themselves, but severe spalling and exfoliation have taken place on the horizontal faces. . . . There are many of the exposed coarser-aggregate pebbles forming pop-outs like the types (*c*) and (*d*) . . ." (above). It is emphasized that there is no sign of chemical reactivity in the aggregates used in this concrete, nor is chemical reaction due to sea-water likely, the salinity of the Baltic being quite low.

These researches and this particular case of the Baltic jetty are revealing, because they clearly demonstrate the mechanical effects of frost attack on concrete surfaces, whether accelerated by pop-outs or otherwise. The need for further investigations of similar damage, particularly in other countries where this has occurred, is implicit in this most informative essay.

NEW SEA-WALL AT ABERDEEN

THE subject of coastal protection is always with us but is seldom nationally publicized until a catastrophe occurs, when a combination of storm and excessively high tides causes the sea to overwhelm existing defences, flooding land behind them, resulting in grave damage to both life and property, to say nothing of the sea-walls and groynes concerned.

Recent work on a section of the coastline between the north pier of Aberdeen harbour and the mouth of the River Don is a case in point. In this example, lack of toe piling coupled with erosion of foreshore during the winter of 1961–62 determined the complete collapse of some 100 ft. of the then existent sea-wall and caused severe damage to the front of the apron over several hundred feet. According to *Concrete Quarterly* (No. 61, April–June 1964; Cement and Concrete Association, London), "The new work now nearing completion consists of two parts. The first and minor portion consists in rebuilding and strengthening portions of the existing wall extending some 2,500 ft. north from the beach bathing station. . . . A completely new wall has been built over the remaining 5,000 ft. or so of sea-front from the existing wall to the Don. A flexible facing of precast concrete blocks, with a post-tensioned precast coping, has been employed".

The construction of flexible revetments by mortaring stone or masonry blocks with a flexible material is a technique which has been known for centuries, ". . . a revetment on the banks of the River Tigris in ancient Assyria, built in 1300 B.C. of limestone blocks and brickwork mortared with bitumen and bituminous mixtures, is still in use to-day, and in good condition, more than 3,000 years later". This new sea-wall at Aberdeen uses much the same formula, only precast concrete blocks instead of limestone, etc., with bituminous jointing material, on a slope of 1 : 2. At the foot the wall is supported by steel sheet-piling topped with an *in situ* concrete capping beam. "Precast ribs at 29-ft. 5-in. centres span between the footing at the bottom and the *in situ* concrete foundation to the precast concrete coping at the top, and give lateral rigidity to the blockwork." It is recorded that some 42,000 precast blocks were involved in this project; these were vacuum-cast on the Miller system; this permits de-moulding to be done within about 4 min; also the use of steel moulds enabled thousands of components to be cast from the same moulds.

Construction of new groynes was an integral part of the scheme, not only to arrest northward drift of littoral sand, but also to help protection of the shore; these groynes are of greenheart timber. Finally, to make doubly sure, and to counteract erosion and stop scour at the northern end of the impermeable wall, there is a terminal section of gabions—permeable wire cages filled with stone—used as a transition section between the wall itself and the existing beach. The illustrations accompanying this article in *Concrete Quarterly* adequately convey the essential constructional details of this new sea-wall, equally a sense of the solidarity of this recent addition to Britain's coastal protection, a matter of great credit to all the engineers concerned.

CHROMOSOMES AND HUMAN MALFORMATION

IN the space of a few years, the enquiry into human variability has been raised from a somewhat speculative stage to the level of exact observation, said Prof. J. A. Böök in a lecture* entitled "Some Mechanisms of Chromosome Variations and their Relation to Human Malformations". The exact observations referred to chromosomal investigations, which have been made possible in recent years through improved techniques of culturing human cells *in vitro*.

Since 1959, when it was first demonstrated that certain chromosomal abnormalities were associated with specific congenital malformations[1,2], a large number of instances have been reported. These cytological abnormalities, Prof. Böök pointed out, were not new cytological phenomena, but demonstrated that man, like other animals and plants, was occasionally subject to abnormalities in the structure of the hereditary system.

The occurrence of an extra chromosome (trisomy), arising from normal parents by chance meiotic or mitotic non-disjunction, was the commonest chromosomal abnormality. In most instances the origin of the abnormal karyotype could be correlated with above-average maternal age—thus revealing the increased risk of chromosomal accidents by ageing. In addition to the three well-established trisomic states [13–15 syndrome, 17–18 syndrome and Downs syndrome (trisomy 21)], the possible differentiation of a fourth syndrome was outlined—involving trisomy for a small acrocentric chromosome—presumably No. 22. From five presumptive cases of this 22 trisomy, the defects in common included microcephaly, deafness, large, low-set malformed ears and pre-auricular papillomata.

The presence of a complete extra set of chromosomes (triploidy) still constitutes a rare abnormality and, apart from the sporadic occurrence in spontaneously aborted fœtuses[3–6], only three instances are known in living individuals[7–9]. The first instance was reported in 1961 (ref. 7) from Prof. Böök's laboratory and occurred in a male infant aged 14 months. In common with the two subsequent cases, the infant was a chromosome mosaic containing both diploid and triploid cells, the latter having the suggested origin from a second fusion with a retained polar nucleus. The most recent observations on this child after an intervening period of three years have shown that the proportion of triploid cells in the skin tissues has markedly decreased from an original figure of 84 per cent to a value of 10 per cent; the decrease being credited (from observations on tissue cultures) to abundant mitotic irregularities in the nature of bridges, lagging chromosomes and tripolar spindles. It should, however, be pointed out that no mitotic instability has been observed in any of the other instances of human triploidy, and it remains to be seen whether the triploid cells in the two other living cases are selectively eliminated. It is further noteworthy that, in the case reported by Ellis *et al.*[8], the child was considerably older (6 years) and yet

* The Galton Lecture delivered before the Eugenics Society in London on May 20, 1964.

had 50 per cent of its skin cells triploid. If the triploid cells in this case are being eliminated, their elimination is occurring at a much slower rate.

Translocations, said Prof. Böök, were probably quite common, but were only microscopically recognizable when relatively large unequal chromosomal segments had been involved in the interchange. The translocations may be transmitted through several generations of phenotypically normal individuals and their presence may only come to light from recurrent malformations, which in some cases may affect 50 per cent of the offspring. In addition to the now well-established examples of translocation between the acrocentric chromosomes (centric fusions), a maternal karyotype was described with a presumptive translocation of the short arms of one of the large chromosomes with a sub-terminal centromere (No. 4–5), to the short arm of one of the small acrocentrics. Multiple congenital malformation with an early death occurred in the progeny when the karyotype displayed effective trisomy for the short arm involved in the translocation.

A similar type of interchange was then considered as the most likely basis for a number of individuals having mental retardation, broad face with flat nose, micro- and retrognathism, hypertelorism, bilateral epicanthus, impaired hearing, retardation of growth and a high-pitched wailing cry. The karyotypes associated with these malformations all showed a deficiency or monosomy for the short arm of a chromosome in the 4–5 group.

Finally, the importance of meiotic observations was discussed in relation to the confirmation of deductions based on somatic chromosome complements. This aspect was illustrated with a male karyotype in which two of the large acrocentrics were represented by a large metacentric element and which, somatically, could have represented a translocation between either homologous or non-homologous chromosomes. The existence of trivalent associations at meiotic metaphase clearly demonstrated an origin from a non-homologous interchange.

In this survey, Prof. Böök excluded all abnormalities involving the sex chromosomes, and limited his text to observations made principally in his own laboratory. His lecture, therefore, clearly demonstrated that with his colleagues he has made many significant contributions in the field of human cytogenetics. J. R. Ellis

THE ANTRAL HORMONE GASTRIN

Structure of Gastrin

EXISTENCE of the antral hormone, gastrin, was suggested first in 1905, when Edkins[1] showed that crude extracts of mucosa from the antral region of the stomach stimulated gastric secretion in anæsthetized cats. Eventually Edkins's observations were confirmed; it was shown that gastrin was distinct from histamine and probably proteinaceous in nature[2]. Only very recently, however, has the successful isolation of pure gastrin enabled precise physiological and chemical characterization. In 1964, Gregory and Tracy[3] described the isolation from hog antral mucosa of two closely similar polypeptide hormones (gastrins I and II), both of which evoked a remarkable range of physiological responses from alimentary tract structures. In particular, both hormones were very powerful stimulants of gastric acid secretion when injected subcutaneously into conscious dogs[3]. Gastrin II has also been shown to stimulate gastric secretion in human subjects[4]. On a molar basis, it is some 500 times more effective than histamine, and has clear advantages over histamine as a secretory stimulant in assessing gastric secretory function[4].

Through the kindness of Prof. R. A. Gregory, we have been able to carry out chemical studies on both hormones. Our results described here show that gastrin II has the heptadecapeptide amide structure:

$$\begin{array}{l} \overline{\text{L}}\text{Glu.Gly.Pro.Try.Met.Glu.Glu.Glu.Glu.Glu.Ala.Tyr.} \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \text{Gly.Try.Met.Asp.Phe.NH}_2 \end{array}$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad\ \ \text{SO}_3\text{H}$$

and that gastrin I differs from gastrin II only in lacking the tyrosyl sulphate ester group.

Amino-acid composition. Acidic hydrolysates (6 N HCl/105°/18 h *in vacuo*) were analysed for amino-acid and ammonia content by the automated ion-exchange method of Spackman, Stein and Moore[5] (Beckman amino-acid analyser model 120*B*). Similar results were obtained with both hormones, and were consistent with the foregoing structure. An unexpectedly high recovery of tryptophan (60 per cent) was obtained in the acidic hydrolysates. This is attributed to the high purity of the isolated gastrin. In contrast, tryptophan-containing peptides which had been separated by chromatography or electrophoresis on paper yielded no tryptophan after acidic hydrolysis. Alkaline hydrolysates (N $Ba(OH)_2$/105°/18 h) revealed the same amino-acid composition, except that gastrin II yielded no tyrosine. Chromatography of a basic hydrolysate of gastrin II on 'Dowex-50' cation-exchange resin and elution with water afforded a strongly acidic amino-acid (anionic at *p*H 2·1), which was identified as tyrosine-*O*-sulphate by comparison with a synthetic sample[12]. Enzymatic evidence has been obtained for the L-configuration of all the constituent amino-acids, except those of the *N*-terminal tripeptide sequence.

End-group analysis. No free terminal amino or carboxyl groups could be detected in either hormone by standard methods. Gastrin II failed to react with Sanger's reagent (1-fluoro-2 : 4-dinitrobenzene), and gastrin I yielded only a colourless derivative of *O*-dinitrophenyl-tyrosine. Neither hormone gave a coloration with ninhydrin. No terminal acetyl, or other simple acyl groups, could be detected by the hydrazinolysis method of Phillips[6]. At this stage it was considered likely that the peptide chain was terminated at its amino-end by a pyroglutamyl residue, and supporting evidence for this was obtained during the course of amino-acid sequence studies.

Carboxypeptidase was without significant action on either gastrin I or gastrin II, and hydrazinolysis failed to liberate a C-terminal amino-acid from gastrin II. Enzymatic degradation (*infra*) afterwards showed that the C-terminus of the peptide chain was blocked by the single amide residue.

Amino-acid sequence of gastrin II. Gastrin II was degraded by treatment with cyanogen bromide (a reagent reportedly[7] specific for cleavage at methionine residues), with chymotrypsin (high specificity for cleavage at aromatic residues), and with enzymes of low specificity, papain and subtilisin. Partial hydrolysis of gastrin II by

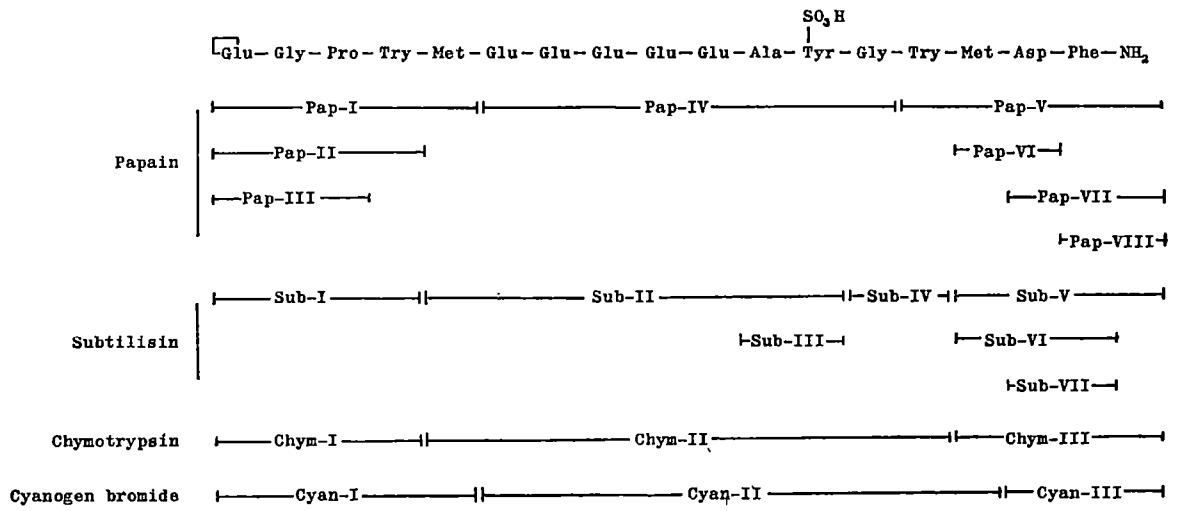

Fig. 1. Peptides obtained by degradation of gastrin II

aqueous acid was also investigated briefly. The most useful results were obtained from the papain and subtilisin digests; the resulting relatively complex mixtures of peptides were fractionated by a combination of paper electrophoretic and chromatographic methods. Most of the isolated peptides were obtained in amounts sufficient for quantitative amino-acid analysis after acidic hydrolysis. Tryptophan was determined after basic hydrolysis or further enzymatic or chemical degradation, or its presence was inferred from a positive Ehrlich test on the intact peptide.

(1) *Papain degradation.* Digestion of gastrin II was carried out at *p*H 7·05 and 37° for 22 h, using papain previously activated with potassium cyanide (enzyme : substrate ratio, 1 : 20). The eight peptides designated Pap-I to Pap-VIII in Fig. 1 were isolated. Pap-VIII was identified as phenylalanine amide by comparison with a synthetic sample. It must, therefore, have been derived from the C-terminus of the peptide chain. The C-terminal sequence, Try.Met.Asp.Phe.NH_2, followed unambiguously from the compositions of the peptides, Pap-V, Pap-VI and Pap-VII. The three peptides, Pap-I, Pap-II and Pap-III, formed a ninhydrin-negative series, and their behaviour on electrophoresis (monoanionic at *p*H 6·1, neutral at *p*H 2·1) confirmed the absence of free amino-groups, and was consistent with the presence of terminal pyroglutamyl residues. They must, therefore, have been derived from the N-terminus of gastrin II. The partial sequence, Glu(Gly,Pro)Try.Met, followed from their compositions. Further digestion of the pentapeptide, Pap-I, with carboxypeptidase liberated methionine and tryptophan, with no trace of the other constituent amino-acids. Furthermore, the residual peptide isolated after carboxypeptidase treatment of Pap-I contained equimolecular ratios of glutamic acid, glycine, and proline. In view of the known inability of carboxypeptidase to hydrolyse past proline residues[8], the sequence of Pap-I, and of the N-terminus of gastrin II, could confidently be expanded to Glu.Gly.Pro.Try.Met.

The central peptide, Pap-IV, was shown to have N-terminal glutamic acid by reaction with fluorodinitrobenzene. Four cycles of the Edman degradation (followed both by identification of the liberated phenylthiohydantoins and by quantitative analysis of the residual peptide after each stage) showed that glutamic acid occupied the first four positions in the peptide chain. The C-terminal amino-acid was identified as glycine (carboxypeptidase). The partial sequence Glu.Glu.Glu.Glu(Glu,Ala,Tyr)Gly was thus established for Pap-IV. The complete hydrolysis of Pap-IV by leucine aminopeptidase showed that all five glutamyl residues were linked by their α-carboxyl groups, and that all the constituent amino-acids were of the L-configuration.

(2) *Subtilisin degradation.* Digestion of gastrin II was carried out at *p*H 8·01 and 37° for 20 h, using a commercial subtilisin preparation ('Nagarse'), enzyme : substrate ratio, 1 : 16. Isolation of peptides Sub-V, Sub-VI and Sub-VII confirmed the C-terminal sequence already deduced. Furthermore, the complete hydrolysis of Sub-VI by leucine amino-peptidase established the α-linkage of the aspartyl residue in this C-terminal sequence. The central peptide, Sub-II, and the dipeptide, Sub-IV, provided overlaps with the papain peptides which confirmed the arrangement of N-terminal, central, and C-terminal sequences suggested above. The central peptide, Sub-II, had N-terminal methionine (Edman degradation), confirming the alignment of Pap-I and Pap-IV. The C-terminal amino-acid was tyrosine (hydrazinolysis), which enabled the sequence of Pap-IV to be extended to:

Glu.Glu.Glu.Glu(Glu,Ala)Tyr.Gly.

The dipeptide, Sub-III (anionic at *p*H 2·1, that is, contained the tyrosine as its *O*-sulphate), was shown to have the alanine N-terminal (Edman degradation), completing the above central sequence. The dipeptide, Sub-IV, was identified as glycyltryptophan by both N-terminal (Edman degradation) and C-terminal (hydrazinolysis) analysis, confirming the alignment of Pap-IV and Pap-V, and completing the entire amino-acid sequence of gastrin II.

(3) *Other degradations.* Cleavage of gastrin II by chymotrypsin and by cyanogen bromide was examined in less detail, but the compositions of the resulting peptide fragment were in all cases consistent with the amino-acid sequence deduced from the papain and subtilisin degradations. Gastrin II was not a good substrate for chymotrypsin, and conditions could not be found for specific cleavage at all the aromatic residues. Hydrolysis at the tryptophan residue (position 4) was rapid, and the N-terminal tetrapeptide, Chym-I, was readily isolated. Cleavage at the second tryptophan residue (position 14) was much slower. The C-terminal tripeptide, Chym-III, was isolated in pure form, but the central peptide, Chym-II, was contaminated with the longer peptide comprising Chym-II + Chym-III. No evidence was obtained for cleavage at the tyrosine-*O*-sulphate residue[9], and the electrophoretic behaviour of Chym-III suggested that the phenylalanine–amide bond was also intact.

The normal conditions[7] for the selective fission of peptides at methionine residues by cyanogen bromide had to be modified because of the insolubility of gastrin II in

dilute hydrochloric acid. However, a moderately satisfactory cleavage was obtained using aqueous trifluoroacetic acid as solvent, and the expected peptides, Cyan-I, II and III, were isolated in low yield. Cyan-I and Cyan-II were presumed to contain C-terminal homoserine lactone in place of the original methionine residues, in accordance with the accepted mode of cleavage by cyanogen bromide. The ninhydrin-negative peptide, Cyan-I, was neutral on electrophoresis at both *p*H 2·1 and 6·1, confirming the absence of terminal carboxyl and amino groups, and of the second carboxyl group of the glutamyl residue. This, again, is in accord with the pyroglutamyl formation. Further support for this structural feature was obtained by the isolation of pyroglutamic acid itself from partial acidic hydrolysates of gastrin II.

Amino-acid sequence of gastrin I. Many of the foregoing degradations were afterwards repeated on gastrin I. All the results were in agreement with the identical amino-acid sequences of the two hormones, except that gastrin I lacked the phenolic sulphate ester group. For example, the central peptides, Pap-IV, derived respectively from gastrins I and II, reflected the same differences in electrophoretic behaviour as were found[3] with gastrins I and II themselves (gastrin II is more acidic than gastrin I), whereas peptides derived from the N- and C-termini of the two hormones appeared to be identical. Furthermore, the central peptide, Pap-IV, from gastrin I liberated all the constituent amino-acids, including tyrosine, on digestion with leucine aminopeptidase, whereas the corresponding gastrin II peptide yielded predominantly tyrosine-*O*-sulphate. The two peptides differed also in their reaction with carboxypeptidase. Pap-IV derived from gastrin I liberated both glycine and tyrosine on digestion with carboxypeptidase at neutral *p*H. However, the gastrin II peptide liberated only glycine, and the residual peptide terminating in tyrosine-*O*-sulphate was inert to further hydrolysis. This behaviour is reminiscent of the inhibitory effect of C-terminal cysteic acid residues on the action of carboxypeptidase[6].

Further proof of the structural relationship between the two hormones has been obtained by their interconversion. Treatment of gastrin II with a mixture of trifluoroacetic and 3 N hydrochloric acids (3 : 1) at room temperature for 70 min results in 70 per cent conversion to gastrin I. Resynthesis of gastrin II from gastrin I has been achieved by treatment of an alkaline solution (*p*H 10) of the latter with pyridine–sulphur trioxide complex, a reagent previously used for the sulphation of the phenolic hydroxyl group of tyrosine[10].

The amino-acid sequences revealed by the foregoing degradations contain several unusual features worthy of comment. The presence of tyrosine-*O*-sulphate in a peptide hormone does not seem to have been encountered before, although the amino-acid has been identified in fibrinogen peptides[11]. The free amino-acid also occurs in urine[12]. The complete absence of basic amino-acids and the high concentration of acidic amino-acids in both gastrins is also noteworthy, especially the presence of five glutamyl residues in a contiguous sequence. The terminal pyroglutamyl residue is not without precedent in natural peptides[13], although it is possible that *in vivo* the hormones possess a glutaminyl residue in this position. On the other hand, the N-terminal pyroglutamyl residue and the C-terminal amide may have the *in vivo* function of protecting gastrin from destruction by amino- and carboxy-peptidases. It is interesting to note, however, that, with the exception of the C-terminal amide function, none of the structural features mentioned above is absolutely essential for biological activity[14].

We thank Prof. R. A. Gregory and Dr. H. J. Tracy for natural gastrin. We thank Imperial Chemical Industries, Pharmaceuticals Division, for a gift of the automatic amino-acid analyser, and for financial support, and Mr. D. Wheeler for assistance. We also thank Dr. D. Boulter and his associates of the Department of Botany, University of Liverpool, for preliminary amino-acid analyses obtained with a 'Technicon' autoanalyser.

Synthesis of Gastrin

Synthesis of gastrin was, in our view, essential both to confirm the sequence deduced from degradative investigations[1] and to remove the possibility that a small constituent, not giving a colour with ninhydrin, had escaped our notice. In the event, synthesis of gastrin I[2] gave the clue to the structural difference between gastrins I and II, effectively revealing the presence of sulphate in the latter. As gastrin II has been prepared from gastrin I[1], this synthesis covers both hormones.

The final step in synthesis was removal of *t*-butyl groups, masking the γ-carboxyl groups of the five glutamyl residues, by treatment of the penta-*t*-butyl ester of gastrin I (Fig. 1, line 6) with 98 per cent trifluoroacetic acid at 20° for 1 h. The product was purified by chromatography on 'Sephadex *G*25' in 0·04 M ammonium bicarbonate, and gradient elution from aminoethylcellulose[3]. In this chromatography, in high-voltage electrophoresis (pyridinium acetate *p*H 6·1), and in thin-layer chromatography, the purified product was indistinguishable from gastrin I, and it gave full biological responses when injected subcutaneously into a conscious dog. Although the identity of the synthetic and natural products is not in serious doubt, we intend to compare enzymatic degradations of them in order to obtain even more conclusive evidence by 'finger-printing'.

The penta-*t*-butyl ester was assembled (Fig. 1)[4] from three components comprising residues 1–5, 6–13 and 14–17 of the sequence. The central (6–13) penta-*t*-butyl monomethyl ester (line 3) was prepared from alanyltyrosylglycine methyl ester by elongation in 10 steps, of which only the last two are shown. This polyester was coupled with the (1–5) azide (line 3) in dimethylformamide solution at 0° during three days; in some experiments Curtius degradation of the azide, shown in a low methionine content of the product, was troublesome[5]. Selective saponification of the extended polyester, suspended in 75 per cent aqueous dioxan, by 4 equivalents of sodium hydroxide during 1·5 h at 20°, yielded an acid (line 5), comprising residues 1–13, which was coupled with the (14–17) tetrapeptide amide (line 5) via the mixed anhydride with diphenyl phosphoric acid[6]. The yield from this coupling was only about 10 per cent, but this can

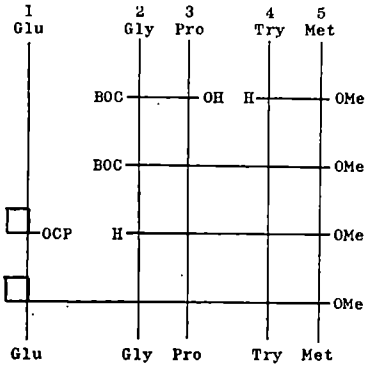

Fig. 2

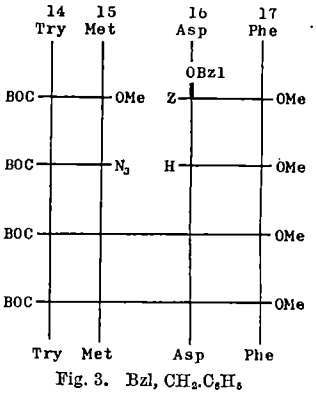

Fig. 3. Bzl, $CH_2.C_6H_5$

probably be improved by variation of technique. Another possible source of improvement is our recent finding that the butyloxycarbonyl group can be preferentially removed from the fully protected (14–17) amide (line 4); the resultant ester-amide can doubtless be coupled by other means.

The (1–5) and (14–17) components actually used in the first successful synthesis were prepared as indicated in Fig. 1 (ref. 4), but the following alternative methods are more convenient. Thus, the (14–17) tetrapeptide amide (Fig. 1, line 5) is made more efficiently (Fig. 3) by an azide coupling of two dipeptides, ammonolysis at the tetrapeptide stage, and removal of the single protecting group[7]. Again, tryptophylmethionine methyl ester, prepared from the butyloxycarbonyl derivative used in the foregoing preparation, can be condensed with butyloxycarbonylglycylproline by di*cyclo*hexylcarbodi-imide at 0° (Fig. 2). Then, after removal of the butyloxycarbonyl group, reaction with the 2,4,5-trichlorophenyl ester of pyroglutamic acid in dimethylformamide at 20° for 60 h yields the (1–5) pentapeptide ester, identical with that prepared by the alternative route (Fig. 1, line 2).

A second synthesis of gastrin I has also been achieved by means of the 2,4,5-trichlorophenyl ester of pyroglutamic acid, probably the most convenient reagent for introducing a pyroglutamyl residue. The final stage is reaction between this active ester and the free (2–17) peptide amide together with 7 equivalents of triethylamine in dimethylformamide during five days at 37°. This hexadecapeptide was constructed from the (2–5) butyloxycarbonyl-tetrapeptide ester (Fig. 2) through an azide coupling with the (6–13) pentabutyl monomethyl ester (Fig. 1, line 3) and subsequent attachment of the (14–17) tetrapeptide amide (Fig. 1, line 5).

Throughout this work the L-forms of amino-acids were used and the syntheses were designed to preserve all the optical activity. At each stage the peptides gave satisfactory amino-acid analyses (Beckman 120*B*). Details of this work, of investigations of alternative syntheses, and of syntheses of smaller peptides related to portions of gastrin will be published elsewhere.

Physiological Properties of a Series of Synthetic Peptides structurally related to Gastrin I

In our description earlier this year of the isolation and properties of gastrins I and II, we showed that both these peptides displayed, in apparently identical form and degree, a wide range of actions in the alimentary tract[1]. At one time or another in the past, all these actions had been recognized to be properties of more or less crude extracts of antral mucosa, and it had been widely supposed that they were attributable to the presence in such extracts of a variety of substances besides the hormone gastrin, which was believed only to stimulate gastric acid secretion.

The actions of the pure natural peptides (gastrins I and II) may be summarized as follows:

(1) *Stimulation of gastric acid secretion.* Subcutaneous, or slow intravenous, injections in appropriate dosage cause a prompt and protracted secretion of highly acidic gastric juice containing little pepsin.

(2) *Inhibition of gastric acid secretion.* In conscious dogs provided with denervated fundic pouches, small rapid intravenous injections inhibit a steady background response maintained by repeated small subcutaneous injections, or slow intravenous infusions, of histamine or of gastrin I or II.

(3) *Stimulation of pepsin secretion.* In the type of experiment described under heading (2), a large output of pepsin is observed in the juice which is secreted as the inhibition wears off. A combination of inhibition of acid (and volume) secretion and stimulation of pepsin secretion is also demonstrable in denervated pouch dogs following large single subcutaneous injections.

(4) *Stimulation of pancreatic secretion.* In conscious or anæsthetized dogs, intravenous injections cause a prompt increase in the volume-flow and enzyme output of pancreatic juice.

(5) *Stimulation of gastric tone and motility.* In conscious dogs provided with denervated fundic pouches, small rapid intravenous injections cause a prompt and powerful spasm of the gastric musculature, usually followed by some increase of motility at a lower level of tone before the normal rhythm is resumed.

(6) *Effects on small intestinal tone and motility.* In conscious dogs provided with isolated jejunal loops, small rapid intravenous injections cause a prompt sustained spasm or rapid series of vigorous contractions, which quickly gives place to more prolonged inhibition, chiefly of tone but often of motility as well.

(7) *Biliary tract and blood-pressure.* In anæsthetized dogs, neither of the gastrins causes contraction of the gall-bladder (cholecystokinin-like activity), nor does either significantly influence the rate of flow of hepatic bile. In similar circumstances neither gastrin has other than a small and inconstant depressant effect on the blood-pressure.

Towards the end of the work described in the previous paper, which culminated in the total synthesis of gastrins I and II, we were enabled through the kindness of our colleagues to investigate the physiological actions of a series of synthetic peptide derivatives comprising, or closely related to, various portions of the gastrin molecule. Most of these peptides were produced during the programme of synthesis, but some were made at our request. We have made a preliminary examination of these peptides for the presence of the types of activity enumerated here for gastrins I and II (with the exception of actions on the biliary tract). In these experiments the same methods, and for the most part the same group of surgically-prepared conscious dogs, were used as described in detail by us[1].

The prime objective of this investigation was to ascertain, as a starting point for the preparation of analogues, which types of activity were shown by each peptide; it was hoped that some localization of function in different

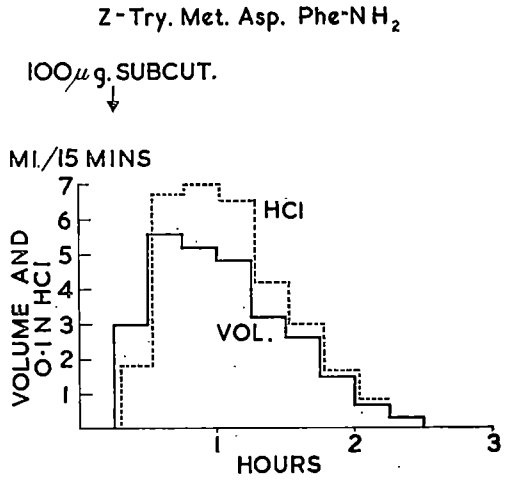

Fig. 1. Response of a conscious dog provided with a denervated fundic pouch to a single subcutaneous injection at arrow of 100 μg of Z.Try. Met.Asp.Phe—NH_2 dissolved in 1 ml. saline

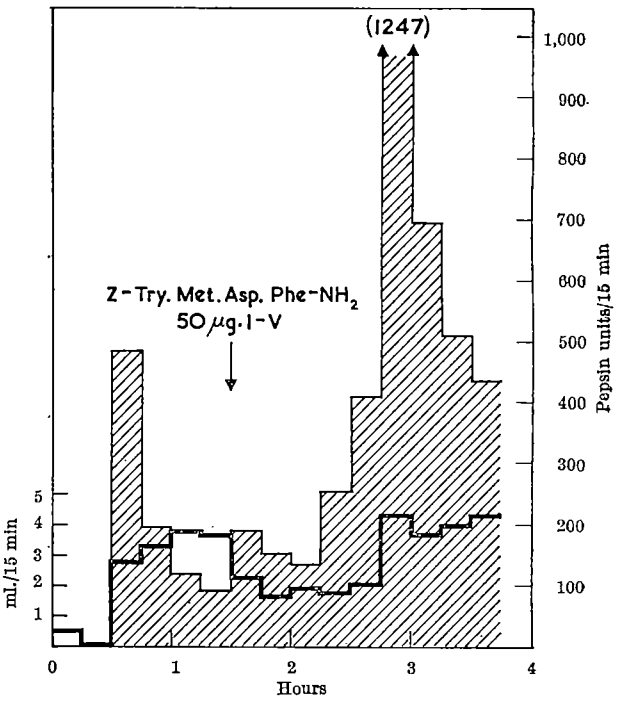

Fig. 2. Volume-flow (heavy line) and pepsin output (shaded areas) of gastric juice from a denervated fundic pouch in a conscious dog. regions of the total molecule might thereby be revealed. At this stage it seemed of little value to attempt any formal comparison of potency in respect of any type of action. However, the amount of each peptide injected, at least in initial trials, was 50–100 μg; and, since ample data were already available for the actions of gastrins I and II when used in such amounts, it was possible to draw some tentative conclusions as to potencies. Comparisons were facilitated by using the same dogs for similar types of test where possible; and these dogs had also been used for previous studies with the gastrins.

In experiments on the stimulation of gastric acid secretion by subcutaneous injections, a wide range and pattern of dosage was used in order to exclude the possibility that a negative result was in reality due to the production of inhibition by too large an initial dose (see under heading (3)). In testing for inhibition of gastric acid secretion and stimulation of pepsin secretion by intra-

* Background histamine response augmented. ?+ Effect very small or doubtful.

venous injection against a background response (headings (2) and (3)), repeated subcutaneous injections of histamine were used as the stimulus.

In Table 1 are set out the constitutions of the 12 peptides to be described on this occasion, compared with that of gastrin I, and the types of activity found in respect of each of them. The results are expressed in the following form: + indicates a decisively positive result, and 0 a negative result; ?+ denotes that the effect observed was very small or of doubtful significance. The effects on gastrointestinal tone and motility were more variable in occurrence and pattern than the other actions, due, no doubt, to spontaneous variations in sensitivity and rhythmical activity of the animal preparations on different occasions, and the component of these responses most difficult to evaluate was that of inhibition following stimulation in the gastric musculature. A further problem in these experiments arose from the observation that, during a given experiment, earlier injections of the same or different peptides influenced later responses (generally decreasing them) although recovery from the earlier responses had apparently ensued. Where, as sometimes happened, a negative result was obtained on one occasion, and a decisively positive one on another, the result is expressed in Table 1 as positive (+).

The following conclusions can be drawn from the present findings:

(i) The entire range of physiological activities displayed by natural gastrin I are possessed by the C-terminal tetrapeptide sequence Try.Met.Asp.Phe—NH_2 (peptides 3 and 12). Whether the N-terminal residue was protected by a benzyloxycarbonyl group (No. 3) or not (No. 12) appeared to have no significant influence on activity. There was some indication that both peptides showed an inhibitory action on gastric tone and motility following stimulation, after intravenous injection; this action has not been consistently observed with natural gastrin. The power to stimulate acid secretion on subcutaneous injection appeared to be about one-fifth that of gastrin on a simple weight basis, and the ability to inhibit gastric acid secretion when injected intravenously seemed to be of about the same relative potency.

(ii) As the peptide chain was progressively lengthened towards the N-terminus (peptides 4, 5 and 6) the general potency of the molecule increased; No. 6, which differed from gastrin only in having two instead of five glutamyl

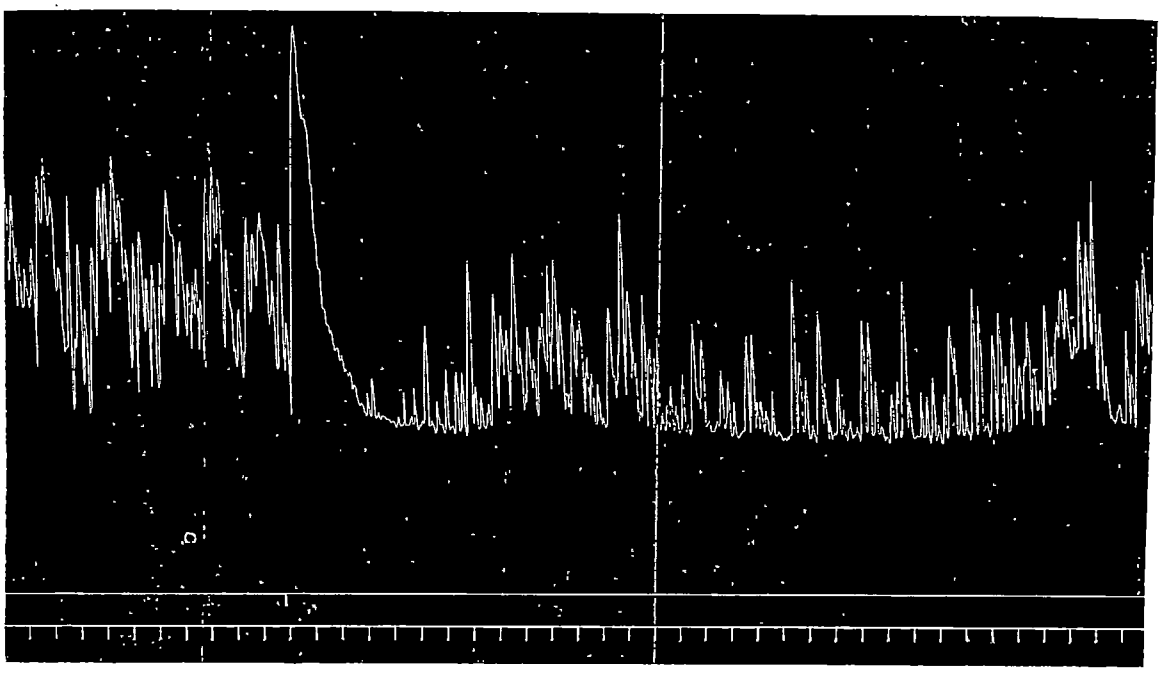

Fig. 3. Record of tone and motility in the denervated fundic pouch of a conscious dog. At signal, 50 μg TFA-NH_3^+.Try.Met.Asp.Phe—NH_2 dissolved in 1 ml. saline was injected rapidly intravenously. Time-signal 10 sec

residues in the body of the molecule, could not be distinguished from gastrin itself in any way.

(iii) The C-terminal di- and tri-peptide derivatives (Nos. 1 and 2) were apparently inactive, except for some indication of inhibition of gastric tone and motility by No. 2.

(iv) The N-terminal sequences Nos. 7 and 8 and a central sequence (No. 9) showed no significant power to stimulate gastric acid secretion when injected subcutaneously in single or repeated doses, nor did they stimulate pancreatic secretion or influence gastrointestinal motility; but two of them (Nos. 7 and 8), when injected intravenously against a background histamine response, augmented this, and there was a small or moderate increase in pepsin output.

(v) The C-terminal pentapeptide and tetrapeptide lacking the amide group (Nos. 10 and 11) could not be shown to stimulate gastric secretion when injected subcutaneously. When injected against a background histamine response, they augmented this and caused a slight or small increase in pepsin output, as had peptides 7 and 8. They had no action on gastrointestinal tone and motility, but still retained the power to stimulate pancreatic volume-flow and enzyme secretion. These actions of No. 11 are in notable contrast to those of No. 12, for the two compounds differ only in that the masking amide group is replaced by

an ester group; the same is true of peptides 4 and 10. Some examples of the closely similar actions of peptides 3 and 12 are shown in Figs. 1–5; these may be compared with Figs. 1, 6, 7, 8 and 9 in Part II of ref. 1 which displays the corresponding effects produced in similar experimental conditions by natural gastrin.

It is remarkable that, of the 17 residues of gastrin, only the C-terminal tetrapeptide sequence is required for the entire range of physiological activities displayed by the total molecule, and that these actions should be so radically changed by the absence from this sequence (or from the corresponding pentapeptide, compare peptides 4 and 10) of the amide group which masks the C-terminal residue. Naturally, at this stage a number of questions concerning the properties of these peptide derivatives remain unanswered; but the investigation continues, and a fuller account will be given elsewhere. It seems clear, however, that the simple tetrapeptide sequence, Try.Met.Asp.Phe—NH_2, with its well-developed and distinctive actions on the gastric and pancreatic gland-cells and on the gastric and intestinal musculature offers promise for the study of structure-function relationships by the synthesis of analogues and exploration of their properties along lines similar to those described here.

DEGRADATION OF TYPE XIV *Pneumococcus* POLYSACCHARIDE BY INDUCED ENZYMES

By Dr. S. A. Barker, Dr. Grace I. Pardoe and Prof. M. Stacey, F.R.S.
Chemistry Department
and
Dr. J. W. Hopton
Microbiology Department, University of Birmingham

Methylation investigations[1] had shown that type XIV *Pneumococcus* polysaccharide contains on average, in every 6 moles of sugar residues, 2 moles of D-galactopyranose non-reducing end-groups, 1 mole of D-galactopyranose linked 1 : 3, 1 mole of D-glucopyranose linked 1 : 4 and 2 moles of *N*-acetyl D-glucosamine linked 1 : 4 : 6. The technique of sequential enzyme induction[2,3] has been used to elucidate further the fine structure of *S.* XIV.

S. XIV (0·1 mg/ml.) was incubated shaken at 34°/24 h with a dense suspension of succinate-adapted cells of *Klebsiella aerogenes* N.C.I.B. 9479 in sterile succinate medium adjusted to *p*H 6·8 with potassium hydroxide[4]. D-Galactopyranose, characterized as the β-penta-acetate and assayed[5,6], was recovered (0·5 mole, calculated on the 6 moles of sugar residues of the polysaccharide cited above) from the dialysable fraction of the cell-free culture filtrate. The partially degraded *S.* XIV, when used for a further induction at 34°/24 h, gave a further amount of D-galactose (0·55 mole) and a trisaccharide (0·16 mole)[5–8].

Two further inductions resulted in the liberation of additional amounts of trisaccharide (0·32, 0·22 moles, respectively). The induced enzyme present in a 48-h cell-free culture filtrate was a specific β-D-galactopyranosidase, hydrolysing lactose and *o*-nitrophenyl-β-D-galactopyranoside but without action on melibiose, cellobiose, maltose or *N,N'*-diacetylchitobiose. When *S.* XIV was re-incubated with the isolated induced β-D-galactosidase, galactose and the trisaccharide were again detected.

The neutral reducing trisaccharide was characterized as *O*-β-D-glucopyranosyl (1 → 4)-*O*-(2-acetamido 2-deoxy)-β-D-glucopyranosyl (1 → 3)-D-galactopyranose. Analysis after acid hydrolysis showed that it contained equimolar amounts of glucose, galactose and *N*-acetyl glucosamine, and did not react with the Morgan–Elson[9] reagents. It was not oxidized by either galactose[6] or glucose[7] oxidases, but both these enzymes reacted with the corresponding sugars in the hydrolysate. Following sodium borohydride reduction, acid hydrolysis revealed glucose and glucosamine, while, after consecutive periodate oxidation, sodium borohydride reduction and acid hydrolysis, glucosamine only was detected. Mild acid hydrolysis of the trisaccharide yielded *inter alia* two disaccharides, characterized respectively as 4-*O*-β-D-glucosyl 2-acetamido 2-deoxy D-glucose and 3-*O*-(2-amino-2-deoxy)-β-D-glucosyl D-galactose.

The release of the trisaccharide in the medium was followed by analysing aliquots of the dialysable fractions for total hexoses[5], galactose[6], glucose[7], hexosamines[8] and calculating the trisaccharide content from these figures. The trisaccharide was a substrate for β-glucosidase, releasing D-glucose (characterized by its specific oxidation by glucose oxidase[7]) and a disaccharide characterized as 3-*O*-(2-acetamido 2-deoxy) β-D-glucosyl D-galactose. Acid hydrolysis of periodate oxidized *S.* XIV had yielded the same disaccharide after acetylation[11]. After mild acid hydrolysis of *S.* XIV, and acetylation of the amino sugars[12], five disaccharides had been isolated: lactose, 4-*O*-β-D-glucosyl 2-acetamido 2-deoxy D-glucose, 3-*O*-β-(2-acetamido 2-deoxy) D-glucosyl D-galactose, 3-*O*-D-galactosyl D-galactose, 3-*O*-β-D-glucosyl D-galactose; also a trisaccharide, *O*-β-D-galactosyl-(1–4)-*O*-β-D-glucosyl (1–4) 2-acetamido 2-deoxy D-glucose.

When the trisaccharide was used as an inducer with *K. aerogenes* cells, a β-glucosidase was induced, for which cellobiose was a substrate, but not maltose, lactose, melibiose or *N,N'*-diacetyl chitobiose. A disaccharide, characterized as 3-*O*-β-(2-acetamido 2-deoxy) D-glucosyl D-galactose, appeared in the medium; the rate of formation was readily followed by increasing response to the Morgan–Elson reagents[10] while the total hexosamine content[9] of the medium remained unchanged. The presence of D-glucose in the medium was detected by glucose oxidase[7], although this sugar was readily fermented[3]. The disaccharide was not oxidized by galactose oxidase. When used as an inducer with *K. aerogenes* cells, a β-D-glucosaminidase was induced, for which chitin and *N,N'*-diacetyl chitobiose were substrates but not the other disaccharides previously cited. The progress of enzymatic hydrolysis of the disaccharide was followed by the appearance in the culture medium of D-galactose, specifically oxidized by galactose oxidase. The disaccharide was hydrolysed by a specific β-D-glucosaminidase to D-galactose and *N*-acetyl D-glucosamine, characterized by its positive reaction with the Morgan–Elson reagents[9].

The presence in the trisaccharide of two β-glycosidic linkages was thus established by the anomeric specificity of the induced enzymes formed when the isolated trisaccharide and disaccharide acted as inducers; these findings were confirmed by the action of enzymes of known specificity. The galactose non-reducing end-groups initially removed from *S.* XIV were also β-glycosidically linked.

The first four units of *S.* XIV were thus: β-D-Galp 1–4 β D-Gp 1–4 β D-GpNAc 1–3 D-Galp. *S.* XIV was a substrate for β-D-galactosidase, galactose oxidase, β-glucos-

aminidase and a constitutive α-D-galactosidase, isolated from *Streptococcus bovis* Bailey strain 1 (ref. 13), which cleaved melibiose but not lactose.

After repeated inductions using *K. aerogenes* cells, a non-dialysable residue was obtained. This contained no glucose, had $[\alpha]_D^+$ 27° (*c* 0·12 in N NaOH) and contained 0·97 moles *N*-acetyl glucosamine per mole galactose. This residue precipitated with anti-XIV serum and cross-reacted with human anti-*B* serum. A disaccharide, characterized as *O*-galactosyl 2-amino 2-deoxy glucose, was recovered from the products of mild acid hydrolysis of the residue. Periodate oxidation of the residue, followed by acid hydrolysis, revealed glucosamine but not galactose. The residue was no longer a substrate for β-galactosidase. It was, however, a substrate for α-D-galactosidase of *S. bovis*[13], which cleaved D-galactose, characterized in the dialysable fraction by its specific reaction with galactose oxidase. The residue was itself a substrate for galactose oxidase. It was also a substrate for β-glucosaminidase (induced by chitin oligosaccharides in *K. aerogenes* cells; or bee venom). Either of these enzymes, when incubated with the residue, removed a disaccharide characterized as 6-*O*-galactosyl 2-acetamido-2-deoxy D-glucose.

The presence in the non-dialysable residue of α-linked galactose non-reducing end-groups was indicated by their removal by α-galactosidase; the cross-reaction with anti-*B* serum supported this view, since blood group *B* substance contains α-linked D-galactose units in the antigenic determinant groups[14]. The failure of the non-dialysable residue to induce a β-glucosaminidase supports this view, while the isolation of a galactosyl-*N*-acetyl glucosamine from the action of a specific β-glucosaminidase suggests the presence of β-linked *N*-acetyl glucosamine units in the residue.

THALIDOMIDE AND INDUCED AMPHIBIAN METAMORPHOSIS

By DR. J. R. TATA

National Institute for Medical Research, Mill Hill, London, N.W.7

ATTEMPTS to determine the cause of the teratogenic action of thalidomide have emphasized the need for more experimental procedures for producing the embryotoxic effects of drugs[1]. The use of mammalian fœtuses[2] for this purpose suffers from two drawbacks: (*a*) complications due to maternal responses to the drug; (*b*) the difficulty of accurate timing of the initiation of embryonic morphogenic processes. In some respects, therefore, the developing chick embryo[3] represents a better experimental system than the mammalian fœtus[2]. In our laboratory, we have been investigating the biochemistry of the precocious induction by thyroid hormones of metamorphosis in the giant American bullfrog (*Rana catesbeiana*) during the long (2–3 years) pre-metamorphic period. Biochemically and morphologically, accelerated metamorphosis induced by these hormones is qualitatively indistinguishable from the slow, normal process[4]. The ease with which effects of various substances on the developing frog embryo could be investigated is obvious. It is also possible to correlate chronologically and accurately any effect to the time of onset of morphogenic changes, such as limb growth, skeletal modifications, tail resorption, etc., following induction of metamorphosis. These considerations prompted a test of the effect of thalidomide during precociously induced metamorphosis in bullfrog tadpoles. The results described here show that thalidomide is quite non-toxic to pre-metamorphic frog embryos but acquires a strong but transient toxicity during early metamorphosis.

Rana catesbeiana tadpoles (6–8 cm long), purchased from Lemberger Co., Oshkosh (Wis.), were maintained at 20°–24° in aerated tap water on a diet of boiled spinach. Thalidomide (α-*N*-phthalimidoglutarimide) and related substances were dissolved in methyl cellosolve or alkaline 1 : 2-propanediol; triiodothyronine was dissolved in 10 per cent 1 : 2-propanediol at *p*H 8·8. The usual experimental procedures consisted of placing groups of 6–10 tadpoles in 2–4 l. of water containing the substance to be tested, or the solvent blank, for periods of 1–6 weeks before metamorphosis was induced by adding 3–15 μg of 3,5,3′-triiodo-L-thyronine/l. medium. In some experiments the teratogenic agent was injected or added at various time-intervals after the thyroid hormone was administered. The water was changed at regular intervals throughout the course of the experiments. The onset and rate of metamorphosis were recorded by determining the ratios of tail-length : total body-length, and hind-limb length : total body-length.

As shown in Table 1, thalidomide had no harmful effects on pre-metamorphic bullfrog tadpoles maintained in water containing doses as high as 200 mg/l. and for periods up to 2·5 months. There were also no signs of toxicity if 1–2 mg of thalidomide were injected intraperitoneally. However, immersion of the tadpoles in low concentrations of 10–20 mg thalidomide per litre proved to be lethal, in all animals, within 4–8 days after induction of metamorphosis. The time of death following the induction of metamorphosis depended largely on the dose of thalidomide and the hormone. In every case, thalidomide had also completely inhibited the onset of metamorphosis as judged by a variety of indexes such as tail and intestinal resorption, eruption or growth of hind or front limbs, appearance of adult hæmoglobin in blood, etc. The early metamorphic changes in control animals were detected between 4 and 8 days after induction.

Fig. 1 illustrates the time-course of these effects as seen in a typical experiment. In this experiment, administration of triiodothyronine provoked the usual accelerated pattern of induced metamorphosis after a lag period of 3–4 days. Those embryos which were treated with thalidomide alone retained normal body dimensions throughout the course of the experiment. Independently of the duration of pre-treatment with thalidomide, an attempt to induce metamorphosis with triiodothyronine caused the death of all animals on the fifth day after the hormone, with no signs of an initiation of metamorphosis as seen at post-mortem. The extreme sensitivity to this teratogenic agent developed by tadpoles was only manifest for the first four days after induction of metamorphosis, as seen from experiments in which thalidomide was given after triiodothyronine administration (Fig. 2). If given on the same day as the hormone or within 3 days thalidomide inhibited metamorphosis as well as being lethal. It did not prevent the progress of differentiation when metamorphosis had

Table 1. Effect of Thalidomide on Triiodothyronine (T_3)-induced Metamorphosis in *Rana catesbeiana* Tadpoles

Thalidomide dose (mg/l.)	Pretreatment duration before T_3	Dose of T_3 (μg/l.)	Survival 7 d. after T_3	Metamorphosis onset (5 d. after T_3)
0	0	0	12/12	–
200	2 weeks	0	8/8	–
200	2 weeks	10	0/8	–
0	0	10	8/8	+
60	10 weeks	0	8/8	–
60	10 weeks	10	0/8	–
20	1 week	0	10/10	–
20	1 week	10	0/10	–
20	1 week	3	2/10	–
0	0	3	7/8	+

Tadpoles were maintained in water containing different amounts of thalidomide for varying periods of time before and after the induction of metamorphosis with triiodothyronine.

Table 2. Effect of Thalidomide, 'Doriden' (Glutethimide) and L-Glutamine on Induced Metamorphosis

Drug	Dose (mg/l.)	T_3	Survival 7 d. after T_3	Onset of metamorphosis on fifth day after T_3
None	0	–	11/12	–
None	0	+	8/10	+
Thalidomide	20	–	12/12	–
Thalidomide	20	+	1/10	–
'Doriden'	20	–	2/12	–
'Doriden'	10	–	9/10	–
'Doriden'	10	+	8/10	+
L-Glutamine	80	–	6/6	–
L-Glutamine	80	+	6/6	+

Tadpoles were maintained for 12 days in water containing the material under test before induction of metamorphosis with 6 μg/l. of T_3.

been induced 4 or more days prior to its administration and also had diminishing lethal effects with increasing time-intervals between the hormone and thalidomide.

A few substances related to thalidomide were tested in order to determine the specificity of lethal effects of this substance in amphibian embryos with respect to its teratogenicity in mammalian species. Of particular interest is 'Doriden' (glutethimide), a sedative which has been widely used in clinical practice but with no known teratogenic properties[1,5]. Both 'Doriden' and thalidomide have the glutarimide ring in common. Unlike thalidomide, 'Doriden' was highly toxic to non-induced tadpoles, with an approximate LD_{50} at 20–25 mg/l. When used at concentrations below 10 mg/l., 'Doriden' failed to prevent the onset of metamorphosis and the mortality frequency was the same in induced and non-induced tadpoles. Glutamine also had no inhibitory effects on the early stages of induced developmental changes. This brief comparison does not conclusively establish the specificity of thalidomide action, as other unrelated substances may inhibit metamorphosis in frogs[6].

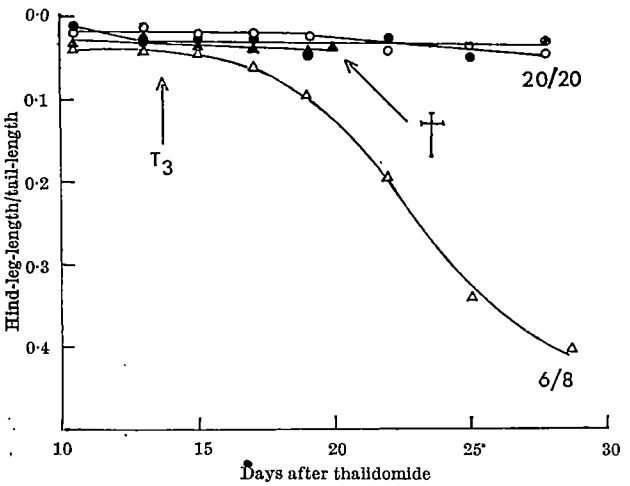

Fig. 1. Effect of pretreatment of *Rana catesbeiana* tadpoles with thalidomide (30 mg/l.) on the induction of metamorphosis by triiodothyronine (10 μg/l.). Treatment with thalidomide was begun on day 0 and continued thereafter. Triiodothyronine was given at the time indicated by the vertical arrow and treatment continued thereafter. ○, controls (no treatment), ●, thalidomide alone; △, triiodothyronine alone; ▲, thalidomide pretreatment and triiodothyronine. The ratio of hind leg to tail-lengths is here used as the index of metamorphosis. Figures at the end of the curves indicate the proportion of the animals surviving at the end of the experiment. † indicates the time (pointed out by the arrow) at which all the animals were dead. T_3, triiodothyronine

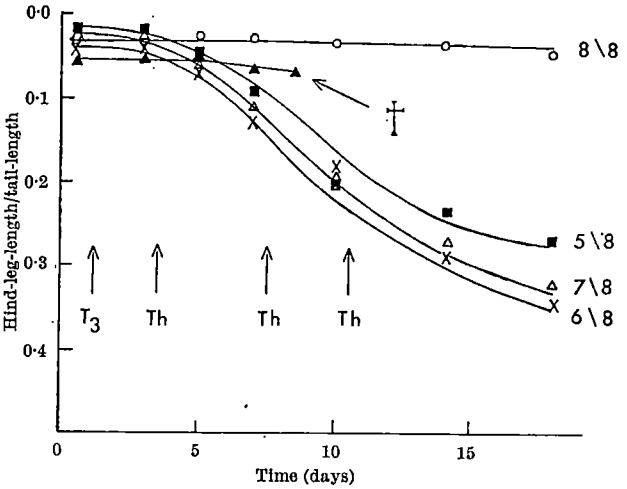

Fig. 2. Transient toxicity of thalidomide as seen after the administration of the drug (30 mg/l.) at increasing time-intervals (indicated by vertical arrows) after metamorphosis was induced by triiodothyronine (6 μg/l.). ○, controls (no treatment); triiodothyronine administered to all other groups. △, no thalidomide; ▲, ■, and *X*, thalidomide treatment begun 2·2, 6·2 and 9·2 days, respectively, after the induction of metamorphosis with triiodothyronine. Th, thalidomide. Other details as in Fig. 1

Judging from the nature of teratogenic effects of thalidomide in mammalian embryos[1,2], I expected at first only a partial inhibitory effect of thalidomide on some specific developmental processes during amphibian metamorphosis, such as a disturbance in limb formation, but not in tail or intestine resorption. The failure to observe such specific effects makes it impossible to say whether identical mechanisms are involved in the embryotoxic effects we have observed in the frog as that in the production of phocomelia in man and other mammals. It is, however, interesting that in both cases the action of thalidomide is only manifest when it is present at stages of differentiation coinciding with limb development and other skeletal changes. It is also noteworthy that during the 72 h following induction of metamorphosis, when thalidomide exerts its lethal action, the extensive modifications in the rate and nature of nuclear and cytoplasmic RNAs synthesized in the embryo are at their peak level[7]. The possibility of testing drugs directly on the isolated embryo and the experimental induction of developmental changes which can be accurately timed justifies further examination of amphibian metamorphosis as an additional system for investigating the embryotoxic effect of substances like thalidomide. If the transient, induced sensitivity of the tadpoles at the onset of metamorphosis and the teratogenicity of thalidomide in mammalian embryos represent different manifestations of the same phenomenon, then the amphibian system of the type described here can be potentially useful as a screening procedure for predicting harmful effects of drugs on embryonic development.

I thank Mr. A. J. Bell for his assistance. I also thank the Distillers Co., Ltd., for a gift of thalidomide, and Dr. D. F. Elliott, of Ciba Research Laboratories, Horsham, for the sample of 'Doriden'.

EARLY LYMPHATIC REGENERATION IN THYMECTOMIZED RADIATION CHIMERAS

By Dr. H. BALNER* and H. DERSJANT
Radiobiological Institute TNO, Rijswijk Z.H., Holland

THOUGH thymectomy of adult animals has no detectable effect on their immune reactivity, there is now ample evidence that the presence of the thymus is required to ensure normal restoration of immune reactivity in sublethally irradiated adult mice[1,2] as well as in lethally irradiated mice surviving with an isologous bone marrow graft[3]. The mechanism by which the thymus, whether left *in situ*, grafted subcutaneously or enclosed in a diffusion chamber, effects such morphological and functional recovery of the irradiated lymphatic system has not been fully elucidated.

The apparent effectiveness of thymus grafts implanted in diffusion chambers no doubt favours a humoral factor as the active principle. Investigations of cell migration, however, have indicated that the thymus (*in situ* or grafted subcutaneously) provides a suitable environment for lymphoid cell proliferation and maturation both in the developing young animal[4] and in the recovering, irradiated adult animal[5].

It has been repeatedly emphasized that the two hypotheses, namely: (1) a thymus passage of lymphoid precursor cells followed by 'peripheralization', or (2) a humoral stimulation of lymphoid proliferation and maturation elsewhere in the lymphatic tissues, need not be mutually exclusive and may, in fact, both be operative.

Chromosome markers have been used during investigations concerned with the involvement of the thymus in the migration of injected donor cells in isologous radiation chimeras. With this method Ford and Micklem[5] have demonstrated that the thymic cell population is derived from the injected bone marrow, even when lymph node cells had been injected simultaneously. The permanent population of the chimera's lymph nodes was also derived from the donor bone marrow, not from the injected lymph node cells. This undoubtedly suggested a selective attraction of the thymus for lymphoid precursors (contained in the donor bone marrow) followed by seeding of supposedly 'instructed' cells to the periphery. However, the earliest identification by Ford and Micklem of the thymus cell population was made six weeks after irradiation and bone marrow treatment, so that the initial fate of the injected cells was, in fact, not observed.

It seemed interesting to examine the fate of the injected donor marrow both in normal and thymectomized chimeras during the early period after irradiation. Since thymectomized chimeras do not regain normal immune reactivity, the proliferative pattern of injected lymphoid precursor cells might be expected to be different from that seen in non-thymectomized controls.

In the present study the isologous donor marrow was labelled with tritiated thymidine. Localization and proliferation of hæmopoietic cells labelled with tritium can be readily followed autoradiographically after injection into lethally irradiated animals[6]. Unlike in chromosome investigations, donor cells which are not dividing in the host can be recognized while the fact that the histological pattern of the surrounding host tissues remains intact is also advantageous.

Female (*CBA* × *C57BL*)F_1 mice were thymectomized or sham-thymectomized when 6–8 weeks old. Four weeks thereafter they were lethally irradiated (912 r., 250 kV, half-value layer 2·15 mm copper) and 3 h later given 25 × 10^6 tritium-labelled viable isologous bone marrow cells intravenously (viability determined by dye exclusion). To obtain a maximal number of labelled 'precursor' cells the donor marrow was obtained from isologous F_1 chimeras (one week after irradiation and bone marrow injection). Preliminary tests had shown that such 'regenerating' donor marrow produced an identical pattern of initial hæmopoietic and lymphatic regeneration in irradiated hosts, as did 'normal' donor marrow.

The donor mice were labelled *in vivo* by two intravenous injections of 25 μc. tritiated thymidine (Schwartz Bio-Research, Inc., N.Y., spec. act. 1·9 c./mM), with an interval of 10 h; they were killed 1 h after the last injection and a bone marrow suspension in Tyrode's solution was obtained from the femurs. Autoradiographs of the donor marrow (Kodak '*AR* 10' stripping film, six weeks' exposure, staining with hæmatoxylin and eosin) showed labelling of about 40 per cent of all cells, with an average of about 20 grains per nucleus.

The danger of damage to the proliferative potential of the labelled cells has been kept to a minimum by labelling the donors with about 2 μc. tritium/g body-wt.; this amount of tritium is accepted as innocuous to the proliferative potential of the animal's bone marrow[7]. In view of previous work along similar lines, the likelihood of host cell labelling and autoradiographic detection of 're-utilized' thymidine is extremely small in the present experimental design.

The recipients were killed at 3 h and at 1, 2, 4, 6 and 8 days following irradiation and injection of the labelled bone marrow, one thymectomized and one sham-thymectomized mouse at each interval. Autoradiography was done on sections of bone marrow, spleen, mesenteric lymph nodes, thymus (in the sham-operated mice), lung, liver and intestines. Initial settling and proliferation of labelled donor cells were scored as reported previously[6]. Though a precise morphological differentiation of the various cell types is difficult in tissue sections covered with stripping film and stained afterwards, it was usually possible to determine whether agglomerations of labelled cells were of the myeloid, erythroid or lymphoid series.

Contrary to what one might expect in view of the marked difference of immune reactivity at a later stage, the thymectomized and the sham-thymectomized mice showed identical localization, proliferation and initial follicle formation by labelled mononuclear cells.

Fig. 1 gives a schematic representation of the findings for both groups of chimeras. A few hours after the injection of the bone marrow suspension the labelled cells were still randomly distributed. Far from seeking the thymus (in the sham-operated controls), the labelled cells generally seemed to avoid that organ already at this early stage. The few cells that could be located in the thymus were rather highly labelled large cells reminiscent of reticulum cells.

During the next few days (1–2 days) labelled cells had virtually disappeared from all except the lymphatic and hæmopoietic tissues. At that time, large numbers of them could be seen in the spleen and lymph nodes, which were still highly atrophic due to radiation damage. Agglomerations of cells of the erythroid or myeloid series, containing up to 30 labelled cells and occasional labelled mitoses, indicated the onset of hæmopoietic regeneration in spleen and lymph nodes which eventually led to dilution and disappearance of the label in the erythroid and myeloid

* Member of the Biology Division of Euratom.

cell lines. This no doubt explains the scarcity of labelled cells in the bone marrow sections by the time the donor cells started repopulating the marrow cavity (day 4–6).

Agglomerations of labelled mononuclear lymphoid cells were rarely seen during the first two days in any organ. Between the 4th and the 6th day, however, the spleen and lymph nodes slowly regained their pre-irradiation histological pattern; areas containing labelled and unlabelled mononuclear cells were now visible round the central arterioles (the sites of the lymphatic follicles before irradiation), while extensive hæmopoiesis was evident in the red pulp causing an enlargement of the spleen. Labelled mononuclear cells were found exclusively in these peri-arteriolar areas, often in large numbers and arranged somewhat concentrically. A similar concentration and presumably proliferation of mononuclear cells were seen in the sub-cortical areas of the still atrophic lymph nodes. Again, labelled mononuclear cells, obviously lymphoid in nature, were seen exclusively in these areas of early follicle formation, usually in groups of 10–30 cells (Fig. 2). Most of the labelled cells had clearly proliferated (dilution of the label); others may have divided very slowly or not at all as judged from the rather high grain count on some nuclei on day 8.

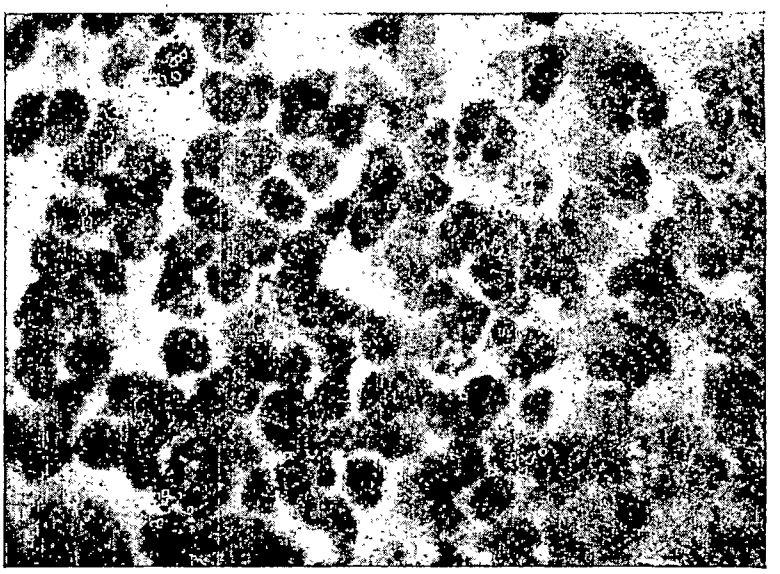

Fig. 2. Group of labelled mononuclear donor cells in lymph node of thymectomized chimera on the sixth day. Cells with a relatively high number of grains may have divided once or not at all after their transplantation

The thymus in the sham-thymectomized controls remained atrophic during the entire first week. The small number of labelled cells observed therein from the very beginning could still be spotted in the thymus sections on the 6th and 8th day. Contrary to what was seen in spleen and lymph nodes, proliferation of labelled cells could not be observed in the thymus. A return of the lymphatic cortex of the thymus was first seen on day 8, but these lymphocytes were not labelled.

Though not yielding a detectable difference in the pattern of lymphoid regeneration in thymectomized and non-thymectomized chimeras, the experiments described here nevertheless allow the following conclusions: The identical distribution and proliferation of apparently all cell lines in the two kinds of chimeras suggest that, whatever the influence of the thymus on restoration of the lymphatic system in chimeras may be, it is not discernible during the first 8 days of recovery, at least not morphologically. The sham-thymectomized controls seemed to confirm this impression since there was no traffic of labelled cells in the thymus during that period. The few large labelled donor cells, found in the thymus at any time, never showed a tendency to proliferate during the period when obvious proliferation of presumably immature labelled lymphoid cells was occurring in the spleen and lymph nodes. When lymphoid proliferation was finally resumed in the thymus cortex on day 8, these lymphoid cells were not labelled. They were, therefore, not derived from the few obviously inert labelled donor cells continuously present in the thymus. Since a chimera's thymocytes will be of the donor type, as has been repeatedly proved, it seems plausible that they were seeded from the 'primitive' follicles in spleen and lymph nodes, where proliferation of labelled mononuclear cells had been going on since the 4th day; this had led to a loss of the label in most of these cells on day 8. An alternative hypothesis would assume a separate kind of 'stem cell' for thymocytes in the donor marrow which had never incorporated any label. Afterwards, these 'thymocyte-precursors' would have localized preferentially and unrecognized in the recipient's thymus. Such an alternative is, however, rather unlikely.

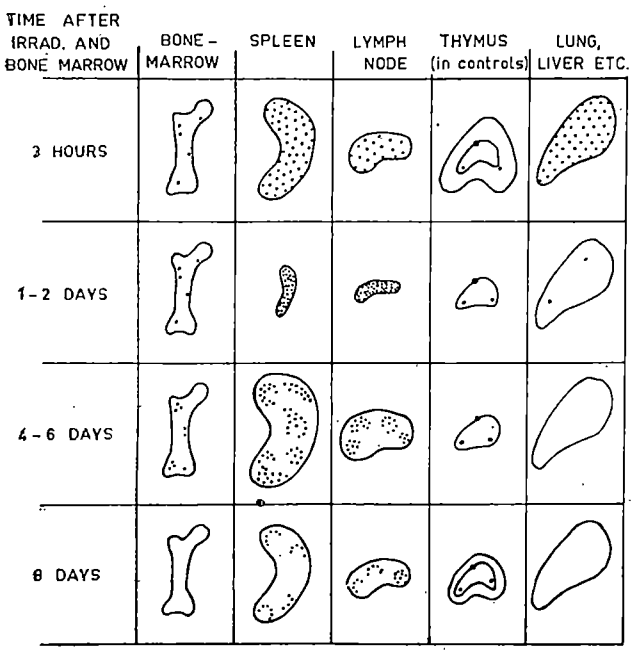

Fig. 1. Distribution and relative number of tritium-labelled donor cells in thymectomized as well as in non-thymectomized isologous chimeras

It seems, therefore, that a 'thymus passage' of lymphoid precursor cells in the non-thymectomized animals is unlikely during the first eight days, while a humoral influence, if already existent, has no effect on the morphology of initial lymphoid regeneration. It is postulated that if a thymus passage of lymphoid cells for the acquisition of immunological competence indeed takes place, it starts after a latent period of at least one week when mononuclear cells, probably derived from primitive follicles in spleen and lymph nodes, start to repopulate the thymus cortex.

We thank Dr. D. W. van Bekkum for advice.

This work was performed under contract with Euratom (European Atomic Energy Community), 51–53 rue Belliard, Brussels, Belgium.

EFFECT OF SERUM FROM NORMAL AND DIABETIC SUBJECTS ON INCORPORATION OF GLUCOSE 1-CARBON-14 INTO INDIVIDUAL FATTY ACIDS OF RAT ADIPOSE TISSUE

By PROF. ALLEN R. HENNES and DR. KOZI AWAI
Department of Medicine, Wayne State University School of Medicine
AND
LAWRENCE POWER
Department of Medicine, University of Michigan Medical School

WE have compared the effect of serum from control and untreated insulin independent diabetic subjects on incorporation of glucose 1-^{14}C into fatty acids by rat epididymal adipose tissue.

In the first group of experiments, serum from six controls and five untreated hyperglycæmic insulin-independent diabetics, with fasting blood sugar less than 150 mg per cent, was obtained in the fasting state, 20 and 120 min after ingestion of 100 g of glucose. Glucose concentration in serum was adjusted to 300 mg per cent in all investigations. Two ml. of serum containing 5 μc. of 1-^{14}C glucose were incubated with fragments of epididymal fat pad from 200–225-g Wistar rats[1]. Serum from controls and diabetics was incubated with adipose tissue from the same group of rats. After incubation for 3 h, the tissue and serum were extracted[2], fatty acids were saponified, and the carbon-14 in one aliquot was determined in a liquid scintillation spectrometer. Another aliquot was methyl esterified[3]. The methyl esters were then separated on a 20 per cent diethylene glycol succinate column. Each peak and the areas between the peaks were trapped separately by a method developed in this laboratory[4] and carbon-14 in individual fatty acids was determined.

Serum from the five hyperglycæmic diabetics stimulated less incorporation of glucose 1-^{14}C into fatty acids than did serum from six controls. Because of the small number of samples, differences were only significant when the effects of serum obtained 20 min after glucose were compared. However, differences were almost significant ($P < 0{\cdot}10$) when fasting, and 120 min post-glucose sera were compared. Further, there was no overlap between individual values in the two groups. It therefore appears that the net effect of serum from mildly hyperglycæmic, ketosis-resistant diabetics on incorporation of glucose 1-^{14}C into fatty acids is less than normal (Fig. 1).

Serum from controls and hyperglycæmic diabetics had similar effects on the distribution of carbon-14 among the individual fatty acids with one noteworthy exception—percentage of fatty acid carbon-14 in oleic acid was significantly less when adipose tissue was incubated with fasting, and post-glucose serum from the hyperglycæmic diabetics.

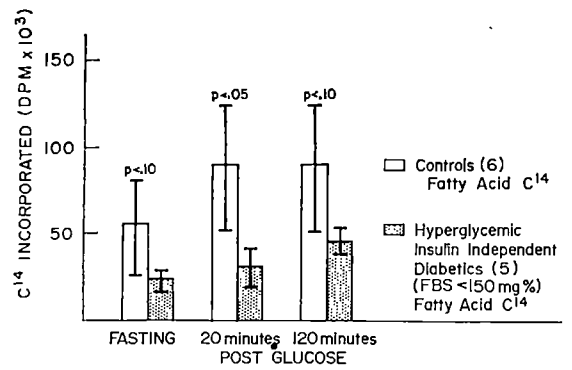

Fig. 1

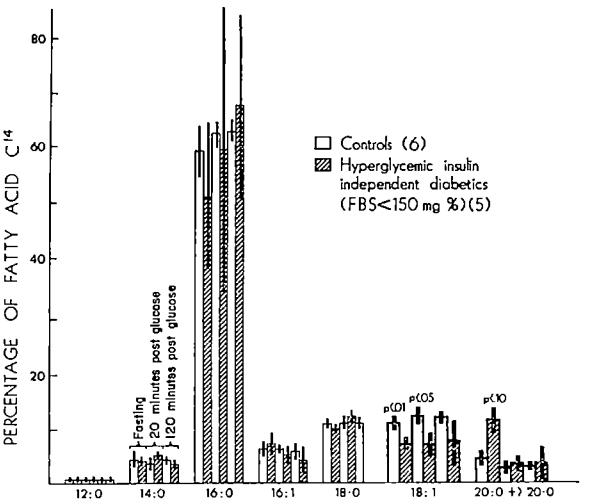

Fig. 2

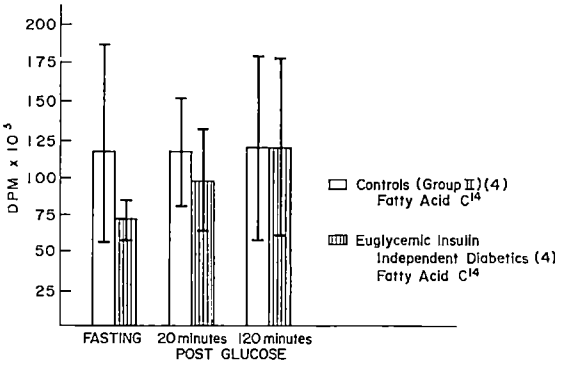

Fig. 3

In contrast, no significant difference was noted between the effect of fasting, 20 or 120 min post-glucose serum obtained from four untreated diabetics with normal fasting blood sugar and four other controls examined at the same time. Nor was a difference in incorporation of carbon-14 into individual fatty acids found (Figs. 3 and 4).

Incorporation of carbon-14 into fatty acids was much greater in the second group of experiments in both controls and diabetics than in the first group. It appears that the sensitivity of adipose tissue to stimulation of incorporation of glucose 1-^{14}C into fatty acids by serum varies with different groups of rats. Therefore, control and diabetic sera should be tested against adipose tissue from the same group of rats.

With the increase in incorporation of carbon-14 into fatty acids, there was a striking increase in percentage of carbon-14 in oleic acid. When total disintegrations per minute in fatty acids were plotted against percentage of carbon-14 in oleic acid, there was a striking positive cor-

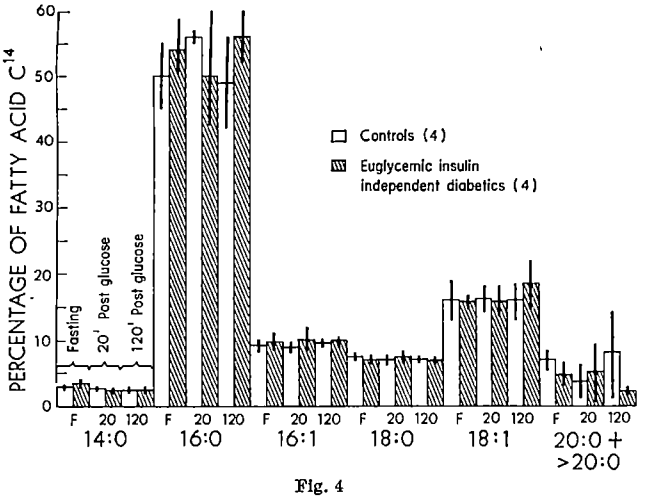

Fig. 4

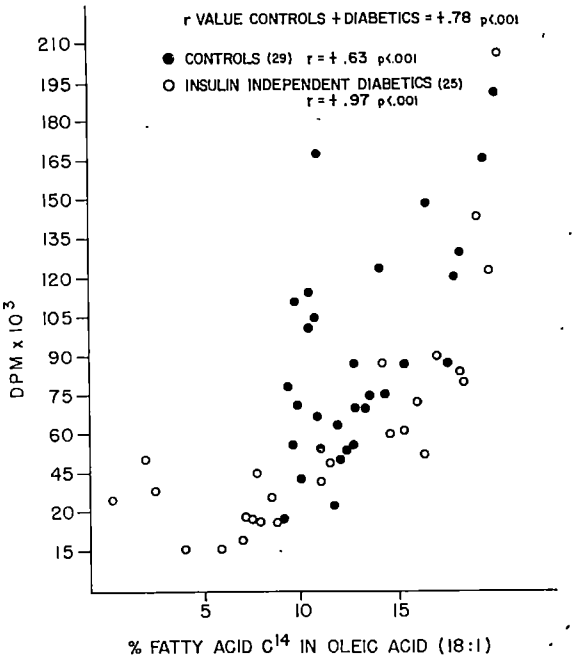

Fig. 5

relation. This was particularly remarkable when fat pads were incubated with serum from diabetics (Fig. 5).

It therefore appears that the net effect of serum from normal and diabetic subjects on stimulation of formation of fatty acids by epididymal adipose tissue is related in some way to stimulation of formation of one particular fatty acid, oleic acid. It is of interest that compounds which may be oxidized by mitochondria, such as ketones, or may be involved in electron transport (quinones), or may serve as hydrogen donors (ascorbic acid), almost selectively stimulate formation of oleic acid in preparations of human blood cells[5]. This fatty acid appears to be made in a mitochondrial system separate from that for long chain, saturated fatty acids[6]. Degradation of oleic acid formed by blood cells shows a distribution of carbon-14 compatible with formation of this fatty acid by a chain lengthening pathway, presumably mitochondrial[7]. Perhaps the disproportionate stimulation of oleate formation in these various situations is a reflexion of increased oxidation by mitochondria. Formation of oleate from stearate appears to require TPNH[8]. It is conceivable that formation of oleate in the mitochondria could serve to re-oxidize the reduced TPNH formed at the isocitric dehydrogenase step. Formation of this fatty acid might then be expected to increase whenever mitochondrial oxidations proceed at a rate which exceeds the capacity of transhydrogenase or of the TPNH cytochrome *c* reductase systems to re-oxidize TPNH.

Benjamin and Gellhorn have shown that formation of oleate from stearate is greatly decreased in liver and adipose tissue from alloxan diabetic rats. This defect was corrected by administration of insulin *in vivo*, but not *in vitro*, and was apparently unrelated to total fatty acid radioactivity[9].

The present work demonstrates that stimulation, by serum, of incorporation of glucose 1-^{14}C into adipose tissue fatty acids, presumably an effect of insulin in the serum, is closely related to stimulation of oleic acid formation. Whether this indicates a specific effect of insulin on formation of oleic acid or is due primarily to increased substrate utilization by mitochondria is unknown.

We thank Mr. John Juntunen for assistance. The work was supported by grants from the National Institutes of Health (*AM*-5024-08; *AM*-07089-02; and *AM*-05891-2).

DUAL ONTOGENY OF THE MALE *Coccophagus gurneyi* COMP. (HYMENOPTERA: APHELINIDAE): A PHENOTYPIC PHENOMENON

By Prof. STANLEY E. FLANDERS
Department of Biological Control, Citrus Research Center and Agricultural Experiment Station, University of California, Riverside, California

THE ontogeny of the male *Coccophagus gurneyi* Comp. exhibits two courses, ectoparasitic and endoparasitic, with correlated differences in form and behaviour. The course followed by a particular individual is determined by the environment of the deposited egg. Larval morphology indicates ectoparasitism to be the primitive course.

A prerequisite for the dual ontogeny of the male in the aphelinid *Coccophagus gurneyi* Comp., a species which reproduces parasitically on certain mealybug species in the genus *Pseudococcus* (Homoptera: Coccidae), is the divergent ontogeny of the sexes, this being female development as a primary parasite and male development as a secondary parasite of the host mealybug.

The *C. gurneyi* male, like the males of many other aphelinid species, is a general parasite of coccid-inhabiting primary parasites. However, it differs from the males of

other known species of similar habit in possessing the extraordinary capacity of being able to develop along two different paths that are initiated by the two distinctive sites of the deposited egg.

This male dual ontogeny consists of direct and indirect secondary parasitism of mealybugs that serve as hosts of the species, the male *C. gurneyi* developing endoparasitically on a parasitic full-fed larval female when the relation is direct, and ectoparasitically when the relation is indirect. (When secondary parasitism is direct, the parental female attacks only the parasitized host of the primary, or the primary itself; when indirect, the parental female attacks the host of the primary, whether or not that host contains a parasite[1].)

The fact that the larvæ of *Coccophagus gurneyi* are able to develop both externally and internally on several species of mealybug-inhabiting parasites was first noted in 1928 (ref. 2). That this capacity was limited to male larvæ was not known until 1936 (ref. 3).

The phenotypic aspects of the direct and indirect secondary parasitism exhibited by the male *C. gurneyi* remained obscure until their elucidation in 1963 by the late Giulio Zinna. His observations (unpublished)* showed that the indirect secondary relation initiates ectoparasitic development and is established when the haploid egg is deposited in the viscera of a mealybug; the direct secondary relation which initiates endoparasitic development is established when the haploid egg is deposited in the viscera of a parasitic larva inhabiting the mealybug.

The reproduction of the *C. gurneyi* female as a primary parasite of the citrophilus mealybug, *Pseudococcus fragilis* Brain, and of the long-tailed mealybug, *P. adonidum* (L.), has been known since 1928 when the species was imported into California from Australia. Despite such primary reproduction the *C. gurneyi* female does not discriminate between parasitized and unparasitized mealybugs, and prefers to oviposit as a secondary rather than as a primary parasite, when attacking hosts already inhabited by a parasitic larva.

Compere and Smith[2] observed that when citrophilus mealybugs inhabited by the larvæ of the encyrtid *Tetracnemus pretiosa* Timb. are exposed to attack by an excessive number of *C. gurneyi*, the bodies of such larvæ are frequently distended by the numerous *C. gurneyi* eggs deposited therein.

The combination of the obligatory hyperparasitism which characterizes the male of *C. gurneyi* and the availability in the field of primary parasites such as *T. pretiosa* —by assuring the continuity of the male population and the early mating of the *C. gurneyi* female—may be responsible for the citrophilus mealybug population in California being continuously at very low densities[4].

Although *T. pretiosa*, in the absence of *C. gurneyi*, is capable of controlling citrophilus mealybug populations[2], the decimating effect of the hyperparasitic habit of *C. gurneyi* on the *T. pretiosa* population apparently precludes the latter being the numerically dominant species.

Cendaña[5] was the first to note that the progeny of unmated *C. gurneyi* females could not complete their development in hosts not inhabited by parasitic larvæ. However, because he failed to experiment with hosts that were inhabited, he erroneously concluded that males were produced only by mated females. That hyperparasitic development was restricted to the male and was dually ontogenetic was then unsuspected, the essential character of the differential development of the sexes in many Aphelinidae being unknown[6].

Compere and Smith[2] also noted that when a *C. gurneyi* female attacked a host which was not inhabited by a parasitic larva, her eggs generally were deposited free in the host's body cavity and only occasionally in the visceral

Fig. 1. Photograph of *Coccophagus gurneyi* eggs in tap water after removal from the body fluids of a larval *C. gurneyi* female. The single egg showing a fully developed embryo is haploid; the other four are presumably diploid and non-viable because they were deposited in an unfavourable environment

organs. This seemed confirmed by the fact that many supernumerary eggs were phagocytized, a process that occurs in the host's body fluids. Later, Cendaña[5] corroborated this observation. He concluded that the supernumerary eggs deposited by 'mated' *C. gurneyi* females were subject to 'true' phagocytosis as described by Timberlake[7]. Bess[8] reported that female-producing eggs when in *P. fragilis* were more likely to be phagocytized than when in *P. adonidum*, and that when in other species most, if not all, the female-producing (diploid) eggs were readily phagocytized.

When both haploid and diploid eggs are deposited within the body fluids of a larval primary parasite (Fig. 1), only the haploid eggs develop successfully, the diploid eggs aborting without having been phagocytized. It is noteworthy that rarely, if ever, are the male-producing (haploid) eggs subject to phagocytosis whether in the body-fluids of a coccid or of a hymenopterous larva.

Zinna's 1963 observations, however, showed that, when an unparasitized host mealybug is subjected only to a single oviposition by either a mated or unmated *C. gurneyi*, the egg almost invariably is deposited in the sub-œsophageal ganglion. The characteristic stance taken by the female when thus ovipositing is that of standing on the thoracic dorsum of the host facing anteriorly. Previously, Cendaña[5] had noted that the female preferred this oviposition site, but failed to realize its significance.

Unfertilized eggs, when deposited in the sub-œsophageal ganglion of a mealybug, develop, but the development of fertilized eggs if placed in such a situation is questionable.

The facultative ability of the *C. gurneyi* male to develop either ectoparasitically or endoparasitically on the full-fed larva of a primary parasite is not dependent on the species of host mealybug, as erroneously assumed by Flanders[3].

On July 27, 1963, a full-fed female larva of *C. gurneyi* removed from the body of a citrophilus mealybug bore on its surface a yellow, highly sclerotized first-instar male larva (Fig. 2), apparently feeding. The host female larva was then dissected in tap-water and found to contain four translucent second-instar males each partially encased by

Fig. 2. The first instar male of *Coccophagus gurneyi* when ectoparasitic. Photographed after hatching and before feeding. Note the incomplete segmental bands on the thorax and the six anterior abdominal segments that permit body expansion when food is ingested

* Dr. Zinna's observations were made while working under a NATO grant at the Biological Control Laboratory, University of California, Riverside, in 1963. He was then on leave from his duties as assistant director, National Center of Biological Control, Portici, Naples, Italy.

Fig. 3. The endoparasitic second instar male of *Coccophagus gurneyi* before (top) and after (bottom) hatching. Note head capsule, arrow, and exuviæ of the first instar. Oxygen enters the tracheal system by osmosis, not through the spiracles as when ectoparasitic

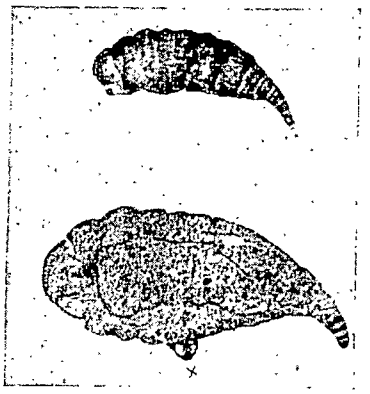

Fig. 4. Ectoparasitic first-instar male of *Coccophagus gurneyi* (top) in condition to moult, and the ectoparasitic second-instar male (bottom) after moulting. Second instar with body somewhat compressed to expose gas-filled tracheal loop. Note the head capsule (*X*) and 'caudal' segments of the first instar

the exuvia of the first instar and the chorion of the egg (Fig. 3).

When ectoparasitic, the larva casts its first-instar exuvia after hatching (Fig. 4). When endoparasitic, the first larval ecdysis occurs before hatching (a phenomenon first observed by Zinna). The second instar in either case possesses a gas-filled tracheal loop with seven pairs of spiracular branches. Only two of these pairs are connected to spiracles. When the second instar is endoparasitic the proximal portion of each spiracle-connected branch lacks gas (oxygen?).

The presence of non-functional spiracles in second-instar males indicates that with this species indirect secondary parasitization evolved prior to direct secondary parasitization.

The third instar male, whether endoparasitic or ectoparasitic, has seven pairs of open spiracles. Prior to emerging from the primary parasite, the endoparasitic male is encased by a sheath of cocooning material as are many endoparasitic chalcidoids[9]. This sheath may be necessary to protect the seven pairs of open spiracles from the host's body fluids. The sheath, which occurs as a very thin transparent film adhering tightly to the male's body, may have been formed, in part, during the second instar. When the male is ectoparasitic this sheath is lacking.

In one 'direct secondary' experiment in which specimens of citrus mealybug, *Planococcus citri* (Risso), were parasitized by *Leptomastix dactylopii* (July 5) and later (July 7–8) exposed for 24 h to unmated females of *C. gurneyi*, a *Leptomastix* female that had mummified its host mealybug, and then pupated, yielded a third instar *C. gurneyi* male (July 16).

In an 'indirect secondary' experiment in which *P. citri* was first parasitized by unmated *C. gurneyi* (July 26) and then by *L. dactylopii* (August 8), the emergence of a male *C. gurneyi* began August 27. The length of the male's life-cycle was prolonged by the interval between the two exposures to parasitization.

Cendaña[5] removed from a parasitized mealybug an unhatched live male larva 85 days after it had been deposited as an egg. This larva had apparently moulted once, but had retained the moult skin in position.

Table 1. Sequence of Developmental Phenomena characterizing the Dual Ontogeny of the *Coccophagus gurneyi* Male

Indirect	Direct
Differential host relations	
Haploid egg	
Deposited in viscera of mealybugs	Deposited in viscera of primary parasite of mealybugs
Minimum period of embryonic development 3–4 days	
Respiratory system of unhatched larva with two pairs of spiracles	
Growth	
Discontinuous	**Continuous**
All instars feed ectoparasitically	Only last stage of third instar feeds ectoparasitically
Hatching of egg dependent on consumption of host viscera by the primary host	Hatching of egg dependent on first larval ecdysis
First instar	**First instar**
Body segments become indurated forming yellow distinct bands. Pear-shaped when engorged	Body segments do not become markedly indurated and yellow. 'Hymenopteriform' when engorged
Respiratory system	
Second larval instar	
Two pairs of functional spiracles	Two pairs of non-functional spiracles
Third larval instar	
Seven pairs of spiracles	
Protected by larva-secreted sheath	Not protected by larva-secreted sheath

The facultative dual ontogeny of the *C. gurneyi* male (Table 1), therefore, is dependent on whether or not the mealybug host is inhabited by a primary parasite at the moment that the unfertilized (haploid) egg is deposited. If such a larva is present, its viscera receives the haploid egg; if absent, the mealybug's viscera receives the egg.

In the first case, male development is more or less continuous, whereas in the second case it is discontinuous, the hatching of the male larva being contingent upon the mealybug being inhabited later by a full-fed larva of a primary parasite.

ORIGIN OF METEORITES

By B. J. LEVIN

O. Schmidt Institute of Physics of the Earth, U.S.S.R. Academy of Sciences, Moscow

IN the report to the eleventh U.S.S.R. Conference on Meteorites (held in Moscow during May 1964) I proposed that the most highly differentiated and recrystallized types of meteorites, namely, irons, stony irons and achondrites, represent a product of a phase separation in chondritic material which occurs by diffusion in the solid state. This process must have been a continuation of the transformation of carbonaceous chondrites into ordinary

chondrites, which, according to Mason[1], was due to dehydration, reduction and recrystallization in the solid state. (Mason designates the formation of chondrules as spherulitic crystallization. However, the primitive chondrules are not completely crystalline but contain glass. Moreover, the investigations of microstructures of carbonaceous chondrites[2,3] had shown that the formation of 'high-temperature' minerals begins with the formation of minute globules (microchondræ). Probably the process of chondrule formation (at least its initial stage) is similar to the separation of glass into two metastable liquids which was recently examined in the laboratory during the course of developing a glass-ceramic[4].)

The formation of Widmanstätten structures in octahedrites occurred at 350°–500° C over a period of 10^7–10^8 years. The diffusion coefficients are very temperature-dependent and at greater temperatures much larger changes must have occurred during the same interval of time. But the central parts of larger asteroids were about 10^9 years at temperatures of 800°–1,000° C (ref. 5).

A greater solubility of smaller grains due to surface energy (surface tension) follows in the agglomeration of nickel–iron into larger inclusions and redissolution of small ones. The first step of this process occurred during the transformation of carbonaceous chondrites into ordinary chondrites. In the central parts of parent bodies, where the thermal changes proceeded much beyond the formation of crystalline chondrites, the agglomeration of nickel–iron into larger and larger bodies had to produce 'inclusions' of the size of largest iron meteorites found on the Earth. To achieve this in 10^9 years the diffusion coefficient must be of the order of 10^{-3}–10^{-10} cm²/sec. Such values could be attained at 8,000°–1,000° C.

At fragmentation of parent bodies large iron inclusions became separated from surrounding silicates because of differences in densities and elastic properties. These surrounding silicates, which were also strongly altered by diffusion processes, were almost free of nickel–iron. Achondrites must represent samples of them. As was noticed by Prior (1918), many achondrites are similar to the silicate parts of some stony irons.

The stony irons are probably samples in which the separation of metal and silicates was stopped at some intermediate stage by cooling. They do not come from some branch but from the main path of formation of irons. When silicates became locked inside metal the more diffusible ones escaped while the less diffusible became trapped. This was probably the formation process of pallasites. The predominance of olivine in them is possibly due to its high melting temperature. At temperatures more than 500° below the melting point it probably has a low solubility in nickel–iron and/or small diffusion coefficient. The pallasites with rounded or angular olivine-grains must have originated at different temperatures, but in such an interval of time that the temperature-dependences of the 'force of crystallization' and of the surface-tension coincided.

The pallasites, the great nodules of troilite and graphite in metal, are usually interpreted as formed in the melt. But the rate of gravitational differentiation in such a melt is very fast even when gravity is low (Anders, E., personal communication).

On the other hand, the tendency towards phase separation existing above the melting point in many cases continues to exist at lower temperature as well. But in the solid state enormous intervals of time are needed to permit this phase-separation tendency to manifest itself. The meteorites, or rather the meteorite parent bodies, had life-histories which just fitted the necessary conditions.

If such large-scale diffusion occurred in meteorite parent bodies, then chemical fractionation by diffusion must have occurred on a large scale. The fractionation of trace elements in meteorites possibly can be explained in this way, including a varying behaviour of some elements which can be due to differences in environment and temperature.

I trust that this re-interpretation of observed features of meteorites will confirm that diffusion in the solid state was a decisive process in meteorite parent bodies, no part of which was ever molten.

MICROWAVE FARADAY ROTATION IN FERRITE POWDERS

By Dr. PREM SWARUP and NARENDRA KUMAR
Institute of Armament Technology, Poona, India

A SYSTEMATIC investigation has been made of non-reciprocal microwave rotation through ferrite powder, magnetized below saturation, as a function of magnetizing field and packing density at 9 kmc/s at room temperature. Philips 'Ferroxcube IV' fine powder was pressed into standard cylindrical pellets (2 cm long and 1·95 cm in diameter) of varying packing density. The experimental arrangement consisted of a 2 k 25 klystron, a standard x-band microwave bench (consisting of isolator, attenuator, wave-meter and tuner) feeding a circular wave-guide in TE_{11} mode, which in turn was terminated in a matched 1N23 detector through a swivel-head joint calibrated in degrees. A solenoid slipped over the circular wave-guide provided the variable longitudinal magnetization. The ferrite sample filled the circular wave-guide completely.

Assuming lossless permeability tensor, the specific rotation of the plane of polarization of a plane wave is given by[1]:

$$\frac{\theta}{l} = \frac{w\sqrt{\varepsilon}}{2c}\left[\left(1+\frac{w_m}{w+w_0}\right)^{1/2} - \left(1+\frac{w_m}{w_0-w}\right)^{1/2}\right] \quad (1)$$

where θ is the rotation of the plane of polarization in radians; l, length of the ferrite rod (2 cm); ε, dielectric constant of ferrite (about 13); c, velocity of light; w, operating angular frequency ($2\pi \times 9$ kmc/s); w_0, resonance frequency given by Kittel's formula; w_m, resonance frequency corresponding to saturation magnetization ($\gamma 4\pi M_0$); γ, magnetogyric ratio ($1{\cdot}76 \times 10^7$ radians/sec/œrsted); M_0, saturation magnetic moment per unit volume.

In the case of unsaturated ferrite operating at a frequency much below resonance, the relation (1) can be simplified to:

$$\frac{\theta}{l} = \frac{\sqrt{\varepsilon}\, w_m}{2c}. \quad (2)$$

ε and w_m are both functions of the packing density while w_m depends on the applied magnetic field also. The dielectric constant of the powdered sample is related to the packing density by the relation[2]:

$$\frac{\varepsilon - 1}{\varepsilon + 2} = C_1\rho \quad (3)$$

where ρ is the packing density and C_1 is a constant. This gives the value of dielectric constant of the sample as:

$$\varepsilon = \frac{1 + 2C_1\rho}{1 - C_1\rho} \quad (4)$$

To evaluate w_m in case of unsaturated ferrite powder, M_0 is to be replaced by the unsaturated value M, as such:

$$w_m = \gamma 4\pi M = \gamma 4\pi H_{\text{eff}} X \quad (5)$$

where γ, magnetogyric ratio; X, static low field susceptibility; H_{eff}, effective magnetic field in the sample after taking account of the demagnetization factor N_z. The expression for H_{eff} is given by:

$$H_{\text{eff}} = \frac{H_a}{1 + 4\pi X N_z} \quad (6)$$

where H_a is the applied field. The susceptibility also depends on the packing density. The permeability varies with the density in a fashion analogous to the permittivity and is given by:

$$\frac{\mu - 1}{\mu + 2} = C_2\rho \quad (7)$$

where C_2 is a constant. Since $\mu = 1 + 4\pi X$, X is given by the expression:

$$\frac{4\pi X}{3 + 4\pi X} = C_2\rho \quad (8)$$

substituting equations (8) and (6) in equation (5), the expression for w_m is given by:

$$w_m = \frac{\gamma H_a 3C_2\rho}{1 + C_2\rho(3N_z - 1)} \quad (9)$$

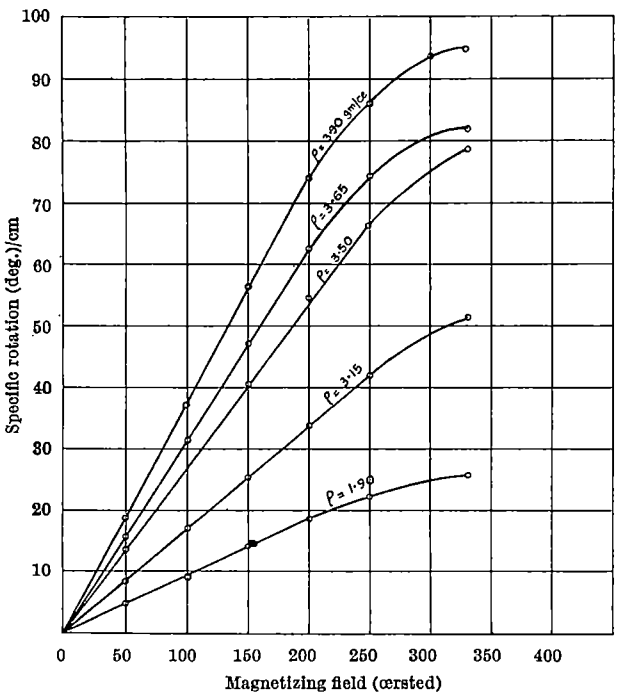

Fig. 1. Specific rotation in ferrite powder samples of varying density plotted against the applied magnetizing field at 9,060 Mc/s

substituting the expression for ε and w_m in the expression (2), the specific Faraday rotation is found to be given by:

$$\frac{\theta}{l} = \frac{(3\gamma)}{(2c)} \times \frac{\sqrt{(1 + 2C_1\rho)}}{\sqrt{(1 - C_1\rho)}} \times \left[\frac{C_2\rho}{1 + C_2\rho(3N_z - 1)}\right] H_a \quad (10)$$

It is seen from relation (10) that: (*a*) the specific rotation is linearly dependent on the applied field; (*b*) the specific rotation is highly superlinearly dependent on the packing density.

Finely powdered ferrite was pressed under various pressures into cylindrical samples of packing densities varying from 1·9 g/c.c. to 4 g/c.c. The specific rotation was measured in each case in the axial magnetic field up to 330 œrsteds. The experimental results showing the specific rotation versus magnetic field are plotted in Fig. 1. It is observed that in all the cases the specific rotation is linearly proportional to the applied field in the unsaturated region. In order to verify the nature of variation of the specific rotation with packing density, the equation (10) was used for theoretical computation. The various constants were determined experimentally. The constants are as follows: ρ, 1·9–3·9 g/c.c.; c_1, 0·20; c_2, 0·23 (c.g.s., unrationalized system of units was used); N_z, 0·12.

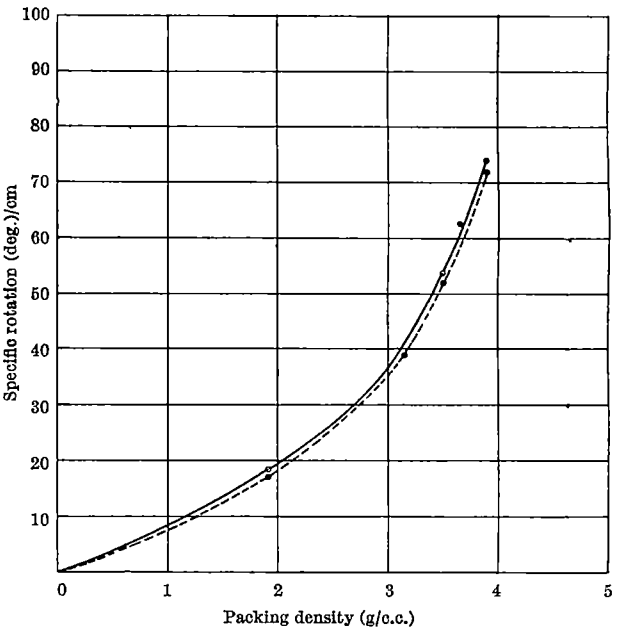

Fig. 2. Specific rotation in ferrite powder samples at an applied magnetizing field of 200 œrsteds plotted against the density at 9,060 Mc/s. ——, experimental; — — —, theoretical

The demagnetization factor N_z was estimated by a magnetostatic method using the constancy of the tangential component of the magnetic field across the cylindrical surface of the sample immersed in axial magnetic field. The theoretical graph and the experimentally observed data on the variation of the specific rotation with packing density are plotted in Fig. 2. It is observed that the nature of the specific rotation variation with the packing density agrees excellently with the theoretical curve, though the numerical agreement is not to be over-emphasized.

We thank Lieut.-Colonel S. Mishra for providing facilities for work and advice and Commodore M. K. Lele, dean of the Institute, for permission to publish the results.

Supplement to NATURE

No. 4962 DECEMBER 5, 1964 Vol. 204

FROM A DROP IN THE OCEAN?

The Chemical Origin of Life

By Alexander I. Oparin. (A Monograph in American Lectures in Living Chemistry.) Pp. xxvii+124. (Springfield, Ill.: Charles C. Thomas, 1964.) 6.75 dollars.

OPARIN has already made outstanding contributions to the most fundamental problem of biology, and *The Chemical Origin of Life* summarizes the present state of his thinking. Apart from being profound scientifically, it is scholarly in range and style, and it has the touch of poetic inspiration which belongs to all the best science.

Oparin observes that "the origin of life is an inalienable part of the general orderly process of development of the Universe in which each successive stage is inseparably bound up with the one before and can only be understood in the light of a study of that predecessor". Consistently with this view he devotes his first chapter to a broad description of astronomical and geological dating, the evolution of different stellar types, the origin of elements, and the formation of the Earth. About 2×10^9 years ago it probably possessed an atmosphere containing water vapour, hydrogen sulphide, ammonia and hydrocarbons, but no significant amount of oxygen. The atmosphere as we know it to-day is perhaps about half this age, and came into being by the action of various forms of life.

The second chapter is devoted to the way in which organic compounds were built up on the primeval Earth under conditions when the ultra-violet radiation was much more intense than now (in the absence of an ozone screen) and when there were no micro-organisms to devour the compounds which might be formed. The main reason, as Oparin remarks, why life cannot now arise *de novo* under natural conditions is that it has already arisen. To form an idea of the course of events, therefore, it is no good looking for evidence left over from the past, but we must rely on reconstruction experiments in the laboratory. These, in fact, show that compounds like amino-acids can be formed by the action of silent electrical discharges on mixtures of methane, ammonia, hydrogen and water vapour; thence in various ways of which analogues are known, optical asymmetry could have arisen. Elaboration and polymerization of the primary organic compounds can also be envisaged, and this now includes the possibility of non-enzymatic synthesis of polynucleotides. The various kinds of model experiment are discussed in some detail.

At the beginning of Chapter 3 we have reached by purely abiogenic means a 'nutrient broth' containing organic compounds similar to those which build up living matter to-day. How do self-reproducing organisms arise in this organic chemical free-for-all? Oparin considers that a key step in the evolution is the formation of 'coacervate droplets' from solutions containing polymerized substances. Polymers do, in fact, separate out from aqueous media in droplets well demarcated from their environment. This boundary formation is a first essential in the evolution of individual organisms. Numerous observations and experiments on coacervate droplets of various kinds are described and in some of these systems significant biochemical reactions can be made to take place efficiently. Coupled biochemical reaction in the droplets can also be believed in, and we arrive at the stage of what Oparin calls 'protobionts'. These could increase their mass at the expense of their environment. They can incorporate extra components, catalysts and so on. Presently an element of replication is introduced when polynucleotides engage in the now well-known game of 'base pairing'. The ordering of amino-acids then becomes coupled with this. "A mechanism of this sort could, of course, only have arisen in the course of the prolonged evolution of living systems. However, we now have fully grounds enough for believing that even at far earlier stages of the development of organic matter, the inclusion of polynucleotides in coacervate droplets or protobionts had a certain effect on the polymerization of the amino-acids in those systems". It must have needed some luck even in 10^9 years. But Oparin's case, even if there are passages of superficiality, is well argued and, on the whole, well documented.

Chapter 4 covers a wide range of biochemical facts in a discussion of the course which the further evolution of the first living organisms may have taken, a central thesis being that the complex mechanisms known to-day must have been elaborated by a process of gradual addition and improvement.

The final section is devoted to a brief examination of geological evidence relating to the chronology of the whole story.

The book is beautifully written, and if we do not feel that all the mysteries are solved the questions are presented and much evidence is marshalled in a way which sheds real illumination. C. N. HINSHELWOOD

PRIMATE EVOLUTION

Evolutionary and Genetic Biology of Primates

Edited by John Buettner-Janusch. Volume 1. Pp. xiv+327. 86*s*. Volume 2. Pp. xii+330. 89*s*. 6*d*. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1963 and 1964.)

A NEW generation of students has moved into the field of primate research—not only new, but also a much more numerous one than we have ever known before. It makes its presence felt in ways far more novel than just the perennial debate about the relevance to human evolution of some fossil fragment which usually becomes known through the heat of partisan advocacy rather than as a result of dispassionate anatomical study. We have symposia on the behaviour, anatomy and physiology of the primates. We have new journals devoted to primate studies. Regional primate centres spring up in the United States at a cost of millions of dollars a year. Some enthusiasts are even trying to describe all this field of interest by the term 'primatology', although here we hope unsuccessfully, since this is scarcely a happy step in a far too rapidly fragmenting world of science.

The two volumes edited by Dr. J. Buettner-Janusch, and entitled *Evolutionary and Genetic Biology of Primates*, are the latest sign of this renaissance of interest in the primates. They are a valuable addition to the library of our knowledge of the mammalian order to which man belongs.

The opening chapter of Volume 1, written by the editor, describes the order and discusses its classification. It is followed by a critical and scholarly reappraisal of fossil primates deriving from Tertiary deposits, and from which we learn that more fossil genera are known in the order of Primates than in all but six of the thirty-three orders of mammal recognized by Gaylord Simpson.

Chapter 3 deals with functional and structural phylogenetic aspects of the primate nervous system, including the visual apparatus. The fourth considers the skin of primates in general, and the fifth the sweat glands of the Lorisidae. The chapter which follows provides an up-to-date account of what is known of nerve endings in primate skin. The final chapter of Volume 1 is a first-rate summing up of present-day knowledge of the chromosomes of primates.

Volume 2 opens with an account of the taxonomic implications of the susceptibility of primates to different viruses. This is followed by an illuminating chapter on primate serum proteins. Chapter 3 deals with primate hæmoglobins. The three final chapters deal in turn with the reproductive physiology and behaviour of the Lemuroidea, the use of the hand in lower primates, and with what are called the 'behavioural displays' of the order.

So rich a fare does not lend itself to review. All that I can do is to light arbitrarily on a few striking facts, for example, that man sweats more and more readily than any other animal, and that his sweat glands are more responsive to different stimuli than those of any other creatures; that "the primate can be characterized by the innervation of its skin just as correctly as by its bipedal gate [*sic*] and its dental formula"; that the pattern of cutaneous nerve endings is the same in all Primates; and "that a ball of non-myelinated neurofibrils has been found in the hairless skin of all Primates studied to date". It is interesting to learn that chromosome numbers in primates vary from $2n = 34$ to $2n = 72$, and that the fact that the only common denominator is 2 rules out the possibility of polyploidy having been a mechanism of chromosome evolution in Primates. It is equally interesting to read that "the karyotypes of many groups of primates studied show a remarkable correlation between low chromosome numbers and low numbers of acrocentric chromosomes and between high chromosome numbers and high numbers of acrocentrics". This suggests that centric fusion has played an important part in the chromosome evolution of the Primates.

We learn, too, that there is a correlation between the spectrum of susceptibility of primate cells to a given virus on one hand, and chromosome counts on the other, and that the anthropoid apes are prey to all human virus diseases that have been tested so far, while Old World monkeys are susceptible to many viruses which affect neither New World monkeys nor the lemuroids, which in turn are both susceptible to some other range of the spectrum of human viruses.

From the bibliographies at the end of each chapter it would seem that few, if any, of the authors who contribute to these two volumes began working in their particular fields of primate study more than ten years ago. Some, indeed, reveal themselves as post-doctoral research students. This makes for a refreshing treatment of the subjects which are discussed. But it also diffuses a certain *naïveté*. For, however up-to-date the chapters, the scope of the two volumes is neither as comprehensive, nor is their focus as novel, as the reader is encouraged to believe. Unless one stretches the meaning of the term beyond recognition, the editor's view that his two volumes constitute a "representative" sample of contemporary research on the primates can scarcely be accepted. All but one of the contributors are young American writers. Some important fields of primate study that are being cultivated in the United Kingdom are not even mentioned by name, and presumably work in other countries has also failed to gain recognition. Equally, the present collection of essays is certainly not the first attempt to bring to bear the results of physiological and other functional investigations on the evolutionary history of the Primates. A volume in which I attempted to do just this more than thirty years ago has, no doubt with justice, and certainly without regret on my part, passed entirely into the limbo; it is not even referred to by name in the present volumes. A certain lack of restraint and discernment also intrudes here and there. It is odd, for example, to read that Landsteiner's discoveries about the specificity of antibodies were "empirical as a phenomenon and vague as a concept". When Landsteiner's generalizations saw the light of day some sixty years ago they represented something far newer in the world of science than anything which has yet been provided by the present set of authors. It is almost as though one of to-day's Ph.D. students in physics were to describe J. J. Thompson's contributions to our understanding of the atom as incomplete and lacking in precision. The quality of scientific novelty and imagination with which Landsteiner's concepts still endure is, alas, hardly characteristic of most of the fact-garnering which goes on to-day in the particular branch of zoology with which Dr. Buettener-Janusch has concerned himself.

But, nevertheless, there is something inspiring about the enthusiasm of the authors who have contributed to his two volumes. Let us hope that the sense by which some of them are animated, that there is some mystery about primate evolution which is bound to be unfolded as new facts become available, will one day be realized.

SOLLY ZUCKERMAN

BIOLOGICAL BASIS OF PSYCHOSOCIAL EVOLUTION

Human Biology

An Introduction to Human Evolution, Variation and Growth. By G. A. Harrison, J. S. Weiner, J. M. Tanner and N. A. Barnicot. Pp. xvi + 536. (Oxford: Clarendon Press; London: Oxford University Press, 1964.) 42*s*. net.

THE proper understanding of human biology is becoming increasingly necessary as a background for all our efforts at practical, social, economic and cultural development. This book is important as being, so far as I am aware, the first to treat it as a subject of study in its own right, as part of a general university curriculum.

It is a valuable attempt at establishing what Prof. Medawar in his foreword calls "a new conception of the natural history of mankind". If it fails fully to achieve this highly desirable result, it is because it has not been adequately planned so as to present human biology in an integrated way, as the study of the unique organism called man, and therefore with its own important difference from general biology.

Let me begin, however, by emphasizing the large amount of valuable facts and ideas, largely based on the most modern disciplines and techniques, which it makes available on human genetics and evolution, growth and development, physiology and biochemistry, pathology and demography, variation and ecological adaptation.

Dr. Tanner's section on "Human Growth and Constitution" is admirable, bringing out the progressive acceleration of pre-adolescent development and its striking individual variation, the concept of physical developmental age and its relation to mental development, the classification of physique and its relation to disease and behaviour. (The lack of planning has resulted in Dr. Barnicot also including a treatment of human physique and its variation in his section.)

My only criticism of Dr. Tanner is that he makes no reference to the facts and implications of differential (allometric) growth-gradients (as opposed to maturity gradients), in spite of the exhaustive treatment of the subject by Rensch in his fine book, *Evolution Above the Species Level*, where he points out that both in development and evolution the description of characters has had to give place to a study of gradients and their effects. No mention is made of Rensch's remarkable demonstration that in many groups (including some invertebrates) increased absolute brain-size is correlated with improved

behavioural performance, and that this is due to the positive allometry (and therefore relatively as well as absolutely greater size) of the higher, more recently evolved regions of the brain, though this is of special relevance to man's evolution and present variation.

Harrison's section gives an excellent summary of human genetics which will be especially valuable to medical men, psychiatrists, psychologists, social scientists and historians, especially in view of the numerous 'anti-geneticists' still unfortunately to be found in their ranks. The long-overdue inclusion of E. B. Ford's rational nomenclature for the blood-groups in a general text-book is welcome.

None of the authors draws the important distinction between survival selection and reproductive selection, though it is especially relevant in man, where reproductive selection has become relatively far the more important. The results of both are lumped together under the fashionable but misleading term 'Darwinian fitness' (it was Spencer who influenced Darwin to use the unfortunate phrase 'survival of the fittest' in later editions of the *Origin*; and Darwin glimpsed the difference by distinguishing sexual from natural selection).

I hope that in the new edition, which will assuredly soon be called for, they will point out that man shows the highest degree of genetic variation known (Roger Williams's work is not cited), and that this makes possible the desirable 'varied excellence' and division of cultural labour that are basic for social structure, education, and possible eugenic improvement.

I hope, furthermore, that they will devote more space to the subject of morphism, the convenient term for Ford's balanced genetic polymorphism. Apart from colour-blindness and PTC taste-blindness, they do not treat the remarkable human sensory morphisms, such as smell-blindness, to hydrocyanic acid and the scent of freesias, taste-blindness to benzoate of soda, brucine and two separate components of mannose, and myopia; nor do they discuss the fascinating suggestion, in Darlington and Mather's *The Elements of Genetics*, of a correlation between O blood-group frequency and ease of pronouncing fricative dental sounds like *th*: this could readily be scientifically investigated, but the challenge has not yet been taken up.

Yet morphisms are an outstanding challenge to the biologist, since they all involve special genetic mechanisms, selective balance, morph-ratio clines, interesting geographical distribution, and evolutionary persistence (thus PTC taste-morphism certainly exists in chimpanzees, and probably in rats). And sensory morphisms are of special interest to the human biologist since they can most readily be detected and investigated in man, and their balance of selective advantage and disadvantage (which the authors have well brought out in regard to the non-sensory sickling hæmoglobin morphism) can be explored by experiment in animals as well as by comparative analysis in man.

As regards blood-group morphisms, it will be important to discover why in most ethnic groups the morph-ratios appear to remain constant over long periods, whereas in, for example, sickling the morph-ratio changes rapidly in new ecological (malaria-free) environments.

Any genetically determined characters the incidence of which is, say, more than 0·25 per cent must be in morphic balance. This will prove of great importance for psychiatry when the undoubted genetic basis for various mental diseases with high incidence, such as schizophrenia, has been properly ascertained.

Harrison and Weiner's section on "Human Evolution" and Weiner's on "Human Ecology" are full of valuable up-to-date information, notably on hominid evolution in the Pleistocene, on the adaptation of ethnic groups to different habitats, on tolerance and acclimatization to heat, cold and climatic variables in general, and on the history of population-control in the pre-technological world. On this last point, however, Weiner fails to point out that population-increase has now entered on a wholly new 'explosive' phase, which urgently demands large-scale research and study by biologists, social scientists, economists, politicians, publicists, and religious leaders, with immediate practical follow-up, if we are to avoid disaster and lay the basis for a population policy for the human species.

My only other criticism is that Harrison and Weiner's excellent account of the evolutionary history of the primates is almost too detailed for a book of this type, while they fail to mention the basic fact that large evolutionary advances occur by the rare emergence of new dominant types of organization with new and improved patterns of general organization. On the other hand, their account of the evolution of human behaviour is too brief, and makes no mention of its biological basis in modern ethology—even the word is absent from the index, as well as names like Lorenz and Tinbergen.

There remains one major defect in the book as a whole. In spite of Prof. Medawar's stress in his foreword on the distinctive features of human biology, among which he includes "love, showing off, real or sham aggression", and especially man's distinctive methods of communication and behaviour and consequent "non-genetical system of heredity", there is no adequate treatment of what I would call its basic premiss—the uniqueness of man as an organism, and the unique consequences flowing from that fact.

Man is unique in virtue of a combination of characters—erect posture, the highest known variability, front-to-front copulation, manipulative hands, size of cerebral cortex, tool-making, neoteny and a much-prolonged period of immaturity and educability, true (symbolic) speech and other communication systems, and the capacity for conceptual thought, creative art and purposeful planning. These in combination give him a highly effective second hereditary system in the shape of cumulative tradition. In the new resultant psychosocial phase, evolution is primarily manifested by cultural instead of genetic transformation. Hence the anagenetic improvement of cultures, their cladogenetic (confusingly spelt kladogenetic in this book) diversification, and their occasional stasigenetic overstabilization, together with the novel integrative process of cultural diffusion. Hence also the recent preponderance of reproductive over survival selection, to which I have already referred. These processes all rest on purely biological foundations, but are unique properties of evolution in its human phase, and should be fully dealt with as such.

Clearly a book on human biology should not attempt to provide potted summaries of social anthropology and religion, political and social structure, economics and ethics, history and the arts. But if it is to deserve its title, it must give a general account of the unique characteristics of man and of the main principles and features of his psychosocial evolutionary transformations. Let us hope that a second edition of the present work will include such an account: it is badly needed. Meanwhile, let us be grateful to the four authors for their valuable contributions to this new and rapidly growing field of study.

JULIAN HUXLEY

CHIMERAS AND CLASSIFICATION

Classification and Human Evolution

Edited by Sherwood L. Washburn. Pp. viii+371. (London: Methuen and Co., Ltd., 1964.) 63*s*. net.

THIS useful volume *Classification and Human Evolution* might have been more appropriately entitled "Human Evolution and Classification", for it is evident that the symposium on which it is based was initially stimulated by some of the remarkable discoveries of fossil primates (and particularly of fossil hominids) reported in recent years.

When fossil remains of creatures are found showing a mixture of anatomical characters that in modern types have been taken as distinctive of different taxonomic categories, their taxonomic position inevitably becomes a matter for debate. More than this, they also arouse renewed interest in the validity of accepted systematics as applied to zoological groupings in general. There is of course nothing novel in taxonomic reappraisals of this kind; they have frequently been required in the past following palæontological studies of hitherto unknown types of fossil vertebrates. But the discovery of fossil hominids and other higher Primates has now directed the attention of palæo-anthropologists to evolutionary principles already well recognized by their zoological colleagues, such as mosaic evolution, the gradational expression of micro-mutations, the importance of the selective effects of changing ecological conditions, the need to base definitions of major taxonomic groups on evolutionary trends rather than on the terminal results of evolution, and so forth.

During the past few years a number of symposia and colloquia have been published as the direct result of discoveries of extinct representatives of the higher Primates, and *Classification and Human Evolution* is one of them. The contents of such collections of papers and essays are bound to be of unequal value simply because they are the products of different authorships. They occasionally tend to repetitiveness for the reason that the same authors dwell on the same themes in successive publications, and they are sometimes characterized by a certain *naïveté* of approach from contributors who are not sufficiently acquainted with well-established principles of evolutionary processes and zoological taxonomics. Not that these are necessarily faults; for one thing, repetition and re-emphasis may be of considerable importance in order to gain acceptance of conclusions resulting from new discoveries. Naturally, it has always been recognized that definitions of taxonomic categories would become more difficult and more arbitrary as gaps in the evolutionary record become filled by intermediate links. But taxonomic definitions and distinctions have to be made simply as a matter of practical convenience, even if they are arbitrary. Whether *Oreopithecus* is a catarrhine monkey that has paralleled the Pongidae in many of its anatomical characters, or whether it is a pongid retaining some catarrhine characters, or whether (as has been suggested) it is an aberrant Pliocene offshoot of the Hominidae—all these are possibilities to be considered, and it is no doubt wise of Dr. W. L. Straus in his discussion of this problem to temporize by placing it in a family of its own, Oreopithecidae. On the other hand, the question whether *Australopithecus* is to be properly placed in the family Pongidae or in the Hominidae has now passed beyond the realm of serious controversy, for this early Pleistocene genus is well recognized to be a primitive hominid. Such problems as these are only to be decided by a close scrutiny of the combinations of morphological features that they present, and it is interesting to note that much more consideration is now being given to their functional and behavioural significance.

The chapter by G. A. Harrison and J. S. Weiner on "Some Considerations in the Formulation of Theories of Human Physiology" is of importance in this regard, as also are the chapters by S. L. Washburn on "Behaviour and Human Evolution", and by J. Napier on "The Locomotor Functions of Hominids". It may be that undue anxiety about the niceties of definitions is sometimes to be detected; for example, the suggested distinction between 'tool-modifying' and 'tool-making' seems to be a distinction without any obvious difference (in any event, in reference to simple bone or stone implements), and the impossibility of making a sharp distinction between brachiators and non-brachiators, which of course was to be anticipated, has now become clear from the anatomical characters of the Miocene ape *Proconsul*. The fact is that most Primates (even *Homo sapiens*) might be called brachiators in the sense that they can, or do on occasion, use their arms in swinging from one branch to another, but it is still a matter of convenience to limit this term to those Primates that use this mode of progression to the exclusion of leaping or running among the branches of trees by the propulsive force of their hind-limbs. Whether it is wise to invent the term 'semi-brachiator' for those monkeys that are somewhat more inclined to use their arms in arboreal locomotion is perhaps questionable, for this may lead to still further attempts at defining intermediate functional grades—'semi-demi-brachiators' and so forth.

The ancillary evidence for taxonomic relationships of Primates based on serology, the molecular constitution of proteins, the patterns of chromosomes, and the principles of genetics are dealt with in this book by authorities on these different subjects, with the interesting result that their conclusions serve in large measure to confirm the taxonomy previously based almost entirely on morphological criteria. It is true some writers have gone so far as to claim that the gorilla and chimpanzee should be included with *Homo* in the one family Hominidae, but it seems most unlikely that such a drastic redrafting of the classification of the higher Primates will be acceptable. After all, the distinctive characters of man, morphological, functional and psychological, are so obtrusive as to demand a far-reaching divergence from the modern anthropoid apes, even if they do not demand a divergence so far back in geological time as one or two extremists in the opposite direction would like to think.

WILFRID LE GROS CLARK

ANTIQUITY OF MAN

The Problem of Man's Antiquity

An Historical Survey. By Kenneth Page Oakley. Pp. 85–155. *Bulletin of the British Museum (Natural History), Geology*, 9, No. 5. (London: British Museum (Natural History), 1964.) 28*s*.

The Prehistory of East Africa

By Sonia Cole. Pp. 382. (London: Weidenfeld and Nicolson, Ltd., 1964.) 55*s*. net.

The Evolution of Man

By G. H. R. von Koenigswald. Pp. 148. (Ann Arbor Science Library: Ann Arbor, University of Michigan Press, 1962.) 5 dollars.

MOST people would agree that complete, impersonal objectivity in pioneer research is an impossibility. Even if there is no prejudice, the intellectual and imaginative equipment of an original scientist will affect the nature of his results. Accepting this as inevitable and not necessarily damaging, it still comes as a shock to discover how often preconceived ideas have affected the investigation of human origins.

There is, of course, nothing like a fake for exposing such weaknesses among the experts. For example, to look back over the bold claims and subtle anatomical distinctions made by some of our greatest authorities concerning the recent human skull and modern ape's jaw which together composed 'Piltdown Man', rouses either joy or pain according to one's feeling for scientists. As these books show, there is no reason to suppose that tendencies to error have grown very much less.

Dr. Kenneth Oakley's agreeable survey, *The Problem of Man's Antiquity*, can be seen as a history of changing attitudes and prejudices in human palæontology. Inevitably it begins with the greatest of them all: the refusal during the first two-thirds of the nineteenth century to recognize the immense antiquity of the human fossils and artefacts that were then being brought to light. While much of the resistance was due to religious opinion

on the mode of man's genesis, scientific conservatism also played its part. As Sir Charles Lyell commented, new finds of ancient man provided "Unwelcome intelligence opposed to the prepossessions of the scientific as well as the unscientific public". Dr. Oakley's material illuminating this great dispute includes a lively satirical drawing of the Paris Academy debating the affair of the Moulin-Quignon jaw (a fraud, as it turned out). Touches such as this, together with the sensitive approach and writing, make *The Problem of Man's Antiquity* an excellent example of the value of the history of science as a bridge between the 'Two Cultures'.

After the triumph of the evolutionary point of view, Dr. Oakley shows how the vast oceans of Palæolithic time that had been opened to exploration were gradually charted. Cultures were discovered, classified, and began to be given their chronological place relative to one another and to their geological context. This last-mentioned process is still very far from complete, while the situation has been revolutionized during the past decade by methods of absolute dating through radioactivity and chemical analysis. Dr. Oakley ends his survey with a suggestion for systematizing chronological terms. He proposes a double series of symbols (*R* 1–4 and *A* 1–4) for quick reference to the different forms of relative or stratigraphical dating and absolute or chronological dating. Although some of us would like to resist any specialist devices that raise unnecessary barriers against the uninitiated, there is no doubt that this system would be of convenience to professionals, and seems likely to be widely adopted.

The only thing to be regretted in this survey is that it stops too soon. One would very much like to have Dr. Oakley's latest judgements on the great series of fossil finds made in Africa during the past forty years—and particularly on the fossil men of East Africa that form the core of Mrs. Cole's book.

The Prehistory of East Africa is one of the best regional prehistories ever written. Indeed, it is more than than that, for although the bulk of the material comes from Tanganyika, Kenya and adjacent regions, the discussion of human origins and the earlier fossil hominids reaches out to involve the whole of the Pleistocene world.

Any book of this title is bound to have Dr. Louis Leakey as at least an unofficial hero. The work which he and his family have done in East Africa, and the brilliance of its results, should make one of the greatest heroic epics of science. Most important of all have been their discoveries in the natural section through Pleistocene time at Olduvai Gorge in Tanganyika. Here the Leakeys have not only found Early and Middle Pleistocene fossil hominids that are of outstanding significance, but have also been able to relate them to the evolution of the hand-axe cultures.

Where Dr. Leakey is a hero there will be argument and partisanship. For, even more than most men of original genius, he exemplifies the theory that the mental equipment of such men will shape and colour their interpretations. In the first place his impetuous enthusiasm has made him—as Mrs. Cole would put it—a "splitter" rather than a "lumper". That is to say, as new fossils have been extracted from their ancient matrices by Leakey or his wife or son, and he has recognized their exciting points of difference, he has tended immediately to proclaim each as representing a new genus—when later it has sometimes seemed wiser to recognize only a specific or sub-specific status.

In the second place, if this is not too disrespectful a way to put it, he has always played a hunch that our ancestral line of pre-*sapiens* hominids split off from the rest earlier rather than later. That is why he was, in a sense, working against himself when he found the decidedly pithecoid man, whom he named *Zinjanthropus*, apparently associated with the pebble tool culture at Olduvai; and why, when he found what he held to be a larger-brained, more progressive type at a lower level, he claimed it as "a quite distinct form of early hominid", and suggested that it was this man and not the unwelcome *Zinjanthropus* who had made the pebble tools. Many authorities would prefer to see *Zinjanthropus* himself as a racial variety of *Australopithecus robustus*, and the 'pre-Zinj' breed also among the australopithecines—although possibly looking towards the progressive type, *Telanthropus*.

Mrs. Cole deals with these crucial issues with admirable detachment. She also allows more room for manœuvre in evolutionary argument by tentatively accepting the recent potassium–argon datings, which would give *Zinjanthropus* an age of at least a million years, and approximately double the hitherto accepted length of the Pleistocene period.

Although the importance of East Africa in the work on human origins focuses interest on this part of her book, Mrs. Cole deals equally well with other subjects and later periods. There is a full discussion of climatic phases, of the whole sequence of stone-using cultures, of the beginnings of cultivation, of pottery making and the introduction of iron. There is a chapter on rock paintings and engravings and another on the equally difficult problems concerning modern African races and their history.

Mrs. Cole covers a wide field of knowledge with the precision to be expected of serious scientific exposition, and with exceptional clarity and style. But what makes her book even more outstanding is her courage in making it at the same time a human document. She enables us to see the settings of excavations, the conditions under which people worked, the telling personal details of the great moments of discovery—all are well described and fully integrated with the scientific narrative. *The Prehistory of East Africa* deserves a very special prize.

Prof. von Koenigswald's little book seems to show a bias cruder and far less acceptable than Dr. Leakey's zestful championing of his 'prepossessions'. The author occupies the chair of palæontology in the State University of Utrecht, and has himself obtained important pithecanthropine fossils in Java. It is impossible not to feel that it is this background that has caused him to declare that probably "Asia was the original centre of the hominids"—so opposing the African claims to primacy which seem every year to be more strongly based. He also sets the whole range of African australopithecines outside the direct line of our human ancestry, and claims that they, too, may have originated in Asia. He gives no consideration to the possibility of a much longer duration for the Pleistocene Age, nor, although his book was first published a year after their discovery, does he mention either 'pre-Zinj' or the Chellean man from Olduvai. (There are, indeed, signs that part of his text was written before any australopithecines were known from East Africa.)

Moreover, Prof. von Koenigswald's special knowledge of dentition makes him give what might be judged excessive weight to this limited part of the evidence, while at the same time loading both text and illustrations with more facts about teeth than are likely to be welcome to the general public. *The Evolution of Man* contains plenty of useful factual material, much of it set out in tabular form, but it can scarcely be recommended as a well-balanced handbook.

JACQUETTA HAWKES

PIONEER OF MODERN ANATOMY

Andreas Vesalius of Brussels, 1514–1564

By Prof. C. D. O'Malley. Pp. xv+480+64 plates. (Berkeley and Los Angeles: University of California Press; London: Cambridge University Press, 1964.) 10 dollars, 80*s*. net.

NO full-scale life of Vesalius has previously been written except that of Moritz Roth[1]. Since Roth's biography a wealth of Vesalian literature has appeared, including Harvey Cushing's *Biobibliography*, published

in 1943 and edited by John Fulton, and Charles Singer's studies. Furthermore, much new information has come to light in the intervening seventy years. Prof. C. D. O'Malley, the pre-eminent authority on Vesalius, has been engaged on this definitive biography for many years, and all medical historians will welcome the fruit of his labours in this well-produced volume.

Galen's anatomy was based on dissection of animals, and when applied to man was often confusing and erroneous. For centuries his teaching was held to be incontrovertible and above criticism. Yet, as Prof. O'Malley shows in his first chapter on pre-Vesalian anatomy, certain enlightened men like Berengario of Bologna and Leonardo da Vinci were dissecting human bodies and making their own observations which did not always accord with Galenic teaching.

Andreas Vesalius, son of an apothecary to the Emperor Charles V, was born in Brussels on December 31, 1514. He received a classical education at the University of Louvain; and in 1533 studied medicine at the University of Paris, where he worked with Guenther of Andernach and Sylvius and learned Galen's anatomy. Returning to Louvain for his M.B. degree, he carried out further dissections and discovered the corpus luteum in a female body. In 1537 he published his *Paraphrasis* (probably his M.B. thesis) which was a translation of the writings of Rhazes with a comparison of Arabian therapy with that of the Greeks. In the same year the University of Padua conferred the degree of M.D. on Vesalius and appointed him professor of surgery and anatomy.

At Padua, Vesalius became distinguished as an anatomist and teacher who taught anatomy not from books but from scientific observation. In 1538–39 he published three brief works, the *Tabulae anatomicae*, a revised edition of Guenther's *Institutiones anatomicae* and the *Venesection letter*. They still embodied Galenic teaching. From 1539 until 1540 Vesalius and John Caius lived together in a house in Padua engaged on Galenic texts. Vesalius contributed to the Giunta edition of Galen's *Opera omnia*, 1541–43. Ultimately, the friendship of these two great men was broken off, because Caius adhered to Galen's anatomy in which Vesalius had already found flaws.

In 1543 *De Fabrica* (with its *Epitome* for the use of students), the anatomical work which replaced Galenic tradition by scientific observation, was published at Basle and made Vesalius famous for all time. It evoked admiration, praise, controversy and bitterness from the Galenists, including in 1551 a virulent attack from Vesalius's old teacher, Sylvius. Guenther, on the other hand, was encouraging and friendly. In 1543 Vesalius resigned his chair to become physician to the Emperor Charles V. He accompanied the emperor in his many campaigns and after his abdication to Spain, becoming later physician to King Philip II. Vesalius's reputation was now international, for after King Henry II of France sustained a fatal head injury in a tournament, he was summoned to Paris where he met Ambroise Paré in consultation at the king's bedside.

By 1563 Vesalius was anxious to regain his chair at Padua, which he was offered on the death of Fallopius. He obtained leave from King Philip to make a pilgrimage to Jerusalem. Prof. O'Malley shows that there is little foundation for the legend that this journey was made because Vesalius had done a necropsy on a Spanish grandee whose heart was still beating. The pilgrimage was performed; but on the return journey to Padua Vesalius became ill and died in 1564 on the Island of Zante.

It may be noted that the *De Fabrica* soon came to the notice of English anatomists and surgeons, for as early as 1545 Thomas Geminus brought out an abridgement entitled *Compendiosa totius Anatomie delineatio* with copper-plate engravings copied from Calcar; it was dedicated to Henry VIII. In 1553 Geminus published an English translation of his compendium, made by Nicholas Udall, the author of the first English comedy, *Ralph Roister Doister*. This was dedicated to Edward VI. The third edition in 1559 was dedicated to Queen Elizabeth I.

In this book Prof. O'Malley has blended knowledge of medical history, of anatomy, of physiology, scholarly appraisement, original investigations and researches and literary charm together, and the result is a biographical masterpiece. There are also notes and references to the copious Vesalian literature.

Vesalius in the *De Fabrica* produced a great work of original research. As Charles Singer was wont to say, "he is the ideal subject for the investigation of the beginnings of science". It is therefore important to trace all the processes in his life—mental, social, personal, political—by or through which Vesalius, starting as a classical scholar, became a scientific inquirer. This task, one of supreme difficulty, has been accomplished by Prof. O'Malley. He has done a great service to history and to comprehension of the evolution of science.

ZOO MAMMALS

The Management of Wild Mammals in Captivity

By Lee S. Crandall. Pp. xv+761+11 plates. (Chicago and London: University of Chicago Press, 1964.) 13.50 dollars; 97*s*.

WILD beast shows have been a popular entertainment for several thousand years and are now as popular as ever and more numerous than at any previous time. A minority of people object, for moral or sentimental reasons, to the keeping of wild animals in captivity, but the vast majority never consider these matters; those who do pause to think appreciate the educational and recreational value of living zoological collections. Wild animals are now exhibited in all parts of the world; zoos are of almost universal appeal, as is shown by the rapid increase in their number everywhere and the crowds of people who flock to them. The influence of television in spreading this cult has been considerable, and the increasing public awareness that the human population explosion is threatening the continued existence of many of the larger and more spectacular animals has given added interest and concern.

It is peculiar that, until well on in the present century, the management of wild animals in captivity was largely a matter of rule-of-thumb, lore, and the 'green fingers' of those gifted with a 'way with animals'. An immense amount of lore had been accumulated by zoo men, much of it by oral tradition, less by the written word, but until the twentieth century zoologists were so pre-occupied with the remains of dead animals in the museum and laboratory that few had directed serious attention to the many problems confronting those in charge of menageries. When zoology began paying court to physiology as well as morphology, and the expanding experimental approach demanded ever-increasing numbers of experimental animals, the scientific methods devised for the management of the laboratory animal-house were soon adopted and adapted by the better zoos. As a result the health, longevity and breeding success of captive wild animals have improved enormously during the past twenty-five years; many animals formerly regarded as impossible to breed, or even to maintain alive, in captivity are now the pride of their keepers. More recently, the rapidly progressing discipline of ethology is adding valuable knowledge to the art of animal keeping, and is showing how the mental well-being of captive wild animals is as important as their bodily health.

The zoo-keeper, however, has a double problem, for he is concerned not only with the good management of his

animals but also with their exhibition to the public—a group of animals in perfect health living in conditions closely simulating those of the natural environment, where they remain cosily concealed all day, may be eminently satisfactory to the research zoologist, but a complete failure to a public interested only in looking at unfamiliar strange creatures. Zoos, therefore, must compromise, and always remember that their first purpose is to show animals to their public in a manner as æsthetically pleasing as possible while maintaining them in full health and vigour in reasonably congenial surroundings. Zoos, too, have much to teach the public about its attitude towards menagerie animals; there still lingers much of the old-fashioned 'stir him up with a long pole and make him roar' spirit, and an almost universal anthropomorphic approach. Education is gradually overcoming these primitive reactions and leading to a dawning appreciation of the true interest and value of the world's fauna to mankind.

Lee S. Crandall worked for fifty years in the New York Zoological Park, the final fifteen or so as general curator. He is pre-eminently one of those fortunate people gifted with 'green fingers', and to his natural gifts he has added a life-time devoted to the scientific study of animals, especially those in zoological collections. He is *persona grata* with his colleagues throughout the world and has thereby reaped a rich harvest from the experiences of his friends. Now he has set down all he knows at first hand, and all that he has learnt from his confreres, about the management of wild mammals in captivity—and what a splendid book it makes!

Wild Mammals in Captivity is an exhaustive treatise, and there can be little of importance relating to the subject that has been overlooked, in spite of the author's modest disclaimer. It goes systematically through the orders of living mammals, omitting only the Cetacea, dealing with all the species that have ever been kept in zoos and mentioning some others that have not. Descriptions are given of all the main groups and of many individual species, with a summary of their distribution and habitats, followed by particulars of the natural diets and those found acceptable in captivity. Details are given of the enclosures and housing that have been provided in different menageries, and records of longevity and breeding successes are added. More valuable even than these are the personal experiences of the author with an enormous number of different species, set down clearly and with the occasional touch of humour that makes them fascinating reading. The book is very well documented and well indexed, and the typography and format are excellent. It is embellished with some splendid photographic illustrations; that of the gibbons in the New York Zoological Park drinking by dipping water from the lake below them while riding the branch-tips of an overhanging tree is a beautiful composition, apart from its zoological value.

Crandall's book will be the zoo-keeper's bible for many a year, and all zoologists interested in mammals, whether or not they are directly concerned with zoos, will feel a debt of gratitude to him for the immense labour he has devoted to the making of this outstanding and comprehensive work.

L. Harrison Matthews

INSECT PHYSIOLOGY WITHOUT TEARS?

The Life of Insects

By Prof. V. B. Wigglesworth. (The Weidenfeld and Nicolson Natural History.) Pp. xii+360+36 plates. (London: Weidenfeld and Nicolson, 1964.) 55*s*. net.

THIS is the first zoological contribution of the new Weidenfeld and Nicolson Natural History, which is planned as a series of volumes by authors who are all well-known scientific authorities, each of whom will deal with some specific group of organisms*. The effect of this policy is predictable. No one will be surprised that this book by Sir Vincent Wigglesworth, about the life of insects, is very largely concerned with insect physiology. He makes use of his unrivalled personal knowledge in this field to illuminate and give meaning to the wonders of insect life. The book is written in a clear and lively style and Lady Wigglesworth has provided many new line drawings, most of which are excellent and likely to find wider use. The half-tone and colour plates are very good, with the exception of parts of Plates 6 and 7, where reds have been printed as brown and white a strange blue shade.

The seventeen chapters cover a wide range of topics such as movement, diet, eggs, luminosity, vision, offence and defence, population problems and insect societies, and the book ends with a 30-page illustrated catalogue of the major insect orders. The discussion of physiological mechanisms in insects is often illuminated by simple analogies with familiar processes. Thus, the hardened insect cuticle is compared with a starched shirt-front and the method by which insects survive extreme cold is compared with our use of antifreeze in cars. However, in the chapter on movement, the mechanism of insect flight is likened to that of a 'flying machine'. This charming Edwardian term conjures up mental pictures of Blériot and the machines flown by his contemporaries. Will the younger generation think only of the supersonic jet or will they be sufficiently sophisticated to wonder which of the many different possible mechanisms of powered flight is really intended? What a pity the specific analogy with certain designs of helicopter was not pressed more closely!

The chapter on growth and metamorphosis is particularly stimulating, because this is one of the author's special interests. The treatment tends to be dogmatic rather than critical, so that the vexed question of whether there is a true 'prepupal' stadium within the puparium of flies is not discussed, but avoided both in the text and in the illustration of the metamorphosis of the house-fly.

The amateur entomologist should not be deterred from collecting and studying the Arctiid moths by the alarmist report that "In some insects such as the tiger moths (Arctiidae) these spines become contaminated at times with the venom from the body and then their effects can be severe". This sweeping statement is, in fact, based on very limited positive evidence. The rarity of reports of any reaction to these common gaudily coloured moths suggests there may be variable human susceptibility to them.

The attempt to popularize results which have been published in the scientific literature has its pitfalls, and Sir Vincent has occasionally fallen into the trap by supplying common names for insects incorrectly. Thus the fig insects are not gall-wasps, and *Nysson* is not a bee but a sphecoid wasp. Regrettably there are also many mistakes in the scientific names both of insects and plants—sometimes species are given names which have not been in current use for almost a century; there are many simple spelling mistakes of the names of common insects (the generic name of the orange-tip butterfly is rendered in three different ways) and there are some misidentifications of insects which are illustrated. An author finds it almost impossible to avoid errors of this kind, so the editors must in future take the necessary steps if this series is to be authoritative.

One regrets these minor faults in a book which nevertheless deserves to reach a wide public. The sixth form school-boy and the undergraduate will get a very good introduction to insect physiology. The amateur entomologist, with his specialist knowledge of one particular group, and the general naturalist, who have been speculating about the ways insects work, will begin to realize that professional entomologists are now finding

*[See also p. 958 of this issue of *Nature*.]

answers to many of their questions. University teachers should take account of the book, which brings an up-to-date factual account of insect physiology within the reach of all undergraduates. It will allow teaching to concentrate more on the processes of research, on how we plan our observations and measurements and how we interpret them to reach the conclusions so persuasively and simply expounded in this book. G. C. Varley

THE FUNCTIONAL UNIT OF LIFE

Allgemeine Cytologie:

Eine Einführung in die Funktionelle Morphologie der Zelle. Von Prof. Ekkehard Grundmann. Pp. viii+423. (Stuttgart: Georg Thieme Verlag, 1964.) 59.70 D.M.

TO-DAY the gulfs in our ignorance are widening because the quantity of information forthcoming is so great. The more we learn the more we realize how little we really know. Even in his own field of study the scientist must restrict his attentions to a relatively small area.

True progress in science, however, depends on integrated knowledge, which can be provided by reviewing the relevant information in a comprehensive manner. The part played by those responsible for 'synthesizing' scientific information becomes more and more important, but their task also becomes more difficult due to the increasing amount and complexity of the information they have to handle. This is probably the reason why, nowadays, monographs are usually written by several authors, each having a restricted interest and knowledge of the subject under review. As a consequence, these 'monographs' tend to lack uniformity and leave many gaps in our knowledge.

Allgemeine Cytologie is the work of one author who is well known in the field of cell morphology, pathology and cytochemistry. The sub-title indicates the scope of the book; it is intended as an introduction to the functional morphology of the cell. According to Prof. E. Grundmann, the cell is the 'ultimate' organized unit of life and therefore knowledge of it is essential to all who are studying or are interested in biological sciences and medicine. Commencing with the discovery of the cell, the review is all-embracing, and it would seem that every structure and particle which have ever been seen, named or described by cytologists, pathologists, geneticists, cytochemists or electron microscopists, are given space in the book. This gigantic task involved the use of about 3,000 references. There is no doubt that the book is a valuable source of information on everything which concerns the cell.

After a brief historical review, the reader is introduced to the architecture of the cell; 100 pages are devoted to the nucleus, a similar number to the cytoplasm and even more to the various processes of cell division. In presenting his information the author follows a definite pattern: first he deals with the morphology, then with the chemical structure or composition of the particular cell constituent, and finally he discusses its function and relationship to other units of cellular metabolism. Prof. Grundmann tries hard to be objective, and as a consequence the text is full of references. It is not a rare occurrence to come across sentences broken at two or three places with the names of several authors. The reader might question the value of the references to descriptive works of the nineteenth century which occur throughout the book. What is the advantage, apart from a purely historical interest, of knowing who first saw and named the astrosphere, sphäroplasma, holschisis, kinoplasma, paragenoplastin, archoplasma, or phragmatoplast? The author's attempt to ascribe roles to them is frequently based on either circumstantial evidence or only assumption. Considering the vast field of information which is summarized in the book, it is not surprising to find, occasionally, a certain lack of critical judgement. The fine structure of the chromosome and the modern concept of DNA replication are discussed in seven pages, while twice as much space is given to 'amitosis', a special type of nuclear division, the occurrence of which is restricted to particular cells. On the other hand, the author deserves praise for the short chapters (Rückblick) in which topics previously described are summarized, the important findings are pointed out and attention is directed to the gaps in our knowledge concerning this particular subject.

Technically, *Allgemeine Cytologie* is well produced, the illustrations are clear and the diagrams are informative. The references are in small print and occupy 50 pages in double columns. There is a comprehensive subject index which makes access to information an easy task.

Next year it will be the three hundredth anniversary of the discovery of the cell. In *Micrographia* (1665) Robert Hooke published two pictures showing "minute bodies" in cork; to him they resembled little empty compartments with firm boundaries. During the ensuing 300 years similar "empty compartments" have been observed to contain the most astonishing array of structures, each with a purpose in cellular function, now well summarized by Prof. Grundmann. His monograph is a fitting tribute to the forthcoming tricentenary. P. C. Koller

CELL BIOLOGY

The Cell: Biochemistry, Physiology, Morphology

Edited by Jean Brachet and Alfred E. Mirsky. Vol. 6: Supplementary Volume. Pp. xiv+564. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1964.) 128*s*. 6*d*.

THIS is the sixth volume of a large and important treatise on cell biology which has been published over the past five years. Its six articles are concerned with topics which were either absent from the earlier volumes or were only touched on briefly.

The first two articles are on the Protozoa. K. G. Grell discusses their nuclei, and W. Trager their cytoplasm. Both authors give a certain amount of space to protozoan physiology, but their main emphasis is on structure, dominated in Trager's article by the recent work with the electron microscope. There is no doubt that a knowledge of Protozoa ought to be more widespread among cell biologists. They show many interesting variations on the common pattern of higher cells and they should be as helpful as invertebrate physiology has been in the development of mammalian physiology. To take two examples, Trager points out that the kinetoplast may provide important clues about the development of mitochondria and the nature of independent organelles, and the abnormal nuclear divisions of many Protozoa (Grell has striking photographs of these in *Aulacantha*) may help us to relate the amitotic division of bacteria to true mitosis.

J. R. Raper and K. Esser give an excellent account of the fungi. In the comparatively short space of a hundred pages, they deal clearly and comprehensively with the genetics as well as the morphology and the complex patterns of life-cycles and sexuality. Fungi, like Protozoa, are a group which should not be left only to the specialists. Although *Neurospora* and yeast have been worked on widely, there are many other fascinating organisms among the fungi. It may well be, as the authors suggest, that they are going to provide the best material for solving the central problem of differentiation.

Another good and comprehensive article (the longest in the book) is that by S. F. Jackson on connective tissue cells. She discusses this subject at all levels, from molecules

to whole cells, and acts as an admirable guide through a complex literature. R. Cordier gives a shorter general survey of the structure of sensory cells in the Metazoa, mostly at the level of the light microscope. The subject, though not the account, is somewhat unsatisfactory at the present time because of the difficulties of relating form to function. Cordier concludes "... that morphological research on sensory cells, even at the submicroscopic level, does not furnish a safe and reliable base on which the satisfactory understanding of their function and activity could be founded", and contrasts this with recent progress on secreting cells.

Finally there is an article on the form and function of the plant cell by B. R. Voeller, with electron micrographs by Ledbetter and Porter. The author does not have space to do full justice to the subject, particularly on the physiological side, and this is indeed a criticism which might be made of the treatment of the botanical material throughout *The Cell*.

Since this may be the last volume, it is worth making a few remarks about the whole series. It is, without doubt, an impressive treatise of high standard which should be in all biological libraries. Equally, it is unlikely to be on the personal shelves of many biologists because it is too expensive and, for students, too detailed. It is made up of detailed review articles and it should therefore be compared with a review journal such as *The International Review of Cytology*. It has the advantage of an editorial policy that can ensure a more or less complete coverage of a field. But a journal has the even greater advantage that it can keep up to date by repeating reviews in a rapidly moving field. As an example, the two reviews on nucleo-cytoplasmic relations in the first volumes of *The Cell* already show signs of ageing. For these reasons, I would predict that the days of the review treatise on this scale are passing.

J. M. MITCHISON

BIOLOGY OF RUSSIAN INLAND WATERS

Fauna and Flora of the Rivers, Lakes and Reservoirs of the U.S.S.R.

By V. I. Zhadin and S. V. Gerd. Translated by A. Mercado. Edited by R. Finesilver. Pp. 626. (Jerusalem: Israel Program for Scientific Translations, 1963.) 128*s*.

NEARLY one-sixth of the land surface of the world lies within the U.S.S.R. and many of the world's largest lakes, river systems and reservoirs are among her numerous water bodies. Considerable resources are devoted to hydrobiological research, much of which is little known in the Western world. Despite the language difficulty, the original Russian version of this book has been an indispensable source of information for hydrobiologists, so an English translation is most welcome.

Better accounts of the general principles of fresh-water biology can be found elsewhere, and these sections have an elementary and old-fashioned approach with some loose writing. Nevertheless, the emphasis put on unfamiliar aspects stimulates thought, and the sections on topics which have been particularly examined in the U.S.S.R., such as rivers and reservoirs, are full of interest. Investigations of the evolution of lake populations and the distribution of species receive special attention and several Russian systems for classifying water bodies are described.

There is a wealth of information on the location, morphology, characteristics and populations of all the larger water bodies (except the Caspian and Azov Seas) as well as the better-investigated smaller water bodies. Leading Russian hydrobiologists and their laboratories are introduced. Special attention is directed to the management of reservoirs and other water bodies, to exploit their biological resources, for which the Russians have many new and unusual ideas.

There is a curious statement on p. 35 (apparently correctly translated) about bacteria being "primary producers", which may be justifiable, but not from the context. The unfamiliar use of "dystrophy" for the condition of severe oxygen deficit under a snow and ice cover should be noted.

The print shows through the pages more than one would expect from an expensive book, and the photographs (which were poor in the original) are not well reproduced. The line drawings, however, are excellent. Many more references to original work would have greatly increased the value of the book. Only authors, water bodies and species are indexed. This deficiency is accentuated by the frequent use of unusual and superfluous technical words and only partly offset by the detailed contents list and the repetitive text. The translation appears to be free from serious error, but there are a few curiosities and some words and phrases which are American or Russian rather than English.

D. F. WESTLAKE

FIGHTING FOREST FIRES

Soviet Progress in Forest Fire Control

Edited by N. P. Kurbatskii. Authorized translation from the Russian. Pp. iii+38. (New York: Consultants Bureau, 1964.) 10 dollars.

RUSSIA has a history of forest fires, but only in comparatively recent times has any attempt been made to estimate the areas involved. These statistics indicate that enormous losses of timber occur as a result of the fires, many of which seem to be located in Siberia. There is no indication in *Soviet Progress in Forest Fire Control* of the causes of the fires. There is one mention of forests being burnt along the Siberian railroad from Tomsk to Krasnoyarsk, a distance of some 300 miles, but the reader is left to make his own deduction of the cause. However, it is pointed out that "during the years of Soviet power the flammability of forests decreased substantially". To substantiate this statement, statistics are given for two 4-year periods, 1906–10 and 1940–44, when the area of forest fires was respectively 269·2 and 124·8 thousand hectares!

The first report in this book is on the comparative fire resistance of different tree species in the Taiga zone, near Tomsk. Statistics are used to demonstrate the differences, but really no new facts emerge. No one would argue with the summing up that, "the thicker the bark of trees, the deeper the root system, the higher the crown, the lower the resin content and content of volatile oils, the less the danger of fire injuries".

The second article is on the effect of relief on forest fires in Western Sayan (west of Lake Baikal). One-third of the forests of the U.S.S.R. are in the mountains, where they are important not only on account of the timber they yield but also for their protective and water regulating roles. The author considers the problem of the relief on the conditions of the outbreak, development and after-effects of forest fires in mountainous areas, but, in trying to suggest control measures, he appears to rely on water courses to act as natural barriers. He states that a network of fire-fighting barriers will be practical only in forests that are being exploited. In other words, as is well known, a good communication system does help in fire-fighting.

The principles of extinguishing forest fires are discussed in a third article, and some of these go into great mathematical detail concerning rates of absorption and heat liberation. Indeed, the author is at great pains to describe how water and fire-resistant chemicals function, but at the end of the article the reader is left wondering to what

use this information has been put in *Soviet Progress in Forest Fire Control.*

The last report is an analysis of the calorific value of moss, fern, grass, conifer needles, branchlets and resin.

This publication is somewhat disappointing; this may be due in part to the expectation gained from the title that the reader is going to learn a lot about forest fire control. He does not, which is a pity.

C. J. TAYLOR

THE WORLD OF PLANTS

The Life of Plants

By E. J. H. Corner. (The Weidenfeld and Nicolson Natural History.) Pp. xii+315+41 plates. (London: Weidenfeld and Nicolson, 1964.) 55*s.* net.

BOTANISTS often wonder why their subject, critically concerned as it is with the food and therefore the primary welfare of the whole human race, has remained so long the Cinderella of the biological sciences. A cynic might suggest that the neglect springs from a deep-seated disinclination in the human mind to grapple with essentials, but there is another and simpler reason. When botany and zoology emerged from their purely descriptive phases the latter was able to advance rapidly because zoologists, being themselves examples of their own subjects, could interpret a good deal about them in terms of personal experience—an advantage that was denied to the botanists. For this reason there has always been a certain difficulty in coming to grips with the study of plants, which has in consequence tended to become either chemistry or physics or, alternatively, taxonomy. Only in recent years has an awareness begun to grow that an enquiry into the principles on which the life of plants is ordered may reveal truths quite as important as those derived from the study of animals. *The Life of Plants* is a valuable amplification of this still small voice and deserves a warm welcome.

The author has a mind of considerable originality and powers of penetration, and he has made good use of both to write an introduction to the world of plants which is novel without being eccentric. Furthermore, the book is very well produced, and notable because nearly all the many illustrations are either new, in the sense that they have not appeared in a book of this kind before, or have been drawn or re-drawn with skill and care, though it must be said, more in sorrow than in anger, that Fig. 96, with its Mercator's projection, is the exception which proves the rule.

The book has fifteen chapters of which the first six provide a remarkable study of the algae, mainly from the point of view of their significance as the modern representatives of the aquatic forerunners of the present sub-aerial land-flora, and it is pleasant to notice here a long-overdue tribute to the neglected writings of A. H. Church. The next six chapters are, in effect, almost entirely concerned with seed-plants, though many others are included, and these amount to what has been sadly lacking in the past, namely a broad general exposition of the flowering plants by one with a really wide interest in, and experience of, tropical vegetation, and this part of the book is certainly likely to draw most attention and applause. Mr. Corner would have been more than human had he refrained from riding one or two hobby-horses, but even these exercises are spirited, and excellent for the sluggish botanical liver. The last three chapters deal with Mr. Corner's second (or is it first ?) love, the fungi, and they are as interesting as the rest.

To do full justice to this unusual book is a hard task and perhaps the most sober verdict that can be brought in with regard to it is that no one can possibly read it without being a better botanist and without knowing more about plants afterwards than he was or did before. To advanced students, and especially to the best of them, it will be a delight, and something to be savoured when all else begins to pall.

Apart from its factual content the book does, however, raise two issues of considerable interest and wider context. The first, and lesser, is how far it is possible to breathe new life into familiar and perhaps dry facts by clothing them in new words. Mr. Corner's expressive style of writing is one of the pleasures of his books, but at times it seems to take him dangerously near incoherence and there is a risk here and there that the less-sophisticated reader may fail to understand, or may even misunderstand, his meaning. The book is unlikely to prove easy reading to anyone without a sound grounding in botany.

The second point is more serious. The central theme of the book is, as it must be in all biological writings which are neither formal nor systematic, that of organic evolution. A writer dealing with this subject can easily slip into a "slough of despond" from which escape is difficult, and it is a tribute to Mr. Corner that he avoids this peril. Nevertheless one must feel some regret that so acute a thinker has not, apparently, been able to free himself more completely from the indoctrination of an outworn Darwinism, or to take more account of the change in attitude towards this in recent years.

R. GOOD

A NEW AGRICULTURAL ATLAS

An Agricultural Atlas of England and Wales

By Dr. J. T. Coppock. Pp. 255 (205 maps). (London: Faber and Faber, 1964.) 63*s.* net.

THIS new *Agricultural Atlas of England and Wales* contains, in addition to a large number of maps, a substantial text providing historical and explanatory comment. The author is to be congratulated on its comprehensive nature, because only by reference to such a detailed study can the considerable diversity of agricultural activity in these areas be appreciated.

After a brief statement of the aims of the *Atlas* and a description of the methods used in its preparation, the first chapter presents an interesting discussion of the factors, other than the more obvious physical and economic ones, which can affect enterprise choice and combination in farming. The second and third chapters provide a well-illustrated physical and economic background for the distribution of crops and livestock. There are then three chapters dealing in some detail with the distribution of tillage crops, grassland and horticulture, and a chapter covering the distribution of the various classes of farm livestock. In these four chapters, which comprise the major portion of the *Atlas*, the problems of describing crop and livestock distribution graphically have been given full consideration. By using more than one map for the individual tillage crops and types of grassland, the author has attempted to illustrate not only their distribution as a proportional area but also their relative importance. In order to map the regional importance of different classes of livestock, a weighting system based on relative feed requirements has been used. This converts the various classes of livestock into a common unit, the "livestock unit". The resulting difficulties of map interpretation can, however, be overcome by reference to the accompanying text. The distribution of separate classes of livestock is shown both in relation to the distribution of other livestock and in relation to land use. An interesting feature of the chapters on tillage crops and livestock is the inclusion of maps indicating the most common associations of crops and of livestock, and how these associations are distributed.

The remainder of the book is devoted to a chapter dealing with combinations of enterprises in farming, and

a chapter discussing the future possibilities for mapping more fully the agricultural information which has been, and is, accumulating in such quantity throughout England and Wales.

There are three appendixes and a select bibliography. The first appendix provides additional information about sources and the construction of individual maps. The second, contributed by A. Sentance, of Birkbeck College, London, is a technical description of the processing of data for the *Atlas* by computer. The third contains details of the various crop, livestock and enterprise combinations, and some selected statistics. The bibliography is restricted to publications of direct relevance to the contents of the *Atlas*, and is helpfully classified by reference to the various chapters. J. L. BEVERIDGE

MILESTONES IN VIROLOGY

Selected Papers on Virology

Edited by Nicholas Hahon. Pp. xv+363. (Englewood Cliffs, New Jersey, and London: Prentice-Hall, Inc., 1964.) 60*s*.

AN alternative title to this book might be "The Birth of a Science"; virology, that ugly word of doubtful parentage, is now a dynamic biological discipline.

For his compilation, Dr. Hahon has selected forty papers, spanning nearly two centuries, beginning with the paper by Edward Jenner on cowpox in 1789, and ending with the recent work of Trentin, Yabe and Taylor on the quest for human cancer viruses published in 1962.

It is difficult to make a representative selection of only forty papers out of such an immense field; but the author has carried out his invidious task with care and perspicacity. Whatever his choice, it is inevitable that some criticism of it would be made. One feels that Iwanowski deserves more than casual mention, for it was he who first proved the existence of the 'ultramicroscopic filterable viruses', to use a phrase now long obsolete, by showing that the agent causing tobacco mosaic was still infectious after passage of a Pasteur–Chamberland filter candle. F. C. Bawden and N. W. Pirie also deserve a niche in this hall of fame, since it was they who showed that the virus of tobacco mosaic, isolated by Stanley in 1935, was a nucleo-protein.

The time has long gone by when it could be stated that "plant viruses are of an entirely different nature from that of the animal viruses". We should recognize now that there are not four different kinds of infectious agents, each in its watertight compartments of bacterial, plant, insect and animal hosts. The science of virology comprises the study of viruses, no matter from what type of host they are derived. Once freed from the host cell, the similarity between some viruses of completely different origin is remarkable, and who would be bold enough to say at a glance whether a small near-spherical virus, when viewed in the electron microscope, was that of poliomyelitis or turnip yellow mosaic ?

The boundaries which separated these four types of viruses are indeed becoming indistinct and doubtful, and the versatility of viruses and their ability to adapt to different hosts are increasingly alarming. Certain plant viruses can multiply in their insect vectors; the virus of swine influenza, which is thought to be a relic of the great influenza pandemic of 1918–19, can multiply in a parasitic lung worm as well as in the pig, and a plant virus causing 'wound tumours' in legumes is thought to have a serological relationship with one of the reoviruses pathogenic to man.

The final paper in this book deals with an absorbing aspect of virology, the viral causation of tumours and the possible relationship of viruses with human cancer. It shows that a virus from man, one of the adenoviruses, has oncogenic properties and produces tumours when injected into new-born hamsters. Again, who would have predicted that the Rous sarcoma virus, originally only transmissible between certain strains of chickens, is now apparently capable of producing tumours in Primates ?

By compiling this book, Dr. Hahon has rendered a great service to virology. He has brought within easy reach many early papers, often difficult to obtain, and, in the increasing *tempo* of virus research, has emphasized the discoveries of major importance. K. M. SMITH

DRUGS AGAINST VIRUSES

The Background to Chemotherapy of Virus Diseases

By Prof. C. H. Stuart-Harris and Dr. Lois Dickinson. (A Monograph in the Bannerstone Division of American Lectures in Living Chemistry.) Pp. xi+175. (Springfield, Ill.: Charles C. Thomas, 1964.) 10.50 dollars.

THERE is a feeling in the air that after many years of frustrated hopes we may be about to get somewhere in the field of chemotherapy for viruses. We have learnt so much more recently about the chemistry of viruses and how they multiply that it is now possible to approach the subject in a logical way: no need any more to take bottles off the shelf in alphabetical order and test them in a hit-or-miss manner.

This little book is by the professor of medicine in the University of Sheffield and a senior worker at the Research Department of Boots Pure Drug Co., Ltd., in Nottingham. Between the two, they well know the difficulties of the subject both from the clinical and laboratory angles. The background of the subject is presented in the first three chapters on the chemical composition and multiplication of viruses, their pathology and on the phenomena of virus interference and interferon. The matter is briefly presented in an interesting and up-to-date manner, but does not contain anything much that is not covered in similar accounts in recent text-books and reviews. Chapter 4 gets down to the subject proper, describing recent experimental work in the field, with results obtained in tissue culture, in infected eggs and in laboratory animals. Formulæ of the more important groups of compounds are given and the rationale of their use is discussed. Chapter 5 contains a particularly useful account of the criteria necessary to establish that a drug is of value in a human infection. I myself feel that rather more prominence might have been given to the very encouraging results of using a thiosemicarbazone compound for prophylaxis of variola in Madras. In Chapter 6 the authors deal with the rickettsiæ and the psittacosis–lymphogranuloma–trachoma (P–L–T) group. They write that "the taxonomic position of the rickettsiæ and, to an even greater extent, of the P–L–T group of organisms is still controversial". This is scarcely true any longer: it is almost universally agreed that these are bacteria rather than viruses. The authors contrast them with "the true viruses", but occasionally talk of them as if they really were viruses. Their inclusion in this book is understandable, since it is only against them that chemotherapy has proved its worth: knowledge about this may prove of value in describing a 'background'; it at least shows that we need not despair of tackling an obligate intracellular parasite. A final chapter deals with antibacterial chemotherapy, the action of steroids, and the use of serum as additional aids in the fight against viruses.

Despite our hopes for the future, present achievements in the field of virus chemotherapy are admittedly very meagre. This book simply tells of present difficulties and will serve, one hopes, to consolidate a jumping-off ground for future advance. But for less than 120 pages of straight text, a price of 10.50 dollars is indeed fierce.

C. H. ANDREWES

CHEMOTHERAPY

Advances in Chemotherapy

Vol. 1. Edited by Abraham Goldin and F. Hawking. Pp. xi+579. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1964.) 125*s*.

THE number of 'Advances in . . .', 'Reviews of . . .' and, in general, scientific books which carry the names of editors and not those of authors on their front leaf is increasing steadily and overwhelmingly like cars on the road. This simile is not so far-fetched as it sounds, because the capacity of libraries (and the brains of their users) is limited as much as is the space for traffic. One is therefore inclined to utter a 'Gertrude Stein-like' sigh when looking at another publication: "A Review is a review is a review is a review . . .", or "Advances are advances are advances are advances . . .".

My plea to publishers and would-be editors alike is: Please think again before committing yourself to another tome or series of tomes, unless they fill a real need. Having said all that and believing strongly in this warning against the rapid increase of modern scientific publications, it must be stated with the same force of conviction that *Advances in Chemotherapy* does fill a gap, and is well designed, and that the first volume is very promising.

The names of the editors, one a leading cancer expert, the other a well-known team leader of research into the treatment of infectious diseases, are a guarantee that the choice of new articles by (so it is hoped) new workers in chemotherapy will be a good one. This is indicated in their preface to the first volume which contains the basic outline of the principles which will be applied to future progress reports. There follows a homily on the historical side: nothing new, but well summarized in eight pages.

The editors state in their introduction that articles on clinical chemotherapy, as such, will not ordinarily be included, except in certain cases. This is a pity, because it reveals the enormous rift between experimental and clinical science which instead of getting narrower is widening all the time. Luckily, the editors have thrown their restrictions out of their editorial window and allowed Dr. Zubrod to discuss his ideas about preclinical studies and the quantitative treatment of clinical trials with reference, as he says, to the complex and difficult problem of diseases of unknown ætiology such as the acute leukæmias. A chapter follows on the chemotherapy of protozoal diseases with special reference to trypanosomal ones, and an excellent and brief monograph on viral diseases by R. L. Thompson. Hope is expressed for a frequent review of this topic activated recently by the clinical results with isatin thiosemicarbazone derivatives and the upsurge of interest in the tumour virus field. As an example of the revival of alkaloids as therapeutic agents the survey of the *Vinca rosea* group of natural plant products illustrates that chemotherapeutic remedies of natural origin are not confined solely to products of moulds and micro-organisms. It appears that the *Vinca* alkaloids, which are chemically complex polycyclic indole derivatives, have not only anti-leukæmic and anti-tumour properties but also show, possibly, some effects on viruses. A very extensive and excellent review by Foley and Epstein treats critically a very important aspect of cancer chemotherapy. In several instances the difficulty of interpreting results in animals by clinical terms is discussed in the book. Is it therefore right to go one step further back and use cell culture in its various forms for examination of anti-tumour remedies? It would seem that the authors have made a good case in favour of cellular systems to complement findings in whole animals, but they have gone to greater length than the immediate application of a technique to screening procedures. They thoroughly discuss the properties of cell lines, their nutritional and biochemical status and their possible morphological and mutational changes during prolonged culture. One of their sub-chapters which might carry the greatest promise for future work in relation to drug evaluation deals with organ culture.

The last three contributions describe the present state of research into the role of immuno-reactions during anti-parasitic chemotherapy by Goble, an extensive treatise on drug synergism in cancer chemotherapy by Venditti and Goldin and a stimulating chapter on newer ideas on enzyme inhibition by N. O. Kaplan and M. Friedkin. The existence of a host–drug–parasite complex prompts Goble to review, and most competently so, the interplay of antigen–antibodies not only with infected hosts but also with drug-treated hosts. This is most useful, as the old tag, 'Let Nature take its course', has gained some credence in that more attention is being directed to the part played by the defence mechanisms available to the host even during and after drug therapy.

The question of improving chemotherapeutic effects by applying truly synergistic mixtures or by enhancing the specificity and selectivity of a drug is particularly important in cancer chemotherapy, where the tumour in many instances does not behave like a parasite. It is therefore valuable to be given assessments of nearly all the present-day potential approaches by two experts of the National Cancer Institute, Bethesda. Mixing biochemical, biological and clinical arguments, they arrive at interim conclusions which represent an excellent stepping stone for further experiments and controlled trials.

The contribution from Brandeis University brings up to date the problems of antimetabolites by adding to the classical ones with their slight modification of normal substrates, the unrelated ones which, so it is claimed, achieve their effect by 'allosteric inhibition'—an expression proposed by Monod and Jacob. This widens enormously the possibilities of preparing regulators which will interfere not with peripheral but with central cellular mechanisms.

The volume is well edited and follows the best traditions of Academic Press, but regrettably the subject index is skimpy. If reviews or advances have to be produced, a high-quality index is as important as the high level of contributions.

F. Bergel

ASPECTS OF CHEMOTHERAPY

Antimicrobial Agents and Chemotherapy—1963

Proceedings of the Third Interscience Conference on Antimicrobial Agents and Chemotherapy, Washington, D.C., October 18–30, 1963. Edited by J. C. Sylvester. Pp. xiv+806. (Ann Arbor, Michigan: American Society for Microbiology: distributed in Europe and London by H. K. Lewis and Co., Ltd., 1964.) 12 dollars.

ANTIMICROBIAL Agents and Chemotherapy—1963 consists of 139 papers, which between them touch on many aspects of chemotherapy. Some sections deal with new antibiotics which are receiving clinical trial, some with the further evaluation and limitations of antibiotics the place of which in medicine is already established, and others with more general aspects of the prevention and management of refractory or dangerous infections. Much of their contents is concerned with bacterial infections in man or laboratory animals; but one article discusses the use of sulphonamides, different antibiotics and nitrofurans for the treatment of bacteriæmias in fish—a problem of some importance to the 770 commercial fish hatcheries in the United States; another is concerned with the value of antibiotics, particularly hygromycin *B*, as anthelmintics in veterinary medicine; several deal with antifungal substances, or the treatment of fungal infections; and a few describe antibiotics which have antitumour activity.

The pattern of the articles on the laboratory and clinical evaluation of antibiotics gives some indication of the nature of the clinical problems in bacterial chemo-

therapy which now have particular importance. Thus, a good deal of space is given to gentamycin, a family of antibiotics produced by species of *Micromonospora*, which appears to be related chemically to neomycin and kanamycin. This product aroused interest because it showed high activity against many Gram-negative pathogens, including *Pseudomonas aeruginosa*, which is resistant to most of the antibiotics in common use. But, although it may have a place in the chemotherapy of urinary tract infections, toxicity appears to limit the usefulness of gentamycin for the treatment of bacteriæmias.

A further section contains articles on the use of one of the cephalosporins—cephalothin—and some of the new penicillins for the treatment of a variety of infections, including infections of the urinary tract and bacteriæmias caused by penicillinase-producing staphylococci and by Gram-negative bacilli. These substances are made attractive by their rapid bactericidal action and low toxicity, and it seems that the cephalosporins show the interesting property of provoking no reaction in patients hypersensitive to the penicillins. Together, they widen considerably the possibilities of safe and effective therapy in bacterial disease. But some organisms, such as species of *Pseudomonas*, have so far remained outside their scope, and the existence of different β-lactamases with penicillinase or cephalosporinase activity, or both, still imposes limitations on their range of usefulness.

Despite the revolution in bacterial chemotherapy brought about by antibiotics, the continued importance of measures designed to diminish the incidence of infection in hospitals can scarcely be over-emphasized. The authors of one paper estimate that 31,000 deaths from bacteriæmia by Gram-negative rods might have been prevented in American hospitals in 1962 if safer methods of catheterization had been used. Other papers deal with cross-infection and infection after surgery.

In addition to many articles concerned with the use of antibiotics there are several papers on the chemistry of antibiotics, including two on unusual peptides, one paper on the role of acetate in biosynthesis and others which deal with the mode of action of penicillin, streptomycin, erythromycin and polyene antibiotics respectively. One of the latter, by J. T. Park, leads to the interesting conclusion that penicillin inhibits enzymes concerned with mucopeptide synthesis only under conditions of cell growth and that this is the real reason why penicillin only kills growing cells.

This book contains a number of articles of high quality and its range of topics is likely to make it of wider interest than some of its predecessors. E. P. ABRAHAM

PROBLEMS OF NUTRITION

Proceedings of the Sixth International Congress of Nutrition

Edinburgh, 9th to 15th August 1963. General Editors: C. F. Mills and R. Passmore. Pp. xv+683. (Edinburgh and London: E. and S. Livingstone, Ltd., 1964.) 105*s*. net.

THE sixth International Congress of Nutrition, held in Edinburgh during August 9–15, 1963, centred on a series of symposia on the following subjects: nutrition and health; nutrition and early growth; dietary factors in the genesis of cardiovascular disease in man; nutrition in developing populations; animal production under adverse climatic conditions; nutritional and functional aspects of trace element metabolism; protein–calorie deficiency and its amelioration; absorption of nutrients; endocrine function and reproduction in relation to nutrition; balance experiments and isotopes in nutritional investigations. The papers delivered at these symposia, and also those delivered at a special plenary session on "Nutrition as the Servant of Man", are reproduced in full in the *Proceedings*. The volume also contains a message from H.R.H. the Duke of Edinburgh, an address by the president of the Congress, D. P. Cuthbertson, special plenary lectures on "Nutrition and Numbers" and "Nutritional Factors in Gallstone Formation" by J. G. Harrar and H. Dam, respectively, and abstracts of some 450 papers read at sessional meetings. About 1,300 names are given in a list of members; the Congress was thus not exceptionally large as international scientific congresses go nowadays.

In the wide field of subjects covered, there was some emphasis on nutrition in the developing countries, though the majority of members came from the United Kingdom and the United States, with continental European countries less fully represented. The small number of members from Asia, Africa and Latin America made useful contributions. An optimistic note was struck in many of the papers dealing with protein–calorie deficiency disease, reflecting the progress made in investigating and attacking this world-wide problem during recent years. There was, however, recognition of the vital importance of the 'population explosion' and its effects on world food requirements. Advances in biochemical and physiological research related to nutrition were the theme of some of the symposia, for example, those concerned with growth, trace elements, absorption, endocrines and the use of isotopes in nutritional investigations. The symposium on diet and cardiovascular disease produced nothing very new. At the special plenary session on "Nutrition as the Servant of Man", held at the end of the Congress, papers were delivered on "Food as a Function of History", "Nutritional Problems of Tanganyika", "Nutrition and World Health", "Application of Nutritional Research to Practical Problems of Nutrition", "The Challenge of the Pre-school Child", and "The Pre-school Protection Programme". These titles illustrate some of the broad issues which particularly interest workers in nutrition and associated fields to-day.

The volume is excellently printed and the editors are to be congratulated on having prepared it for publication in so short a space of time. It does not deal with the social side of the Congress, which was well organized; it can be taken for granted that participants in any scientific congress held in Edinburgh will enjoy themselves. The purpose of this Congress as a whole was well stated in the Duke of Edinburgh's message: "Knowledge in the field of nutrition has grown enormously during the past few years, and it has become more than ever imperative for those engaged in providing and applying this new knowledge to come together periodically and to survey the position". W. R. AYKROYD

LAMARCK AS A GEOLOGIST

Hydrogeology

By J. B. Lamarck. Translated by Prof. Albert V. Carozzi. Pp. vi+152. (Urbana, Ill.: University of Illinois Press, 1964.) 4.75 dollars.

JEAN Baptiste Lamarck (1744–1829), the founder of invertebrate palæontology and the begetter of a theory of evolution, indirectly contributed much to the advancement of the science of geology. His systematic study of fossil shells in the Paris Basin helped to establish the science of palæontological stratigraphy, while his theory of evolution passing through the hands of Lyell and Charles Darwin provided geology with a method and a doctrine. In contrast to these important contributions to science, we have the work, *Hydrogéologie*, which was published in 1802 at his own expense. The book is something of a curiosity, because, while it raises new and most fundamental problems in geology, at the same time it produces what would be considered nowadays the most fantastic solutions. Lamarck's contemporaries derided it, later generations forgot it, and historians of geology, with the

notable exception of Archibald Geikie, have ignored it. However, the book has many merits from the points of view both of the problems it raises and the attempts it makes to solve them. The English translation of *Hydrogéologie* by A. V. Carozzi along with his valuable annotations and critical notes represent an important contribution to the history of science. This critical apparatus comprises a large part of this edition. It not only makes Lamarck intelligible to the modern scientist but also puts his work into proper perspective.

Four fundamental problems are discussed by Lamarck: denudation of land by running water and formation of valleys and mountains, origin of continents and oceans, displacement of continents and oceans, and organogenic formation of rocks. In his discussion on the degradation of land, denudation and deposition of sediments in seas and oceans, Lamarck, although aware of the existence of highly inclined strata, assumed that the continents were covered by horizontal strata forming plateaux and carved out by rivers. From this he deduced that all mountains, except those of volcanic origin, were formed from watershed ridges of the plateau. Lamarck was obviously influenced in his conclusions by his immediate surroundings—the Paris Basin. Hutton, on the other hand, living in Scotland had a great advantage over Lamarck due to the diversity of the surrounding countryside. Oceans and seas occupy hollows, while continents are bulges in the Earth's crust. According to Lamarck the hollows are scoured by tidal ebb and flow, while continents represent elevated sea bottoms, a conclusion proved by the abundance on the continents of strata containing marine fossils. Again, forces due to the Moon produce westward drift of oceanic waters, which explains their westward drift over the continents.

While in the first chapter we gain a glimpse of geomorphology, in the second we meet geophysics, or, more precisely, isostasy—where Lamarck discusses the 'centre of the globe' not coinciding with the 'centre of gravity' of the Earth, in reference to the asymmetrical disposition of land masses and oceans. The idea that continents and oceans show a constant displacement contained the embryo of an idea which led to the science of palæogeography and palæostratigraphy. While Hutton, in his famous treatise, laid great emphasis on magmatic processes and said little about organisms, Lamarck as a biologist (he invented this term) grossly over-estimated the influence of organisms as rock builders. He correctly stated that limestones were formed by the remains of calcareous organisms, but then he also stated that clay was formed by plants, obviously mistaking plant ash for clay. Bad as it sounds, this statement is followed by a lengthy argument to prove that in Nature there is a tendency for compounds, such as minerals, to decompose into their constituent elements, while the formation of compounds is due entirely to living organisms, the only pure element being silica. To cross the t's and dot the i's, Lamarck, at the end of his book, provided an "Analytical Index" and here are parts of two entries: "Granite. It is not a primitive material because its components or their derivatives originate from living organisms which therefore must have existed previously . . ." and "Silica or vitreous earth. It is the only existing elementary earthy substance, and consequently the only one which is not of compound nature . . .".

It is to some extent a pity that a genius like Lamarck should have produced such a speculative book in which genius and ridicule appear to be closely intermixed. Obviously this can be put down to his neglect of geological field studies and also to his ignorance of contemporary literature, especially, for example, Hutton's, whose original paper was published in 1788 and his book in 1795, and whose theory is mentioned by J. C. Delamétherie in his *Théorie de la Terre* published in Paris in 1795. However, as the saying goes, it is easy to be wise after the event. Lamarck, in his little book *Hydrogéologie*, raised many of the fundamental problems which concern geologists to-day: geomorphology and the evolution of the land surface, migration of land and sea, and problems of geophysics and palæogeography, gradualism versus catastrophism, actualism versus diluvianism, and the organic origin of certain rocks. Finally, it should be pointed out that Lamarck's fundamental philosophical concept of the world as evolving in a plenitude of time is similar to the fundamental concept of Hutton.

Hutton: "Here is a compound system of things, forming together one whole living world; a world maintaining an almost endless diversity of plants and animals, by the disposition of its various parts, and by the circulation of its different kind of matter."

Lamarck: "On our planet, all objects are subject to continual and inevitable changes which arise from the essential order of things. These changes take place at a variable rate according to the nature, condition, or situation of the objects involved, but are nevertheless accomplished within a certain period of time."

Hutton: "But though, in generalizing the operations of nature, we have arrived at those great events, which, at first sight, may fill the mind with wonder and with doubt, we are not to suppose, that there is any violent exertion of power, such as is required in order to produce a great event in little time; in nature, we find no deficiency in respect of time, not any limitation with regard to power. But time is not made to flow in vain; nor does there ever appear the exertion of superfluous power, or the manifestation of design, not calculated in wisdom to effect some general end."

Lamarck: "Time is insignificant and never a difficulty for Nature. It is always at her disposal and represents an unlimited power with which she accomplishes her greatest and smallest tasks. The modifications to which all things in this world are subjected concern not only their shape and nature, but also their mass and even their location."

S. I. TOMKEIEFF

RELATIONSHIP BETWEEN SPECTRA AND CHEMICAL STRUCTURE

Introduction to Infra-red and Raman Spectroscopy

By Norman B. Colthup, Lawrence H. Daly and Stephen E. Wiberley. Pp. xii+511. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1964.) 86*s*.

Spectra Structure Correlation

By John P. Phillips. Pp. ix+172. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1964.) 48*s*.

SPECTROSCOPIC measurements are nowadays so much a part of everyday chemistry that there is an obvious need for introductory texts which explain the principles involved and make clear the areas of useful application. *Introduction to Infra-red and Raman Spectroscopy* and *Spectra Structure Correlation* are only two of a substantial number of books of this kind that has appeared in recent months, and that of Colthup, Daly and Wiberley, for example, covers much the same sort of ground as Rao's *Chemical Application of Infra-red Spectroscopy*, issued recently by the same publisher. Several other texts are known to be under way, and the chemist is likely to be presented with a plethora of introductory material from which he may find it hard to choose that which best fills his needs.

There is, however, a good deal of scope for variation in treatment and in emphasis. A chemist wishing to use these methods needs to know at least a little about vibration/rotation spectra and of the effects of molecular symmetry on band shapes in the vapour phase. He must

understand enough about symmetry properties and group theory to be able to apply the basic selection rules, and it is at least highly desirable (and in many branches of chemistry, essential) that he is familiar with the concepts of normal co-ordinate treatments and the applications of matrix methods to the detailed analysis of the spectra of small molecules. Add to this the necessity for some instruction in instrumentation, and experimentation, the enormous volume of empirical (and therefore largely incompressible) data on group frequencies, and the much smaller volume of work which contributes to their understanding, and one can see that a good deal of careful selection and compression is required if one is to produce a book and not a many-volume encyclopædia. Indeed, most of these topics (all of which are dealt with in the Colthup text) already have several advanced texts of their own.

In the Colthup book the emphasis is almost equally divided between group frequency data and the more fundamental and instrumental aspects. The first chapters on vibration/rotation spectra and on experimentation are adequately done but are in many ways essentially similar to the monographs which have already appeared in many compendia on physical methods in organic chemistry. It is difficult to see how it could be otherwise with the limited space available, but the facts are clearly stated. The third chapter on the classification of molecules is a particularly interesting one, dealing as it does with symmetry properties, point groups and the application of group theory. This is the area which the average chemist with no spectroscopic training finds most difficult to understand and where there is a real shortage of sufficiently elementary texts to enable him to get to grips with the subject. This chapter and those on the theoretical analysis of molecules and the calculation of thermodynamic functions are well done and attempt to develop the subject in a way that can be followed by those who have no previous knowledge of group theory or matrix algebra. The illustrations showing symmetry elements are particularly good, but the compression required to cover so much ground in so short a space will take its toll of many an organic chemist, who will find he needs to re-read these chapters very slowly and perhaps many times before he has assimilated their contents. Nevertheless, he will be wise to do so, as he will find it hard to locate short elementary treatments of these topics.

The substantial chapters on various aspects of group frequency also suffer somewhat from compression. The chapter on the origins of group frequencies is well done and an astonishing amount of factual data is packed into the 150 pages dealing with group frequencies of specific groups. These chapters are well worth while and probably represent the best that can be done in the limited space available, although with some of the minor groups the compression leads to the text merely restating in words the frequency ranges which are already available in the tables or charts. Perhaps the most significant weakness is the absence of sufficient guidance on the relative reliabilities of the individual correlations. The section on the trustworthy OH stretching frequencies is followed by that on the untrustworthy OH bending modes and there is little indication that the stretching bands are to be preferred. It is true that anyone who has read the earlier chapters with sufficient care could infer this for himself, but organic chemists are not always systematic readers. This point is important because in almost any journal nowadays one can find papers showing how very much more the inexperienced man can read into a spectrum than can his more experienced counterpart.

Despite these limitations this is an excellent text and can be strongly recommended. It fulfils its difficult introductory task extremely well.

The text by Phillips is also an introductory text, but of a different kind and using a much broader brush. Within the limits of 172 pages it reviews spectral structure correlations from the far ultra-violet to the far infra-red. With so wide a scope, something has to go, and in this case it is the instrumental and theoretical side. The author rightly states that theoretical discussions of the broad spectrum here considered, even at the minimum level, would leave no room for the text. This is therefore a handbook and survey of data, tersely and concisely presented. Measurements from several spectral regions often provide a degree of certainty which cannot be obtained from any single region alone, and the collection together of the various correlations is therefore long overdue. The job has been well done, within the limitations of size.

The utility of the book will depend very much on the background of the reader. For those who have some reasonable grounding in spectroscopic theory this will provide a handy, concise manual of correlation data. It will, no doubt, be welcomed also by many who have no such background, but they should be more wary of using it, as the pitfalls of using spectral correlations without some understanding of their origins are many and deep. None the less there are other texts available which will provide the necessary background of theory, and it must be said that this is a useful volume which fulfils well the aims of the author, and it will certainly be widely used in the laboratory. The fact that it is relatively inexpensive is also something deserving of comment and praise.

L. J. BELLAMY

DEVELOPING FIELDS IN POLYMER SCIENCE

The Chemistry of Cationic Polymerization

Edited by P. H. Plesch. Pp. xv + 728. (Oxford, London, New York and Paris: Pergamon Press, 1963.) 200*s*.

Newer Methods of Polymer Characterization

Edited by Bacon Ke. (Polymer Reviews, Vol. 6.) Pp. xvi + 722. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, 1964.) 185*s*.

Configurational Statistics of Polymeric Chains

By M. V. Volkenstein. Translated from the Russian edition by Serge N. Timasheff and M. J. Timasheff. (High Polymers: a Series of Monographs on the Chemistry, Physics and Technology of High Polymeric Substances. Vol. 17.) Pp. x + 562. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, 1963.) 150*s*.

MANY fields of polymer science are to-day in a state of rapid development in which, although classical treatments still provide a broad basis for interpretation, new concepts, refinements and information are being added at an increasing rate. Stimuli given by the work of Ziegler, Natta and many others have intensified work on polymerization and led to the discovery of new catalysts and methods and to new theories of mechanisms. The production of stereoregular polymers and of block and graft copolymers, the search for polymers of high thermal stability and other recent developments have resulted in the production of many complex and often highly sophisticated polymers which require very detailed knowledge in order to understand their structures and interpret their properties. New methods of examination and characterization of polymers, often involving advanced physical techniques and instrumentation, have been and are being developed. New approaches to problems of polymer conformation, configuration and shape have become necessary.

Information regarding such present-day developments is usually scattered in journals, and detailed information, because of limitations of space, is often absent. Comprehensive accounts and critical reviews, at the research-level, are therefore of great value to the polymer scientist. The

rate of development in some fields has become so great that it is often difficult for a single author to produce such an account or review. The alternative, a collection of contributions from experts on different aspects of the field, requires careful editing in order to ensure that the right level is maintained and serious overlapping does not occur. In either type of book it is desirable that recent work should be seen against a background of earlier investigations and theory, and it is essential that references be as up to date as possible. The three books under review illustrate, to varying extents, these points and some of those in the preceding paragraph.

That edited by Dr. Plesch provides an account of addition polymerizations in which the chain carrier is a cation. Although emphasis in recent studies of polymerization has perhaps been on stereospecific and radical polymerizations, cationic polymerization has not been neglected and the publication of this book is timely. Contributions from eighteen well-known experts lead the reader from the relevant fundamentals of organic chemistry to detailed consideration of the cationic polymerization of a wide range of compounds. The first chapter deals with the existence, formation, stability and structure of carbonium ions and is logically followed by the consideration of organic reactions related to cationic polymerization. The mechanisms of radical, cationic and anionic polymerization are then compared, so that cationic polymerization is seen in relation to a wider context. Successive contributions then deal with the cationic polymerization of olefines, aromatic compounds, polyenes and non-conjugated diolefines, vinyl ethers, cyclic and other oxygen compounds, nitrogen compounds and sulphur compounds, the last-mentioned including radical and anionic mechanisms as well as cationic. Other contributions deal with cationic reactions of polymers, cationic graft polymerization and cationic polymerization induced by high-energy radiation. A final chapter contributed by the editor, although short, gives valuable information on experimental techniques.

Omissions, such as separate accounts of heterogeneous reactions and complex catalytic systems derived from metal halides, are pointed out by the editor and are not serious. The level of the contributions is uniform and is that of a research monograph. Inevitable overlapping seems in most cases to clarify rather than confuse. Earlier work is critically considered, and the literature is well covered to the end of 1960. In addition, many important investigations published in 1961 and 1962 are cited in appendixes and editor's notes. The latter, distributed liberally throughout the book, also provide many stimulating comments. Dr. Plesch is co-author of one of the contributions and author of two others. These, the level of the book as a whole and his editor's comments, reflect his enthusiasm and influence in the production of a critical, authoritative and well-balanced review of cationic polymerization.

Newer Methods of Polymer Characterization also consists of separate contributions from different experts, each dealing with a method or methods at present in use, but which has or have not generally been previously described in detail. Each generally proceeds from a brief theoretical interpretation to applications of the method and a discussion of its scope and potentialities. Apparatus and techniques are only described in cases where such information is not readily available. As is perhaps to be expected, emphasis on different aspects varies. Applications are emphasized in a chapter on investigations of microtacticity which critically considers solid-state and solution methods. Another discusses applications of high-resolution nuclear magnetic resonance to configurational and structural problems. A chapter on optical methods of characterization describes different methods of attacking the problem. Five other chapters, dealing with polarization and deuteration in infra-red spectra, optical rotatory dispersion, fluorescence techniques, small-angle X-ray investigations and electron diffraction, may also be classed as optical methods. Two chapters, by the editor, deal with differential thermal analysis and a new method involving differential thermometric measurements during mechanical deformation. The remaining chapters deal with solution or related properties. Two of them, one on column fractionation and largely restricted to elution chromatography of polyolefines and the other on elasto-osmometry, apply a method to a particular problem. Another, on osmometry and light-scattering at elevated temperatures, deals with new techniques in well-established methods. The remaining contributions are concerned with density-gradient centrifugation, flow birefringence and monolayers of polymers.

The influence of the editor is also apparent in this book. In addition to his two contributions he has maintained a reasonably uniform level and generally avoided overlapping with other review publications. Each chapter provides references up to the end of 1962, and in some cases references to work in 1963 are also given. The book as a whole is a valuable and reasonably concise review of some newer methods of characterization and their use and potentialities in polymer research.

Configurational Statistics of Polymeric Chains is by a single author. Knowledge of chain configurations and their statistical distribution is essential to an understanding of the molecular properties of polymers and their behaviour in bulk and in solution. Interpretation of chain configurations in terms of hindered rotations about single bonds in the chain provides a basis for the use of mathematical treatments of models for polymer chains. This approach, extensively used by the author and his collaborators, is developed in detail. As in *The Chemistry of Cationic Polymerization*, the first chapters provide a background, giving a succinct account of relevant polymer theory and detailed consideration of internal rotation in small molecules and rotational isomerism. The concepts developed are then applied to polymeric chains. Different models used to represent such chains are critically discussed. The properties of crystalline polymers and the stereo-chemistry of polymer chains are topics in a chapter which includes theories of melting and chain configurations in crystals. A wide range of polymers, including natural ones, is considered. Real polymer chains are contrasted with model chains and the effects of various factors on chain dimensions are assessed. A chapter on optical anisotropy of polymer chains includes accounts of anisotropic polarizability, photo-elasticity in polymers and the Kerr effect in polymer solutions. A final chapter deals with the stretching of polymeric chains and networks and includes the thermodynamics of rubber elasticity and the network theory of high elasticity.

Treatment is inevitably often mathematical and the methods are frequently advanced. The scope of the book is wide including the consideration of many properties of polymers related to chain configuration and even embracing such aspects as the genetic code in polynucleotides. It was originally published in Russian in 1959 and references to the original literature up to 1958 are full and detailed. As Prof. P. J. Flory states in a foreword, the comprehensive coverage of earlier work lends perspective to newer developments. The rapid progress in this field has inevitably made some sections out of date although this is offset to some extent by Prof. Volkenstein indicating, in the preface, some of the developments made since the book was written. In spite of some omissions of recent work, this book, containing much valuable material not otherwise readily accessible, will be of great value to all research workers concerned with problems related to the configurations of polymeric chains.

Each of the three books represents an authoritative and critical account of a field of polymer science which is in process of rapid development. The level in each case is that of a research monograph. Each book will stimulate further research and increase the already high rate of

important new publications from Academic Press

PHYSICAL PROPERTIES OF MAGNETICALLY ORDERED CRYSTALS

by **E. A. Turov**

- presents a unified phenomenological theory of spin waves in ferromagnets, antiferromagnets, and weak ferromagnets
- demonstrates the use of phenomenological spin wave as a tool for determining qualitative and quantitative relationships of various properties of magnetic crystalline substances

(T820) January 1965, about 225 pp., in preparation.

METHODS IN CARBOHYDRATE CHEMISTRY

edited by **Roy L. Whistler**

Volume 5

- includes sections on general isolation procedures, polysaccharide preparations, chemical analyses, physical analyses, molecular weight determinations, structural methods, derivatives, and other selected methods
- this authoritative series satisfies the demand for a comprehensive reference set giving reliable methods for use in both routine and experimental laboratory work in carbohydrate chemistry

(W348) **Volume 5: General Polysaccharides**, January 1965, about 450 pp., 118s.

INTRODUCTION TO MODERN BIOCHEMISTRY

SECOND EDITION

by **P. Karlson**

Reviews:

"... *a useful addition to the list of modern text-books in biochemistry.*"—Nature

"... *clearly written, well illustrated, and smoothly translated.*"—**Journal of Chemical Education**

- reflects the modern emphasis on turnover and control mechanisms, thoroughly covers the correlations and application of principles and stresses the biological and chemical aspects of biochemistry

(K155) February 1965, 435 pp., in preparation

ELEMENTARY CALCULUS

FIRST AMERICAN EDITION

by **P. R. Masaii, R. C. Patel** and **D. J. Patil**

- introduces calculus to students who have either taken or are taking, concurrently, a course in analytic or co-ordinate geometry
- reveals the conceptual development of calculus, accounting for technical and applied aspects, and conforming to the standards of clarity and rigor prevailing in contemporary mathematics

(M330) February 1965, 335 pp., in preparation

STATISTICAL THEORIES OF SPECTRA: FLUCTUATIONS

edited by **Charles E. Porter**

- papers demonstrate the use of statistical methods for investigating fluctuations in spectra
- places the papers in proper perspective and introduces the subject and the current language of statistical studies of spectra by means of an extensive introductory chapter

(P462) February 1965, about 575 pp., in preparation.

BRIDGED AROMATIC COMPOUNDS

by **B. H. Smith**

A Volume of Organic Chemistry: A Series of Monographs edited by **Alfred T. Blomquist**

- covers the chemistry of all bridged aromatic systems
- explains the chemical and physical behavior of many of the bridged aromatics through reference to the physical methods of analysis, infrared and ultraviolet spectroscopy, nuclear magnetic and electron paramagnetic resonance, and X-ray diffraction

(S366) February 1965, about 525 pp., 100s.

ADVANCES IN MARINE BIOLOGY

edited by **F. S. Russell**

Contents of Volume 2:

J. E. SHELBOURNE, The Artificial Propagation of Marine Fish. JOHN E. CUSHING, The Blood Groups of Marine Animals. ROBINA B. SCHOLES and J. M. SHEWAN, The Present Status of Some Aspects of Marine Microbiology. N. A. HOLME, Methods of Sampling the Benthos. Author Index—Subject Index

(A702) Volume 2, 1964, 274 pp., 57s. 6d.

INTRODUCTION TO THERMODYNAMICS

by **D. C. Spanner**

Volume I of Experimental Botany: An International Series of Monographs edited by **J. F. Sutcliffe** and **P. Mahlberg**

- will help students to acquire a sound grasp of Thermodynamics fundamentals
- contains such topics as—the nature of thermodynamics, the first law of thermodynamics, some mathematical topics, reversibility and irreversibility perfect gases and some other things, the second law of thermodynamics, entropy and free energy, dilute solutions of electrolytes, the thermodynamics of water relations

(S530) 1964, 278 pp., 47s. 6d.

BIOLOGY

DESIGN AND FUNCTION AT THE THRESHOLD OF LIFE: The Viruses

by **Heinz Fraenkel-Conrat**

Review:
"*. . . one of the very few authoritative books that can bridge the gulf between the scientist and the humanist with depth and substance . . . a source of information and inspiration.*" —**Science**

- presents the complex subject matter in a simple, informative style
- makes accessible to the student much vital new knowledge, and provides the basic grounding necessary for future study in an area certain to become increasingly significant in biological research

(X850) 1962, 117 pp., 17s. 6d. (X851) clothbound 44s.

TIME, CELLS, AND AGING

by **Bernard L. Strehler**

Review:
"*This is one of the best available accounts of the present state of research on fundamental causes of aging . . . highly important background material for physicians and biologists alike.*" —**The Lancet**

- reviews the dramatic progress made in cell biology during the past decade, points up its possible implications for gerontology, and elucidates the ways in which physiological changes alter living systems

(X770) 1962, 270 pp., 21s. (X771) clothbound 48s.

ISOTOPES IN BIOLOGY

by **George Wolf**

- covers the related aspects of isotope usage—methods, units, health hazards, principles and applications, rates of reactions in living systems—and makes the subject easily understandable to those with only a general basic training in biology

(X960) 1964, 173 pp., 17s. 6d. (X961) clothbound 44s.

DIVISION OF LABOR IN CELLS

by **Geoffrey H. Bourne**

- covers modern concepts of cytology, integrating knowledge of both structure and biochemical processes of the cell
- develops a comprehensive picture of the interrelated division of labor in the cell
- important for senior undergraduate students in biology and graduate students in all the basic medical and biological sciences

(B524) 1962, 248 pp., 23s.

A NEW SERIES IN PAPERBACK

ADVANCED BIOCHEMISTRY SERIES

edited by Anthony San Pietro

VOLUME I :

PRIMARY PROCESSES IN PHOTOSYNTHESIS

by **Martin D. Kamen**

- publishes a current treatment of research on those elements of photosynthetic processes which occur before the onset of biochemical and physiological phases (i.e. before 10^{-3} to 10^{-4} seconds)
- treats—the natural history of photosynthesis, the photosynthetic apparatus, the era of radiation physics: pts 15 to pts 9, the era of photochemistry: pts 9 to pts 4

(K084) 1963, 182 pp., 17s. 6d. (K086) hardbound 44s.

MATHEMATICS

ELEMENTS OF ABSTRACT HARMONIC ANALYSIS

by **George Bachman**

- succeeds in covering virtually every important feature of the subject while presenting the material at an introductory level
- defines concepts and gives proofs in great detail to make the survey simple and self-contained

(X150) 1964, 256 pp., 24s. 6d. (X151) clothbound 52s.

INTRODUCTION TO *p*-ADIC NUMBERS AND VALUATION THEORY

by **George Bachman**

- an exposition of valuation theory presented as a course of study in itself
- provides a complete and concise teaching format
- contains—valuations of rank one, complete fields and the field of *p*-Adic numbers, calculation rings, places and valuations, normed linear spaces, extensions of valuations

(X154) 1964, 173 pp., 24s. 6d. (X155) clothbound 52s.

MATHEMATICS

NONEUCLIDEAN GEOMETRY
by **Herbert Meschkowski**
translated from the German by A. Shenitzer

- following the course of study set down in this book, the student may move directly from euclidean to noneuclidean concepts
- leads the apt pupil to the study of such subjects as automorphic function, uniformisation of algebraic functions, and the theory of discontinuous groups, in a comparatively short time

(X500) 1964, 104 pp., 17s. 6d. (X501) clothbound 44s.

FINITE PERMUTATION GROUPS
by **Helmut Wielandt**
translated from the German by R. Bercov

- collects the basic theorems on permutation groups
- integrates recent developments, "streamlines" proofs of older theorems, includes many theorems never before or rarely available in textbooks

(X950) 1964, 114 pp., 17s. 6d. (X951) clothbound 44s.

QUADRATIC FORMS AND MATRICES:
AN INTRODUCTORY APPROACH
by **N. V. Yefimov**
edited and translated from the Russian by A. Shenitzer

- explains and evaluates every step as it is introduced —allows the student to understand the importance, function, and interrelation of each stage
- the instructor is saved the need of augmenting the text with illustrative lecture material
- treats quadrics from an algebraic point of view and then proceeds to a geometric interpretation of linear algebra

(X970) 1964, 164 pp., 17s. 6d. (X971) clothbound 44s.

PHYSICS

CRYSTALS:
THEIR ROLE IN NATURE AND SCIENCE
by **Charles Bunn**

- outlines our present knowledge of crystals
- discusses the ways in which crystallography contributes to our understanding of light, X-rays, three-dimensional chemistry, and the nature of the solid state of matter
- a clear, concise presentation for all students and non-specialists who want a basic knowledge of the subject

(X160) 1964, 286 pp., 24s. 6d. (X161) clothbound 52s.

PHYSICS

POTENTIAL BARRIERS IN SEMICONDUCTORS
by **B. R. Gossick**

- provides an inclusive review of related electronic processes
- cogent organization and simplicity of presentation make the material useful to the advanced student, as well as scientists and engineers dealing with the physical processes of semiconductor barrier layers

(X350) 1964, 153 pp., 17s. 6d. (X351) clothbound 44s.

ELEMENTARY DYNAMICS OF PARTICLES
by **H. W. Harkness**

- defines the fundamental concepts of kinematics, develops a reference structure of plane Newtonian mechanics, treats statics as an aspect of equilibrium
- includes—vectors, displacement, velocity, acceleration, and relative motion, angular motion and rolling motion, motion with constant acceleration (uniformly accelerated motion), Newton's Laws of Motion, work and energy, the equilibrium, units and dimensions, hydrostatics, and fluid dynamics

(X400) 1964, 219 pp., 21s. (X401) clothbound 48s.

ELEMENTARY PLANE RIGID DYNAMICS
by **H. W. Harkness**

- presents the basic problems of inertia, oscillation, friction and wave dynamics
- includes—the motion of a rigid body around a fixed axis, the general plane motion of a rigid body, some special problems involving friction, undamped simple harmonic motion, damped oscillations, forced oscillations, Newton's Law of Gravitation

(X404) 1964, 194 pp., 21s. (X405) clothbound 48s.

MOSSBAUER EFFECT:
PRINCIPLES AND APPLICATIONS
by **Gunther K. Wertheim**

- an invaluable study for physicists, chemists, and metallurgists, making possible fruitful experimental attacks on problems that had to be approached theoretically heretofore
- includes—instrumentation, relativity and the Mössbauer effect, atomic motions, the use of the Mössbauer effect in the study of hyperfine structure, isomer shift, quadrupole coupling, magnetic hyperfine structure, the magnetism of metals and alloys, chemical applications, line width and line shape

(X930) 1964, 116 pp., 17s. 6d. (X931) clothbound 44s.

important new publications from Academic Press

THE ANATOMY OF THE LABORATORY MOUSE

by **Margaret J. Cook**

Detailed work is presented on three aspects of mouse anatomy—

- the skeleton
- the viscera
- the circulatory system

The introduction of the method used for injection of the circulatory system will facilitate dissection of the blood vessels. Detailed line drawings, made by the author from fresh or injected material, will interest workers in all laboratories using the laboratory mouse.

(C660) Winter 1964, about 150 pp., approx. 30s.

CRAIGIE'S NEUROANATOMY OF THE RAT

Revised and Expanded

by **Wolfgang Zeman** and **James Robert Maitland Innes**

Long out of print and unavailable in the classroom, *An Introduction to the Finer Anatomy of the Central Nervous System Based upon That of the Albino Rat*, is now published as a completely updated work, tailored specifically for the student and research worker. It is a classic treatment of the anatomy of the rat's central nervous system and its coverings, a study that also includes general principles of mammalian comparative neuroanatomy with ontogenetic and phylogenetic aspects, as well as a brief introduction to higher nervous mechanisms.

(C770) 1963, 230 pp., 68s.

PHOTOGRAPHIC ATLAS OF SHARK ANATOMY

THE GROSS MORPHOLOGY OF SQUALUS ACANTHIAS

by **Carl Gans**

For the first time . . .
a photographic atlas devoted exclusively to the common Spiny Dogfish, *Squalus acanthias*, the species most frequently used in courses of comparative anatomy. Primarily designed for instructional use, the Atlas also provides ichthyologists, fisheries, biologists, and others in allied fields, with a carefully planned and executed series of plates of all gross structures, often in several sections.

(G170) 1964, 106 pp., 31s.

SOLVENT EFFECTS ON REACTION RATES

by **Edward S. Amis**

- treats the mechanistic pictures of chemical reactions and the influence of the solvent on mechanisms.
- presents from the theoretical, hypothetical and correlative viewpoints, an extensive and systematic treatment, citing the pertinent literature.
- lists numerous references through 1963.
- gives specific examples of the various effects.

(A948). January 1965, about 275 pp., approx. 64s.

FLUCTUATION PHENOMENA IN SOLIDS

edited by **R. E. Burgess**

Composed of authoritative and critical accounts of certain contemporary aspects of fluctuations in solids, the material is divided into three broad areas—

- models and analytical techniques for stochastic processes.
- observable aspects of fluctuations.
- experimental data on fluctuations and their interpretation.

The types of solids considered include: ferroelectric, ferromagnetic and antiferromagnetic materials, alloys and semiconductors.

(B868) January 1965, about 400 pp., approx. 107s. 6d.

NEWER METHODS OF PREPARATIVE ORGANIC CHEMISTRY

edited by **Wilhelm Foerst**

VOLUME 3, TRANSLATED BY HENRY BIRNBAUM

CONTENTS:
R. WEGLER, E. KÜHLE, and WERNER SCHÄFER, The Reactions of Sulfur with Araliphatic and Aliphatic Compounds. K. THOMAS and D. JERCHEL, The Introduction of Substituents into the Pyridine Ring. U. SCHÖLLKOPF, Carbonyl-Olefin Transformation Using Triphenylphosphinemethylenes. The Wittig Reaction. L. HORNER and E. H. WINKELMANN, N-Bromosuccinimide, Its Properties and Reactions. The Course of Substitution. F. KORTE and K. H. BUCHEL, The Acyllactone Rearrangement; A Method for the Preparation of Heterocyclic Ring Systems. H. BREDERECK, R. GOMPPER, H. G. v. SCHUH, and G. THEILIG, Syntheses with Acid Amides, Particularly Formamide. W. THEILACKER and E. WEGNER, Organic Syntheses Using Chloramine. F. CRAMER, Preparation of Esters, Amides, and Anhydrides of Phosphoric Acid. K. DIMROTH and K. H. WOLF, Aromatic Compounds from Pyrylium Salts. W. FRANKE, W. ZIEGENBEIN, and H. MEISTER, The Formation of the Acetylenic Bond. F. WEYGAND and H. J. BESTMANN Syntheses Using Diazoketones. Author Index—Subject Index.

(F799) January 1965, 544 pp., 114s. 6d.

INTERPRETATION OF METALLOGRAPHIC STRUCTURES

by **W. Rostoker** and **J. R. Dvorak**

- interweaves discussion of modern physical metallurgy with a large number of carefully selected exemplary microstructures.
- demonstrates that logical framework of interpretation can supplant mental storage of infinite variations.
- gives each micrograph an individual commentary in which the composition and thermal or thermal-mechanical history are related to the particular point which is intended for illustration.

(R688) January 1965, about 250 pp., 80s.

ADVANCES IN CHEMICAL ENGINEERING

edited by **Thomas B. Drew, John W. Hoopes, Jr.,** and **Theodore Vermeulen**

CONTENTS:
J. F. WEHNER, Flame Processes—Theoretical and Experimental. J. H. SINFELT, Bifunctional Catalysts. S. G. BANKOFF, Heat Conduction or Diffusion with Change of Phase. GEORGE D. FULFORD, The Flow of Liquids in Thin Films. K. RIETEMA, Segregation in Liquid–Liquid Dispersions and Its Effect on Chemical Reactions. Author Index—Subject Index.

(A324) Volume 5, January 1965, about 325 pp., 100s.

development of the field or fields concerned. In view of the amount of information in each, and its importance, their prices are not excessive. W. R. MOORE

MASS SPECTRA OF ORGANIC COMPOUNDS

Interpretation of Mass Spectra of Organic Compounds

By Dr. Herbert Budzikiewicz, Prof. Carl Djerassi and Dr. Dudley H. Williams. Pp. xiii+271. (San Francisco: Holden-Day, Inc., 1964.) 8.75 dollars.

ALL laboratories of reasonably advanced organic chemistry now have equipment for the determination of ultra-violet and infra-red spectra and many have nuclear magnetic resonance spectrometers, the cost of the machine and its subsequent maintenance being, of course, the limiting factor. Comparatively few laboratories in Britain have modern mass spectrometers, although the number of laboratories so equipped will certainly increase as fast as funds permit. The mass spectrometer has many uses, but its prime use to the organic chemist is the information regarding chemical structure which it so readily and effectively supplies: this use was first appreciated and applied on any considerable scale by petroleum chemists, but the appreciation is now widely increasing.

It is noteworthy that books on modern mass spectrometry, cited by the authors of *Interpretation of Mass Spectra of Organic Compounds*, number only seven, the first being Dr. J. H. Beynon's *Mass Spectrometry and its Applications to Organic Chemistry*, which appeared in 1960 and which the authors of the present book justly describe as a classic. Prof. Djerassi and his colleagues consider that the many facets of mass spectrometry dealt with in these books, such as instrumentation, sample handling, free radicals and ionization potentials, analytical applications, etc., need not be repeated in the present volume, which deals almost exclusively with the determination of organic structure, and with the spectral fragmentation of organic compounds, which is, of course, an intimate part of the structure elucidation. Aliphatic hydrocarbons are not included, because they are dealt with adequately in the earlier books and are not of general interest to 'structural' organic chemists.

The book considers first the simple and common functional groups, such as the carbonyl, hydroxyl and amino functions, and discusses the fragmentation processes initiated by them on electron impact. The generalizations so obtained are then illustrated by their application to the tropane alkaloids, which have three such groups attached to a small alicyclic framework. Other classes of comparatively simple organic molecules are then considered. A second volume will later deal with more complex polycyclic compounds, particularly those of natural occurrence.

It is also noteworthy that much of the material in the present volume has been published very recently or is still unpublished, and the book contains therefore the latest relevant results obtained in Prof. Djerassi's very vigorous school of research at Stanford.

In a preliminary "Note to the Reader", the authors have attempted "as precise a definition as possible of the different bond fissions and transfer reactions", and they make some refreshingly direct statements. "Standard organic chemical concepts . . . are so readily applicable to the interpretation of mass spectrometric fragmentation processes that a certain sloppiness in symbolism has crept into most of the recent literature." Then after a common example of mechanism, they add that this representation "implies the shift of a proton, which very probably does not bear any resemblance to reality". This 'sloppiness in symbolism' (being, of course, the outward expression of an inner sloppiness of thought) is common in many branches of organic chemistry, and it is heartening to know that the authors will have none of it.

This volume can be strongly recommended to chemists as a clear yet thorough introduction to this branch of mass spectrometry. F. G. MANN

GAS KINETICS

Experimental Methods in Gas Reactions

Second edition. By Sir Harry Melville and B. G. Gowenlock. Pp. viii+464. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1964.) 84*s*.

THE original edition of this book achieved a unique position among research workers in Britain as a source of information on practical experimental methods in gas kinetics that was often difficult to find. Much of its success was undoubtedly due to the exceptional experimental ability of its two authors, whose personality and outlook pervade the whole text.

To revise such a personal work requires considerable courage even when done by the original authors, as the impact of the experimental scientist is usually one of the first casualties in the war against time. The second edition has, however, been revised by a newcomer, admittedly under the guidance of Sir Harry Melville, but unfortunately he has left the manostat and explosion vessel a fair way behind. Perhaps inevitably the book loses something of its flavour, and the somewhat untidy bittiness of its approach, which seemed an essential part of the character of the old volume, now, accentuated by the process of selection and addition necessary to include contemporary material, tempts one to suggest that it might have been better to start afresh.

As the preface to the second edition points out, "Farkas and Melville" has been out of print since 1946 and many of the younger generation of experimentalists may well be not very familiar with it. (I was a little disconcerted to find that in our own library both copies have now been relegated to the reserve stock dungeons.) For this reason perhaps it is only fair to comment on the present edition on its own merits.

Following a useful introductory chapter on the kinetic theory of gases, a wide variety of practical apparatus and methods for the measurement and control of pressure and temperature are considered. The simple feed-back circuit for the constant temperature operation of Pirani gauges on p. 90 seems a happy intrusion into the vacuum field from high-speed anemometer practice and might well be extended to provide fast response katharometers for gas chromatography. The acoustic pump mentioned on p. 53 deserves more attention than it has received. There are some areas where the treatment given is scarcely adequate to do anything useful, such as the very brief discussion of thermistors, but a good range of references is provided. Occasionally, important omissions are obvious as, for example, in the gas control section where the use of critical flow orifices for flow control (for small flows watch bearings are very suitable) is not mentioned.

The chapter on preparation of gases and volatile compounds is excellent and contains a wealth of material which it would be quite laborious to find from other sources. However, in the next chapter, in spite of the authors' comment in the preface, the emphasis on the older methods of gas analysis at the expense of gas chromatography seems incongruous in the light of the fact that the latter has displaced almost every other method. Although a useful survey of most aspects of this important method is given, the treatment is so compressed that it can be misleading. For example, the flame thermocouple detector, which even R. P. W. Scott would recognize as obsolescent, is given undue emphasis, while the difficulties of achieving high sensitivity for permanent gases using ionization methods are not mentioned.

The two final chapters deal with photochemical techniques and experimental methods for investigating gas reactions. The former includes a good description of Norrish's flash photolysis apparatus, but undoubtedly the latter is the most valuable in the book. High-pressure reaction apparatus, static and flow methods, explosive reactions and heterogeneous catalytic systems are all covered well from a practical point of view and will amply repay reading before starting an experimental programme in these fields.

The general presentation of the volume is very similar to the original edition, but the collection of references to the end of each chapter is a significant improvement. A useful bibliography of more specialized texts is included for each chapter as an appendix. D. H. Desty

SOME REFRACTORY METALS

The Science and Technology of Tungsten, Tantalum, Molybdenum, Niobium and Their Alloys

Edited by N. E. Promisel. (Based on an AGARD Conference on Refractory Metals held at Oslo University Centre, Oslo-Blindern, Norway, 23–26 June 1963. AGARDograph No. 82.) Pp. xiii+588. (London and New York: Pergamon Press, 1964.) 140*s*. net.

THE Science and Technology of Tungsten . . . , edited by N. E. Promisel, an acknowledged authority on refractory metals, is a comprehensive version of papers and discussion presented at the conference organized by the Advisory Group on Aeronautical Research and Development on "Refractory Metals" in Oslo during June 1963.

The book is divided into seven sections. The first consists of three short introductory papers which set out concisely the present achievements and long-term objectives of refractory metals technology. Section 2 deals with the physical metallurgy of alloys and, of the four papers in this group, two are devoted to the important aspects of interstitial solutes and their influence on physical and mechanical properties. The emphasis is placed on theoretical rather than on practical considerations. Section 3, entitled "Properties and Engineering Application", follows naturally, and all five papers contain valuable data in respect of the interpretation of physical and thermochemical properties in terms of engineering performance and fabrication. Of special interest is a paper by C. A. Verbraak on the effects of high-energy rate-forming on properties.

Section 4, "Deterioration and Protection", is the longest in the book (140 pages), and it is encouraging to note that a real attempt to cope with the fundamental aspects of oxidation and protection is evident in all four papers and two reports which form this group. A great deal of *ad hoc* experimental work has been a feature of past contributions in this field, and the uniformly clear presentation of facts and interpretation of results is a refreshing novelty. Oxidation phenomena and gas/metal interactions are discussed respectively by Kofstad and by Speiser and St. Pierre. The paper by Di Stefano and Hoffman on corrosion in refractory metal–alkali metal systems underlines the growing importance of this subject for heat-exchange in advanced nuclear reactors. The last papers deal specifically with protective coatings and present a comprehensive up-to-date account of the substantial progress made in this field during the past few years.

The important aspects of analysis and testing are covered in Section 5. It is clear from the papers presented and from the rapporteur's statement that a great deal more work is needed for arriving at standardized techniques of analysis. The need for standardization in testing is also emphasized, and some valuable practical recommendations are made in the concluding statement.

The remainder of the book, Sections 6 and 7, deal respectively with primary and secondary fabrication. The papers concerned with flat rolling and forging review modern trends in primary fabrication although no major new development is reported. Much the same state of affairs is reflected in the four papers on machining, flow-turning, forming and joining.

Taken as a whole, the book is undoubtedly a valuable source of information for all workers in the field of refractory metals. L. W. Derry

STRUCTURE AND PROPERTIES OF UNSATURATED POLYESTER RESINS

Unsaturated Polyesters

Structure and Properties. By Herman V. Boenig. Pp. x+222. (Amsterdam, London and New York: Elsevier Publishing Company, 1964.) 55*s*.

TWENTY years have elapsed since the first commercial application of unsaturated polyester resins. In those twenty years much has been written about these resins, but so little about their chemistry and so much about their applications, that despite its apparently late appearance, Dr. H. V. Boenig's book, *Unsaturated Polyesters: Structure and Properties*, is welcome because of its emphasis on their chemistry.

Probably the main reason why earlier publications have concentrated on applications of unsaturated polyester resins, rather than their chemistry, is because they were the first thermo-setting resins which could be moulded under very low pressures. New methods could therefore be adopted for using them, and so authors, anxious that their new resins should be used as widely as possible, concentrated on making known how they could be used to produce such varied articles as radomes, boat hulls, car bodies and swimming pools. Often the chemistry of making these resins was dealt with in a single brief chapter. Dr. Boenig's book helps restore the balance.

After reviewing briefly the historical development of unsaturated polyesters, the author devotes three short chapters to their basic structure, how they cross-link, and what they are like when they are cross-linked. He then gets down to his main theme of relating structure to properties both before and after cross-linking or hardening.

This is dealt with in four much longer chapters, covering the effect on properties of variations in: (*a*) the additives, like promoters, inhibitors and retarders, made to the basic unsaturated polyester resins; (*b*) the polyester backbone; (*c*) the unsaturated monomers; (*d*) the means by which flame retardance can be achieved. The effect of these structural variations on such properties as the melting-point of the base resins, and the mechanical strength, hardness and heat-resistance of the cured resins, are described in some detail but, oddly, electrical properties are almost ignored. The final chapter of the book is devoted to polyester coating compositions, the emphasis being placed on means of preventing cure inhibition either by structural variations in the unsaturated polyester backbone or by the use of additives. The book is therefore more for those who make unsaturated polyester resins than for those who use them.

There are omissions and imperfections. On the subject of heat-resistance, data for exposures for periods of longer than 5 h at elevated temperatures are available and could with advantage have been included. There is barely a mention of the use of brominated acids or monomers to obtain flame retardance. It is not always clear whether the author is referring to saturated or unsaturated polyesters even though the title of the book seems to limit it to the unsaturated type. In other cases maleates and fumarates are referred to, when it is not clear whether the particular resin was made from maleic anhydride or fumaric acid, or whether the fumarate/maleate content

of the resin had been determined. There are misprints and the contents of Table 7, p. 45, are not what one expects from the title.

Despite the minor faults, the book does well in bringing together much scattered information and relating in a constructive way structure and performance, with useful references to the literature. Chemists working with polyester resins will be grateful to Dr. Boenig for his efforts. The book is well printed and presented, and is good value at 55*s*.

R. N. Lewis

FROM RADICALS TO RADIATION

A History of Chemistry

Vol. 4. By Prof. J. R. Partington. Pp. xxi+1007. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1964.) 210*s*. net.

FEW individuals in recent years have dared to undertake those massive works of learning that were borne so lightly, it seems, in the nineteenth century; and they have been scarce indeed in the history of science. In the United States, Sarton's *Introduction* and Thorndike's eight volumes, both the work of professionals, are clearly worthy members of this class. In Britain, this land of amateurs, we have the magnificent work on Chinese science by Dr. Joseph Needham which is still in progress, and now this massive history of chemistry by the emeritus professor of chemistry in the University of London, of which Volume 4 is the final volume in order and the third to be published. Prof. Partington has long prepared himself for his arduous task: apart from his own investigations in chemistry, his long experience of teaching at Queen Mary College, and his many scientific publications, he has given more than thirty years to the history of his science. For example, his *Short History of Chemistry* (1937) already contains a preliminary sketch of the present volume; and those who are acquainted with Prof. Partington in Cambridge (where he has lived since the War) know him as an untiring reader in the University Library.

This survey of the development of chemistry from the beginning of the nineteenth century into the nuclear age could only be the product of immense industry, since it is based on an exhaustive search through the scientific journals (the list of those cited fills eight and a half large pages). The indexes include more than 2,000 personal names. Moreover, in the final volume of this great enterprise, not only is the amount of chemical work covered far greater than that surveyed in the first three put together, but also the material is that which has been least collected and assessed by earlier historians. Indeed, nineteenth-century chemistry is virtually a virgin field, the fertile soil of which Prof. Partington has turned over for the first time. No one else could have proceeded with such patience, learning and judgement.

The chief feature of the structure of Volume 4 of *A History of Chemistry* is the assessment of the work of individual chemists, and of their influence. Thus, in Part 1 (565 pp.), all but three of the seventeen chapter-titles are personal names. Part 2 (physical chemistry, 178 pp.) is arranged by topics—affinity, thermodynamics, electro-chemistry, and so on; while Parts 3 and 4 (later organic and inorganic chemistry, 177 pp.) are again dominated by individuals. The last short section, on radiation and atomic structure, returns to topics.

Accordingly, though Prof. Partington has devoted roughly equal amounts of space to each half of his subject (before and after 1860), effectively the chemists of the early nineteenth century are treated in greater detail. This period was ruled by the triumvirate of Berzelius, Dumas and Liebig—often at odds with each other, but united in cutting down rivals to themselves. Judging by the length of the principal section concerned with him, Davy (41 pp.) emerges rather strangely as the most important chemist of the whole period, followed by Berzelius (35 pp.), Faraday (29 pp.) and Liebig (25 pp.). In the later nineteenth century Kekulé and Kolbe receive the limelight, though many other chemists and other types of chemistry are generously treated.

Here is a rich mine of information. But this is not an easy book: it has no continuous argument, no historical point of view, and very little time for the outsider. Largely it is history by a chemist, for chemists, setting out exactly and in detail who did what when. There is an explanation of the coining of the name 'aldehyde' (from '*alc*ohol *dehyd*rogenatus', p. 357) but none of the German predominance in chemistry. Occasionally the author takes note of a controversial question: the significance of Wöhler's synthesis of urea (1828), for example. This was claimed as an epoch-making discovery even in its own time, as a breach in the barrier between the organic and the inorganic, or in Liebig's words, "the first beginning of a truly scientific organic chemistry". Later critics have been less impressed, pointing out that Wöhler's reagents were actually derived from organic sources. Prof. Partington retorts that potassium cyanate had been prepared by Scheele and ammonia by Priestley from inorganic materials, so that Wöhler's was a true synthesis. (However, the fact remains that whatever Wöhler accomplished, he did not demonstrate the identity of a synthetic urea derived from inorganic reagents with the physiological product.) These excursions into debate are, like the dry human and personal reminiscences of the author, permitted all too rarely to penetrate into his pages.

It is now roughly a century since the chemical histories of Kopp and Hoefer appeared. They had a long, honourable innings, but their time for retirement had come, and Prof. Partington has given us a new work that is much fuller, much more accurate and up to date. His history, no doubt, will endure at least as long as theirs.

A. R. Hall

GENESIS OF HYDROTHERMAL ORE DEPOSITS

Complexing and Hydrothermal Ore Deposition

By Harold C. Helgeson. (International Series of Monographs on Earth Sciences, Vol. 17.) Pp. xiv+128. (London and New York: Pergamon Press, 1964.) 60*s*. net.

AMONG the problems confronting the geologist, none is more difficult or complex than that of the genesis of the hydrothermal ore deposits. That a close relationship exists between many occurrences of metalliferous minerals and of igneous rocks was recognized by Élie de Baumont in 1847, but the subsequent development of this branch of science has seen much controversy and fluctuation of opinion.

The mainstream of thought has continued to uphold the postulate that hot water is the vehicle for the carriage of metals such as copper, lead, zinc, silver and mercury into fissure veins. Thus, Lindgren[1] states, "the vein-forming solutions were probably liquid from the start, and often highly concentrated. They contained water as the principal constituent and were at all times in a mobile, non-viscous condition. In their constitution colloidal dispersions entered prominently". Bateman[2] held that "the thermal springs that transport metals at the [Earth's] surface are alkaline, and some of the metals have been carried as sulphides. Consequently, it is inferred that the ore-forming fluids also were alkaline".

Experimental investigations of phase and other relationships in relatively simple hydrated silicate systems, at temperatures beyond that of the critical point of water, have been made during the past several decades. It is only more recently that significant progress has been

made in the systematic application of the theoretical and practical methods of physical chemistry to equilibrium in aqueo-mineral systems at low temperatures. The position reached by 1960 was reviewed by Garrels[3].

In *Complexing and Hydrothermal Ore Deposition*, Dr. Helgeson discusses the internal structure of electrolyte solutions at temperatures lying, for the greater part, in the range 25°–400° C. He presents the results, obtained by the use of a digital computer, relating to the equilibria of complex formation in multicomponent systems, and is at pains to make clear that present thermodynamic knowledge falls far short of that required for the construction of a complete theory of hydrothermal ore deposition.

Helgeson, nevertheless, makes positive claims. He believes that his figures demonstrate, at least in the case of lead sulphide (galena), that the metal is carried as chloride complexes in an aqueous fluid containing alkali chlorides, and that the *p*H of such solutions is near to neutral or somewhat acid. This view will certainly draw the critical interest of the experimentalists.

All geochemists will welcome this contribution, though recognizing it as a progress report. Few geologists will be adequately prepared for the exposition of the principles on which the work is founded. It is much to be regretted that the introductory section of the book could not have been written with this readership more in mind.

The usefulness of a possible second edition would be greatly enhanced by an account of experimental methods used in the investigation of aqueous inorganic solutions at high temperatures; by a fuller discussion of hot-spring and of wall-rock analyses; by a review of relevant geothermometric observations based on isotopic and trace element distributions; by descriptions of chosen examples of metalliferous mineral deposits; and a discussion of the possible ultimate sources of the metals carried by hydrothermal complexing and also of the alkali chlorides necessary for this. Consideration could also be given to the genesis of the arsenides, sulph-arsenides and oxides frequently found in high-temperature hydrothermal (hypothermal) veins.

The price, 60*s*., is very high for the size of the book.

ANAXAGORAS REVISITED

Anaxagoras and the Birth of Physics

By Daniel E. Gershenson and Daniel A. Greenberg. (A History of Physics: Its Concepts, Methods, and Theories. Series I: Natural Philosophy Before Aristotle.) Pp. xxv+538. (New York and London: Blaisdell Publishing Company, a Division of Ginn and Company, 1964.) 10 dollars.

Anaxagoras and the Birth of Scientific Method

By Daniel E. Gershenson and Daniel A. Greenberg. Pp. xv+63. (New York and London: Blaisdell Publishing Company, a Division of Ginn and Company, 1964.) 1.45 dollars.

THERE are, apparently inevitably, recurring occasions in the history of scholarship when individuals feel compelled to revolutionize the study of some subject by rejecting traditional views in favour of a totally new approach. So, in fact, do new ideas penetrate the older disciplines. But a contemporary predicts at his peril whether any particular example of such an approach should be praised as useful innovation or damned as blatant impudence.

The authors of *Anaxagoras and the Birth of Physics* and *Anaxagoras and the Birth of Scientific Method*—two young Jewish-American scholars, one a classicist and the other a theoretical physicist—are professedly attempting two root and branch revolutions at the same time. They have planned a necessarily vast work, "A History of Physics: Its Concepts, Methods, and Theories", which is to be "a comprehensive history . . . intended for laymen as well as professional scientists", to be centred about great figures of the past. The authors do not say in what way they find the history of science as now practised deficient, nor why they feel the need to begin *de novo*; indeed, they do not use the phrase 'history of science' nor indicate that they are not the first to study physical concepts in historical perspective. In their review of the literature of Anaxagoras they give pretty short shrift to all the historians (half a dozen or so) whom they mention; but in fairness it must be said that they discuss only what relates to Anaxagoras, to whom historians of science have not, in general, devoted great space.

The authors have very properly begun at the beginning and *Anaxagoras and the Birth of Physics* is a part of Series 1 of their *History of Physics*, "Natural Philosophy before Aristotle" (*Anaxagoras and the Birth of Scientific Method* is Part 1 of *Anaxagoras and the Birth of Physics*, shorn of the more learned footnotes). This reveals the second revolution projected by Drs. Gershenson and Greenberg: an almost total revision of classical scholarship. They reject the work of Diels outright on two grounds: it is not chronologically arranged, and he cites as quotations statements not in Ionic dialect. The first comment is fair enough, and the authors have done a service in providing as Part 2 in their own translations and in chronological order all the statements they could find relating to Anaxagoras, from Plato in the fourth century B.C. to Simplicius in the sixth century A.D. The second criticism seems irrelevant: surely we cannot expect any ancient source to have survived intact, unaltered as to form by copyists and commentators who inevitably 'modernized' even their quotations.

The three parts of the longer work consist, first, of a brief appraisal of Anaxagoras's life and thought; secondly (the bulk of the work), the sources of Anaxagoras's ideas; and thirdly, a tendentious and detailed examination of ancient and modern traditions about Anaxagoras; of the authors cited, Drs. Gershenson and Greenberg place greatest reliance, not unreasonably, on Aristotle. This last part is learned, dogmatic, often characterized by a slightly naïve logic, and vaguely rabbinic in method. It must be for classicists to appraise the reliability of the evidence; they will certainly dislike the practice throughout the book of transliterating Greek—surely a foolish practice of service only to the printer.

The first part of the longer work (and the whole of the shorter) will appeal most to scientists. It is clearly and simply written, in a confident manner; the authors have made up their minds firmly on all relevant points and indulge in none of the doubts or hesitations which laymen find so irritating in the work of specialist scholars. The authors might have helped the reader by explaining the grounds for their prefatory sentence, "Anaxagoras was the first thinker of repute who was a scientist in the sense in which we use the word to-day". For while it is true that Anaxagoras was the first natural philosopher to live and teach in Athens, he had eminent predecessors in the Western Greek world, many of whose concepts, especially those relating to astronomy and cosmology, were more advanced than his. The authors appear to base their predilection for Anaxagoras as the first modern physicist on his theory of matter, which they find satisfyingly up to date. Basing their views as they do primarily on what Aristotle had to say about Anaxagoras enables them to fit Anaxagoras snugly into the atomic, logical, realistic, unified and dynamic tradition of physics. What one misses is the placing of Anaxagoras in the content of Greek thought and in the historical pattern of the development of natural philosophy.

Marie Boas Hall

COAL GAS TECHNIQUES

The Underground Gasification of Coal

(A Report on the work done in Great Britain, prepared for the National Coal Board by Sir Alexander Gibb and Partners, Consulting Engineers.) Pp. xiii + 205. (London: Sir Isaac Pitman and Sons, Ltd., 1964.) 70*s*. net.

THE underground gasification of coal is a subject that must appeal to the imagination of many interested in the production of power as a possible major development in the winning of coal, not actually of the coal itself, but of the energy that the coal is capable of providing. At first sight any measures that hold out the promise of successful techniques with such an objective are to be envisaged as being well worth while, and certainly, in this technological age, as being in the forefront of attractive projects.

The possibility of gasifying coal *in situ* underground has been known for nearly a century, for it was foreseen by Sir William Siemens in a paper to the Chemical Society in 1868, but the first practical attempt at underground gasification was made by Sir William Ramsay, who conducted small-scale experiments in Durham in 1914. The famous Russian chemist Mendeleef is credited with being the father of the idea in Russia about 1888. Large-scale experiments were conducted in the U.S.S.R. during the 1930's, and between 1946 and 1961 intensive efforts had led to the process being brought into commercial use. Several research institutes in the U.S.S.R. are carrying out applied research in the specific problems of underground gasification, and attention is being directed to engineering development and design in connexion with installations either under construction or projected. In the largest of these, at Kholmogorsk in Kuzbass, plans are in hand to use for gas a bituminous highly volatile coal, to generate power to the extent of 1,200 MW.

The present volume constitutes a report of the work done in Great Britain in this project, under the authorship of the consulting engineers, Sir Alexander Gibb and Partners, who carried out the engineering and development work for the Board, when in 1956 they took over the development work, which had been conducted since 1949 under the ægis of the Ministry of Fuel and Power.

The process of underground gasification of coal has the favourable feature that it may be applicable to quite substantial areas of inferior coal never likely to be worked by conventional techniques. The Report sets forth in detail a story that has now come to an end because the project is not now considered sufficiently promising to warrant any further expenditure. There are now more profitable lines of research opening up and they require the available funds. The publication of the Report will ensure that the record of the considerable work done in Britain should be available for those who are interested.

The basic conception of the underground gasification process is to sink two vertical boreholes from ground-level to the coal seam, and to form a link or channel in the seam to connect the two points where the boreholes enter the coal seam. Compressed air is admitted to one borehole, the seam is ignited, and the products of combustion, including some inflammable gas, are emitted at the other borehole. In the early stages this link between the boreholes was established by drilling along the seam from one base to the other.

Combustible gas is made in conventional plant by a number of different methods. In underground gasification these occur in combination and are subject to modifications arising from the special conditions of the process. In point of fact these conditions give rise to a system of considerable complexity. Combustible gaseous fuel is normally made from coal by means of oxygen by a process of partial combustion. The principal reactive elements in coal are carbon and hydrogen, and the products contain carbon monoxide, hydrogen, certain hydrocarbons, carbon dioxide and steam. The proportion of combustible gas in the products of the reaction depends on the degree to which the action of the oxygen has been taken, and the presence of hydrocarbons depends on the amount of carbonization that has accompanied the gasification process. Ideally, the active oxygen in the air should traverse a series of channels in the coal mass, thereby ensuring that there is always an excess of solid carbonaceous matter to react with any residual oxygen in the product gas. The pattern of flow of the gases and the character of the successive reactions, depending as they do on temperature, concentration and rate of flow of the gasifying stream, may become complicated. Yet everything must depend on the manner of breakdown of the solid coal in the seam. How may this be controlled from the surface? Many pages of this volume are taken up with descriptions of the various ingenious devices that have been applied in a solid bed of coal to produce the circumstances that are so readily obtained in a gas producer by suitable sizing of the fuel to form a permeable bed. Ignition has to be effected, and there follows the control of the many factors that determine the course of the process. The pattern of gasification has to be spread over a considerable area. The problem of drilling underground in a satisfactory manner and direction for considerable distances required much experimental effort and extensive practical trial, for coal seams have their wandering habits.

In many trials the quality of the gas, as determined by gross calorific value, varied between 60 and 115 B.Th.U. per standard cubic foot; this is scarcely a range of values to enthuse the prospective user. Most of the trials were carried out at Newman Spinney, near Chesterfield, and after 1950 at Bayton, near Bewdley, in Worcestershire.

An interesting chapter is devoted to the description of the combined performance of the gasification unit in the Sough seam at Newman Spinney together with an experimental power station, constructed on site by the Central Electricity Generating Board. Approximately 3½ million units of electricity were generated, 20 per cent of the total gas supplied being consumed, being 240 million cubic feet of calorific value 59 B.Th.U. per cubic foot. In practice the gas seldom reached the quality on which the design of the boiler was based. Oil fuel had to be used to stop the flame failure device coming into action unnecessarily. The trial was nevertheless regarded as satisfactory. From the data obtained in these trials which cost the National Coal Board £1·6 million it has been possible, following the Russian-type layouts of working from the surface, to derive cost estimates that make underground gasification look quite attractive. Nevertheless it seems that success is unattainable in the normal conception of an experimental-sized plant, and could only be achieved by working on a large scale with correspondingly high investment cost and risk. Even then there are disadvantages and imponderables inherent in the process, from which a direct and reliable economic estimate cannot be derived. It may be in countries outside Britain that there are seams thick enough to make the process really attractive.

To turn to the more rewarding aspects of the venture, many special techniques and apparatus were developed. This applies in particular to the drilling rigs, which had to be used for deflexion drilling, and were equally adaptable to accurate straight drilling in the horizontal direction. Scintillation counters had to be used for detecting radiation intensity in a vertical borehole. The experiences gained threw out suggestions for future progress in other spheres. The ignition devices were many and varied, such as high-tension sparking plugs to ignite the gas stream, chemical fluxes, low-tension electric cooker elements embedded in a wire basket of coal slack. A propane-fed ignition rig in connexion with an electric heater element formed a reliable combination.

Attention is given to the more fortunate development in the U.S.S.R., where the location, character, availability

and dimensions of the seams offered a more favourable set of circumstances for commercial development. Nevertheless, in those cases considerable pioneer work had to be undertaken before any feasible projects emerged.

The book is well produced. It is clearly printed and well illustrated. It would indeed be a boon to the scientific world if all projects of equal merit could be so well reported.

R. J. SARJANT

MATHEMATICS FOR PHYSICISTS

Mathematical Methods of Physics

By Dr. Jon Mathews and Dr. R. L. Walker. Pp. x+475. (New York and Amsterdam: W. A. Benjamin, Inc., 1964.) 13.75 dollars.

PART of the equipment of a modern physicist is a sound knowledge of a wide variety of techniques and theories in pure mathematics. If his interest is in theoretical physics he may have to be thoroughly expert in the theory of functions of several complex variables, Lie groups and functional analysis; even if his own work is primarily in the experimental field he still needs to have a 'reading' knowledge of a wide variety of mathematical methods if only to be able to read the theoretical papers relating to the subject of his own researches. This requirement places a heavy responsibility on teachers of mathematics to provide courses which are at the same time interesting, comprehensible and valuable to undergraduate and graduate students of physics. To anyone charged with such a task the present book will be of interest, since it shows one possible way of proceeding in the sense that within the space of 458 pages (sixteen chapters and an appendix) it attempts to present an account of the major branches of mathematics which are of interest to physicists. Since corresponding to each of the chapters but one there is at least one well-known monograph of roughly the same size as the present volume, it is obvious that the various topics discussed cannot be treated in a completely satisfactory fashion.

The book consists of the following chapters: (1) ordinary differential equations—a brief review but including a fairly full account of the Wentzel–Brillouin–Kramers method; (2) infinite series; (3) evaluation of integrals; (4) integral transforms—with an account of Fourier series and the Dirac delta function; (5) further applications of the theory of functions of a complex variable (conformal transformations and dispersion relations); (6) vectors and matrixes including (in 25 pages!) the theory of linear spaces and spaces of infinite dimensionality; (7) special functions (Legendre, Bessel, Hermite, Laguerre, hypergeometric, confluent hypergeometric and elliptic); (8) partial differential equations—mainly characteristics, separation of variables, use of integral transforms, Wiener-Hopf method; (9) eigenfunctions, eigenvaluos and Green's functions; (10) perturbation theory; (11) integral equations—with applications to dispersion theory; (12) calculus of variations—and its connexion with eigenvalue problems; (13) numerical methods (interpolation, numerical integration, numerical solution of differential equation, the summation of series; (14) statistics and probability; (15) tensor analysis and differential geometry, made up of sections on cartesian tensors in three-dimensional space, curves in three-dimensional space (the Frenet–Serret formulæ) and general tensor analysis; (16) groups and group representations consisting of sections on groups, group representations and characters, infinite groups. Finally there is an appendix of some properties of functions of a complex variable—provided as a review for most readers but as a study guide for readers unfamiliar with the subject already.

Both Dr. Mathews and Dr. Walker are physicists, and they have constructed the book from notes which they used in giving a course in mathematical methods in physics to first-year physics graduate students and senior physics undergraduates at the Californian Institute of Technology. This is reflected in the finished product. The choice of mathematical topics is dictated by their established usefulness in physics, the material is illustrated by examples chosen from mechanics, electricity and magnetism, and wave mechanics, and the level of rigour is that at present accepted in theoretical physics.

In a volume of this size covering so very many topics it is to be expected that most of the topics are treated in much the same way as they would be in an encyclopædia such as the *Encyclopædia Britannica* or the Pergamon Press *Encyclopædic Dictionary of Physics*; but it should be emphasized that they are first-rate articles. The basic definitions and points of theory are clearly stated, the relevance to physics brought out and illustrative examples provided; there are also problems provided by means of which the reader can test his comprehension of the text (but no answers are provided).

The authors are to be complimented in having covered so much material so well in a limited space and particularly in having shown (as so many books in this area fail to do) that there are algebraic methods valuable in physics as well as analytical ones. The nature of undergraduate and postgraduate courses in Britain is so different from the scheme set out in this book that it is unlikely to be of much value to students attending such courses—except as a valuable reference book. It should, however, be studied by university teachers conducting such courses and by scientists and students who have to study the subject on their own, for it will provide them with a clear statement of the fundamentals of most of the topics they are likely to be interested in and guidance towards a deeper study.

I. N. SNEDDON

MATHEMATICS OF RUSSIAN TECHNOLOGY

A Course of Higher Mathematics

By V. I. Smirnov. Vol. 1: Elementary Calculus. Pp. xiii+546. Vol. 2: Advanced Calculus. Pp. xiv+632. Translated by D. E. Brown. Translation edited by I. N. Sneddon. (International Series of Monographs in Pure and Applied Mathematics, Vols. 57 and 58.) (London and New York: Pergamon Press, 1964.) 90*s*. net each volume.

THESE are the first two of a set of five volumes, which cover the topics of mathematical analysis likely to be of use to the engineer and physicist, from the elements of calculus up to partial differential equations, integral equations, set theory, Stieltjes and Lebesgue integrals, normed spaces, and Hilbert space.

The book first appeared in 1924, a collaboration between Tamarkin and Smirnov; after the second edition, Smirnov's name appeared alone. The present version is a translation from the sixteenth Russian edition. Smirnov, though perhaps less well known in the West than Tamarkin, has had a distinguished career, with researches of importance in both pure and applied mathematics, as well as a wide teaching experience. This broad outlook prompted him to construct a comprehensive course of higher mathematics which should have an immediate appeal to the top-class engineer and physicist, without ignoring the demand of the pure mathematician for rigorous exposition.

Volumes 1 and 2 deal with the classical results of the infinitesimal calculus, including vector analysis, differential geometry, Fourier series, and the simpler partial differential equations of mathematical physics. In such a well-gleaned field, no great originality is to be expected, and the main interest lies in seeing how the author has coped with the two-fold demand for physical applicability and for mathematical rigour. The means adopted is the division of the text into two type-founts; in the large

type, we have the intuitive and sometimes informal introduction of calculus concepts, with a variety of physical applications as, for example, bending of beams, stream-lines, Maxwell's equations.

Where a strict account would require difficult theorems of pure mathematics, the results are stated, and we are referred to the relevant small-type sections for proofs, as well as for discussions of such rather more recondite topics as uniform convergence, basic theory of integration, and so on. In this way, by sticking to the large-type paragraphs, progress up to matters such as vector field theory, Green's function, Dirichlet's problem, can be rapid without being entirely superficial. The informal explanations are usually adequate, though there are places where attempts to convey the essence of an important technical concept in words rather than in symbols are not wholly successful; for example, from the statements about limits (1, p. 45) it would be possible to infer that $\sin(\pi/x)$ tends to zero as x tends to zero. These are dangers which beset any attempt to analyse in loose everyday language those concepts which demand extreme precision of definition. The first volume contains a good many exercises, chiefly of drill type, for the student; the second volume, regrettably perhaps, has none.

A treatise which is forty years old and has gone into a sixteenth edition must have solid merits, and must have exercised a substantial influence on the training of the present generation of Soviet scientists and on their splendid achievements. It will be of much interest to see how in the succeeding volumes the transition is made from concepts and techniques which go back to Cauchy, and even to Euler, to topics such as set theory and metric spaces which are essentially of this century. It will be in Volumes 3–5 that Western teachers are most likely to find methods of exposition worthy of close study and modes of presenting the tools of modern pure mathematics to the sometimes reluctant hands of the young technologist.

T. A. A. BROADBENT

CHEMICAL STRUCTURE OF THE UNIVERSE

Space Chemistry

By Dr. Paul W. Merrill. Pp. 166. (Ann Arbor: University of Michigan Press; London: Cresset Press, Ltd., 1963.) 5 dollars; 18*s*. net.

SPACE Chemistry, by the late Dr. Paul Merrill, is from the Ann Arbor Science Library, which also includes works on the Sun, the stars and the planet Earth. The author endeavours to present the vast field of astrochemistry in a form both compact and readily intelligible to the lay public. Very little scientific knowledge is assumed on the part of the reader, although some acquaintance with elementary physics would be of assistance.

The chapters form an orderly sequence, commencing with a review of the dual aspects of Nature, her uniformity and diversity, and continuing with an account of the history of stellar spectroscopy, a discussion of the properties of the chemical elements and molecules and their relationship to the physical structure of the Universe. The book concludes with a brief survey of the new techniques of rocket and satellite spectroscopy and describes a few of the observations made through these media. It is, perhaps, the first chapter that is the most controversial and it is hard to see how one can justify the use of such postulates as: "the uniformity of nature is God's greatest material gift to mankind" (p. 15), and: "the diversity of nature . . . is God's second material gift to mankind" (p. 17) in a scientific book directed towards a general audience. Surely, it is most dangerous to suggest that contemporary science is in a position to substantiate, or reject, such claims, or even to assume that it is its function to do so?

The historical survey is brief but informative and gently introduces the reader to the properties of light and the various types of spectra observed in Nature. In the following chapters, the components of the atom and individual elements and molecules of astrophysical importance are enumerated and described; but the definition of 'isotope' is delayed until the end of the book, and is then only included as a footnote. This is unfortunate, as the main text gives the impression that isotopes can exist only as stable forms of an element.

Only two chapters are devoted to the chemical composition of the Universe, and yet the author succeeds in conveying much information in this limited space. However, his concise style does lead to such questionable statements as: "it is now generally believed the numerous 'craters' on the moon are not of volcanic origin at all but were caused by the impact of large meteors" (p. 80). The agreement on this point is far from general, and it is misleading to imply that the question of the origin of the lunar craters has been settled. On p. 137 it is stated that the distant galaxies are receding from us, their velocities being deduced from shifts in their *H* and *K* lines; and yet no mention is given of the Doppler effect. This is an important omission.

The treatment of nuclear reactions and stellar evolution is simple and lucid. The sentence: ". . . in building still heavier elements, energy is subtracted rather than added, but the amount is relatively small and causes no appreciable cooling of the gases inside a star" presents too simplified a view of the situation. In the case of any particular star, account must be taken of its mass and the role of convection at the core, when deciding how important is the loss of energy through the most endothermic of these reactions.

The task of translating a highly specialized science into language acceptable to the general public is most difficult, and some loss of rigour is to be expected. Dr. Merrill has produced a book which should stimulate many to delve further into the ever-expanding realm of space chemistry.

J. A. DAWE

ASTRO-BIOLOGY

Life Sciences and Space Research II

A Session of the Fourth International Space Science Symposium. Edited by M. Florkin and A. Dollfus. Pp. viii + 440. (Amsterdam: North-Holland Publishing Company, 1964.) 50 guilders; 100*s*.; 14 dollars.

AMONG the many recent *mariages de convenance* between sciences hitherto rather shy of each other, the union of astronomy and biology to study life beyond the Earth may well be among the most enduring. This volume records one of the union's early offspring, the sessions on life sciences at the Warsaw Space Science Symposium in 1963.

The book begins with three review papers. The first, by S. I. Rasool and R. Jastrow, is a useful survey of what little is known about the atmospheres of Mars, Venus and Jupiter. The atmosphere of Mars is the best charted of the three, and it is interesting that although the surface pressure may be as low as 2 per cent of that on Earth, atmospheric pressure is greater on Mars than on Earth for heights above 60 km. The second review paper, by A. A. Imshenetsky, is entitled "Life and Space" and includes some valuable cautionary comments: for example, the author takes a sceptical look at the microbiological analysis of meteorites, and points out how little we know about micro-organisms in the upper atmosphere of the Earth itself. The third paper is a critical review of exobiology by C. Sagan. He remarks that although there is no generally accepted definition of life, the process of self-replication seems to be the critical event in the origin of life, and he

offers an illuminating discussion of the origin of life on Earth and its probable occurrence elsewhere.

The 41 specialized papers which occupy the remaining 400 pages of the book are divided into three groups, beginning with "Extraterrestrial Biology and Organic Chemistry". There are descriptions of 'Multivator', an automatic biochemical laboratory for seeking out life, for example, through detecting hydrolytic enzymes by fluorometry; and of 'Gulliver', which shoots out a sticky string to gather a sample of Martian soil and then examines it. M. H. Briggs and G. Mamikunian make a thorough report on the organic constituents of carbonaceous chondrites, and the possible contamination of these meteorites by terrestrial material. H. Yagoda examines the likely radiation at the surface of Mars, and concludes that the thin Martian atmosphere, far from being a shield, only intensifies the cosmic radiation. Several papers discuss whether terrestrial-type bacteria or other micro-organisms can survive on Mars, and conclude that they may well do so.

The next group of papers, mainly by Russian authors, discusses recent astronomical findings about the Moon and planets. V. D. Krotikov and V. S. Troitsky discuss the heat flow from the Moon's interior and conclude that the surface is porous, and has little dust, a finding confirmed in V. V. Sharonov's paper on the dust covers of the planets. Other subjects discussed include triangulation on the Moon, polarization of the thermal radio-emission of the Moon and planets, polarimetric lunar images, and lunar microrelief. O. N. Rzhiga gives the results of the 1962 radar observations of Venus, which indicated that the most likely rotation of Venus was retrograde with a period of about 300 days. Venus figures in several other papers, which deal with the microwave spectrum on the night side, radio observations, models of the ionosphere and the detection of water vapour. In a number of papers about Mars, the subjects covered include infra-red spectra, circulation in the atmosphere, brightness in the edge zone, polarimetric measurements and radar studies.

"Terrestrial Life in Space" is the title for the final and longest group of papers, which reflect the widespread concern among biologists about the debilitating effects of weightlessness: W. R. Adey discusses at length the effects of gravity on the functioning of the central nervous system; while the grave effects of cardiovascular deconditioning and changes in calcium metabolism are explained by D. E. Graveline and W. F. Neuman respectively. The latter remarks, a little gloomily perhaps, "For all we know of mice and men, when raised in space, they may assume a globular shape". It will apparently be vital to devise suitable exercises for spacemen—perhaps based on a pair of trampolines? Another crucial question-mark is over the effects of solitary confinement in an environment almost free of sensory stimuli, and further experiments on this topic are described by G. T. Hauty. His subjects, mainly military pilots who are said to have volunteered for the adventure, describe their hallucinations vividly. Like several other papers, this one has implications beyond the realms of spaceflight and is perhaps just as relevant to the study of medieval religious mystics. The other main topic in this section is the survival of micro-organisms in space and on other planets, and the best techniques for sterilization. The general impression is that spores are even tougher than was thought, and that, given a dust particle as shield, many a microbe could survive the worst rigours of solar radiation in space. Again there are wider implications here: if, as seems probable, the magnetosphere of Venus has an open tail, Venusian microbes (if any) will be escaping into the solar wind and some may be reaching the Earth.

The book is a handsome one, printed in pleasing type on good paper. All the papers are in English, mostly with Russian abstracts. Misprints are rather numerous, and the English in some of the translated papers is far from perfect. This has its compensations, however, for the language sometimes takes on an almost poetic fire, as when we learn that the "total heat flux out of the Moon's entrails" is $1{\cdot}6 \times 10^{19}$ cal/yr. The book records the latest results on space biology, and will be of interest not only to space scientists but also to those astronomers and biologists who do not intend always to remain earthbound.

D. G. King-Hele

PHYSICAL PROCESSES IN STARS

Stellar Interiors

By Prof. Donald H. Menzel, Prof. Prabhu Lal Bhatnagar and Hari K. Sen. (The International Astrophysics Series, Vol. 6.) Pp. xiii+317. (London: Chapman and Hall, Ltd., 1963.) 65*s*. net.

THERE have been two very good books published in recent years on different aspects of the theory of stellar interiors: *Structure and Evolution of the Stars* (Princeton University Press, 1958), by M. Schwarzschild, and *Physical Processes in Stellar Interiors* (Israel Program for Scientific Translations, 1962), by D. A. Frank-Kamenetskii. Together with Chandrasekhar's classic, *An Introduction to the Study of Stellar Structure* (Dover Publications, 1957), they form an excellent survey of the subject. A new book has to be very good if it is to do more than merely supplement these, although there are two suitable fields for further books: an introductory book for newcomers to the field, stressing the basic physical processes rather than the results of recent calculations, and monographs on specialized advanced topics.

Menzel, Bhatnagar and Sen have attempted to fill the former gap. Thus, more than half their book is concerned with the basic physics of stellar interiors and, although some space is devoted to discussion of detailed calculations, they have not attempted to keep up to date with recent advances in the field of stellar evolution; thus, most of their references to 'recent work' are to papers which appeared in the years 1954–57 and there are only a few references of later date than Schwarzschild's book.

In the first part of *Stellar Interiors* there are discussions of quantum statistics and degenerate matter, the equation of state of stellar material, radiative transfer and the laws of opacity and energy generation. Among topics which receive more attention than usual are the calculation of the mean molecular weight of a partially ionized gas and the related problem of its ratio of specific heats. The latter is of particular importance in the theory of stellar instability because the low value of the ratio of specific heats in a region of rapidly changing ionizations may lead to instability. Menzel *et al.* also give a detailed discussion of the conductive opacity of degenerate material and in their discussion of radiative opacity they direct attention to an error in the theory of electron scattering opacity which has been common for twenty-five years.

There are some minor omissions in their discussion. Their account of convection in stars is very brief, and the impression is given that convection in stars always occurs with a temperature gradient close to the adiabatic gradient and no account is given of convection in diffuse outer layers. The chapter on physical processes which is most liable to change is that on nuclear reactions. Advances in the knowledge of nuclear energy-levels and their spins have modified some of the detailed processes discussed by Menzel *et al.*; as an example a supposed resonance in the reaction $O^{16}(\alpha,\gamma)Ne^{20}$ has now been shown not to exist.

The authors' stated intention is that this should be regarded primarily as a text-book for students; but, as such, it seems to have some serious deficiencies. The first chapter, "Introduction and Brief Survey of Observational Data", is perhaps the most important chapter in such a book, and I find it disappointing. Several concepts are

introduced without being properly defined, and some of the definitions are muddled. As an example, the effective temperature of a star is not defined adequately. It occurs in an equation between luminosity and radius which is written down on the assumption that the star radiates as a black-body. It is not made clear that this is merely a definition of effective temperature (the temperature of the equivalent black-body) and shortly afterwards it is stated that the equation determines the radius of the star in terms of the luminosity and effective temperature. Overall the introduction fails, in my view, to paint a sufficiently clear picture of what are the basic problems, especially those concerned with comparison of theory and observation. It could usefully have been very much longer.

Although the book does not set out to keep up with the details of recent calculation it seems a pity that in a book published in 1963 two topics of very great interest have been omitted. In 1961 Hayashi published a paper that has completely changed views on the pre-main sequence contraction of stars and the Henyey-Le Levier-Levée theory has been largely superseded. For some years workers in the theory of stellar structure have been very concerned with energy losses from stars due to neutrino reactions and these also are not mentioned.

My conclusion is that the book will be read with interest by persons wishing to learn more about some of the basic physical processes in stars, but that it is not an ideal introductory text-book for beginners. It seems unlikely to me that (to quote from the fly-leaf) it will remain the standard text-book on stellar interiors for a long time.

R. J. TAYLER

SPACECRAFT ATTITUDE CONTROL

Torques and Attitude Sensing in Earth Satellites

Edited by Fred Singer. (Applied Mathematics and Mechanics, Vol. 7.) Pp. xiii+261. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1964.) 78*s*.

ONLY on reading to the end of the preface are suspicions confirmed that *Torques and Attitude Sensing in Earth Satellites* consists largely of a number of papers presented at a conference: the second Robert H. Goddard Memorial Symposium of the American Astronautical Society, Washington, D.C., 1962. It is therefore not surprising that the book does not contain a coherent, complete or exclusive account of "torques and attitude sensing in Earth satellites". The preface attempts to deny this statement, but openly contradicts the contents list when it states: ". . . the discussion does not deal directly with the design of attitude control systems, but only with the external torques and with the means of attitude sensing". Meteoroid impact is a notable absentee among the external torques, and detailed discussion of attitude sensing is limited to Earth horizon sensing. Star, Sun and inertial sensing methods receive at the most passing reference. Internal torques are discussed in relation to the damping of nutation of spin-stabilized satellites and of libration of gravity–gradient stabilized Earth-pointing satellites. Some aspects of attitude control system design are directly treated: passive gravity–gradient stabilization, magnetic attitude control of the *Tiros* satellites, satellite angular momentum removal utilizing the Earth's magnetic field. However, while the book does not provide "a scientific basis for the design of attitude control systems" (preface), the attitude control specialist will find, in a handy-sized volume, a useful collection of papers.

Chapter 1, by G. S. Reiter and W. T. Thomson, deals with rotational motion of passive space-vehicles (11 pp.). It discusses briefly the relation between nutation amplitude and energy for a spin-stabilized satellite, and gives a short review of nutation damping methods. R. E. Fischell, in "Passive Gravity–Gradient Stabilization for Earth Satellites" (18 pp.), summarizes the theory of gravity–gradient Earth-pointing stabilization for a 'dumb-bell' satellite configuration. A (largely) magnetic scheme for de-spin and attitude acquisition is described. The method has been applied in the *Traac* satellite, and structural and performance details are given of the 'lossy' spring and magnetic hysteresis libration damping.

In Chapter 3 (42 pp.) J. E. DeLisle, E. G. Ogletree and B. M. Hildebrant discuss gyrostabilizers mainly in relation to the provision of 'semi-passive' damping for 3-axis gravity–gradient Earth-pointing stabilization. Principles and optimization procedures are explained in considerable detail, though from a physical rather than a mathematical point of view. Under the title of "Generalized Gravity–Gradient Torques" (10 pp.) R. E. Roberson presents an interesting, if somewhat academic, answer to the question: What sort of gravity torques will be experienced by a space-vehicle if the gravitational field departs significantly from the inverse square form? In Chapter 5 (16 pp.) W. J. Evans gives a useful theoretical basis for the difficult task of accurate evaluation of disturbance torques due to the Earth's atmosphere and to solar radiation. Application of the theory is hampered by the lack of experimental data on the various reflexion and accommodation coefficients. Shadowing of one part of the satellite by another is discussed and noted as a major source of disturbance torque in an otherwise symmetrical satellite.

S. F. Singer deals with forces and torques due to Coulomb interaction with the magnetosphere (7 pp.) in Chapter 6 and points out that Coulomb forces may be relatively important sources of disturbance not only for small satellites (for example, West Ford needles experiment), but also for large satellites, if these are constructed of wire mesh. If the mesh size is sufficiently small and the mesh is at a suitable potential, it can present a 'solid' appearance to incident plasma. Ordinary aerodynamic and solar pressure forces may be comparatively negligible. A number of control and scientific applications are suggested for this effect. In the following chapter R. A. Lyttleton and S. F. Singer deal with some of the dynamical aspects of the West Ford experiment (9 pp.). This chapter contains a rather specialized application of vehicle dynamics and the effects of environmental disturbances, suggesting reasons for the non-detection of the first West Ford needle belt. Chapter 8 (10 pp.) is a very brief review of some ways in which the effects of magnetic torques might be used to obtain data on the geomagnetic field and satellite temperature, or to provide attitude control. The comparative wealth of illustrations, barely referred to, seems rather superfluous.

In their chapter entitled "Magnetic Attitude Control of the *Tiros* Satellites" (9 pp.) E. Hecht and W. P. Manger discuss the unexpected spin-axis precession observed in *Tiros I* and show how this was found to be due primarily to magnetic torques. A description follows of the simple magnetic system, used in *Tiros II* and *III*, to control the satellites against this effect. Satellite angular momentum removal utilizing the Earth's magnetic field is dealt with by R. J. McElvain in 22 pages. He discusses the use of magnetic torquing for unloading the angular momentum stored in reaction wheels, where these are used as the basic attitude control actuators. This scheme avoids the continual expulsion of mass which would occur with a jet unloading system. The general concept and attitude control scheme of the *Syncom* communications satellite is described in Chapter 11 by D. D. Williams (16 pp.). At synchronous altitude the disturbing torques are found to cause only very slow rates of spin-axis precession (a few degrees per year), making this simple form of stabilization attractive for the application.

Chapters 12 and 13 are concerned with the motion of *Explorer XI* round its centre of mass (16 pp.), and an

investigation of the observed torques acting on *Explorer XI* (15 pp.). These attempt to relate the observed motion of the *Explorer XI* satellite to the environmental factors causing the motion. The two chapters are complementary rather than overlapping. Chapter 13 gives some details of the attitude determination procedures, and examines the orders of magnitude of the various torques. Chapter 12 attempts a detailed explanation of the motion in terms of gravity and magnetic torques.

Chapters 14, 15 and 16 deal with various aspects of Earth horizon sensing. Chapter 15 surveys the physical phenomena and scanning methods which could be used, some mention being made of possibilities with regard to other planets and the Sun. Chapters 14 and 16 present, respectively, theoretical and experimental results concerning the infra-red radiation emitted by the Earth, the object being to discover which spectral bands should be used to give greatest reliability and accuracy in this method of attitude determination.

W. G. Hughes

LUNAR TOPOLOGY

The Lunar Surface Layer

Materials and Characteristics. Edited by John W. Salisbury and Peter E. Glaser. Pp. xxvi+532. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1964.) 86*s*.

THE lunar surface, which tantalizingly beckons the astronaut of the space age, has long been the subject of astronomical investigation at a distance (though we have probably never felt the limitations of this acquaintance more keenly than at the present time); but the urgency of engineering deadlines to be met in the next few years makes it desirable to take stock of our present knowledge in this field, to see what kind of physical picture it will make. A three-day symposium on the lunar surface layer, its materials and composition, was held in Boston in May 1963, the purpose of which was to bring together relevant astronomical observations and supporting laboratory data. The symposium was organized by the editors of *The Lunar Surface Layer*, and thirty-three different authors contributed to its proceedings; their communications are published in this volume.

A wide diversity of subjects relevant to the physics of the lunar surface were covered—including aspects of soil mechanics; the effects of micro-meteoroid bombardment and meteoritic impacts; spattering effects, electro-dynamical effects, photometric and thermal emission examinations, and many other lines of investigation which must be integrated in a coherent picture. Perhaps the most interesting contributions to the symposium were those in the field of photometric investigations and, in particular, on the interpretation of the lunar photometric function (unique among all bodies of the solar system) which makes the intensity of moonlight vary so steeply about the time of full Moon. Hapke's recent laboratory work on the dendritic growth *in vacuo* is both presented and critically discussed. Of other noteworthy contributions, a gradual understanding of the low albedo of the lunar globe has emerged from laboratory investigations of the radiation damage suffered by unprotected solid surfaces exposed to the full range of solar radiation —both electromagnetic and corpuscular.

The most significant feature of this symposium—and hence of the volume—was its attempt to blend together astronomical observations and laboratory investigations into a coherent physical and mechanical model of the lunar surface. It would be too much to hope that an undisputed picture of it would emerge in advance of the actual instrumental or manned landings—everyone seems to have managed so far to draw support from the recent photographs of *Ranger VII* for his preconceived opinions. Drs. Salisbury and Glaser are to be congratulated on a distinct measure of success in advancing this aim. Perhaps the best tribute one can pay to their efforts is to say that, although the parent symposium was held eighteen months ago, its *Proceedings* have lost little of their interest and relevance in the intervening time.

Zdeněk Kopal

A MEDIEVAL MASTER CRAFTSMAN

On Divers Arts

The Treatise of Theophilus: Translated from the Medieval Latin with introduction and notes by John G. Hawthorne and Cyril Stanley Smith. Pp. xxxv+216+16 plates. (Chicago and London: The University of Chicago Press, 1963.) 63*s*.; 8.50 dollars.

THE treatise *De diversis artibus* ascribed to Theophilus is the most interesting of the small group of craft handbooks surviving from the European Middle Ages; as such, it has been often edited, several times rendered into English, and also translated into French, German, and Polish. The text was most recently edited (and translated) by C. R. Dodwell (1961); the present book, though begun earlier, was able to make some use of its immediate predecessor. Its particular advantage is the metallurgical and historical experience of Prof. Cyril Stanley Smith, whose previous work of the same kind is well known.

The present translators agree with Dodwell in identifying the pseudonymous author with a Benedictine monk and metal-worker, Roger of Helmarhausen, examples of whose skill are preserved at Nuremberg and Paderborn. *On Divers Arts*, accordingly, was written in the first half of the twelfth century, at a time when the first renaissance of learning was commencing. The author, however, was no literary technologist nor compiler of traditional recipes; rather "when first written down his *Treatise* had a comprehensiveness and originality, a down-to-earth quality that makes it far superior to any other technological manuscript for some centuries to come". Theophilus, avoiding idleness and frivolity as productive of nothing but "slander, idle curiosity, drunkenness, brawling, fighting, murder, riotous living, thieving, sacrilege, perjury and other things of this kind", sought to be "the humble quiet man working in silence in the name of the Lord and obedient to the precept of the blessed apostle Paul" enjoining worthy labour. His experience extended to three of the arts most closely associated with the Church: painting on walls, wood panels, and vellum; glass-making including vessels, windows and faience glazes; and fine metal-working. The craftsman, of course, began at the beginning; he prepared his own pigments from mineral or herbal sources; fused glass from sand and beech-ash; made his glues from fish-bones, cheese, leather and horn; formed the mould in which the lead cames for his windows would be cast, built his own furnaces from clay and horse-dung, and so on. The art was in the preparing and the doing; there was no theory, no calculation, and very little design. No one need reasonably feel that there was some lost science behind medieval works of art, on either the small scale or the large.

The translation is agreeable to read, and is copiously supplied with the technical annotation without which the methods and processes described would be virtually unintelligible. Where necessary figures (derived largely from Theobald's German edition of 1933) have been added to improve intelligibility. A series of fine plates illustrates the works produced by Theophilus's techniques. There may be occasional slips (surely cinnabar was not "to Theophilus . . . artificial mercury sulphide"?), but these are few indeed in a volume which is—if a slight emphasis on the Gothick be accepted—splendidly produced.

A. R. Hall

CREATIVE THINKING

The Act of Creation

By Arthur Koestler. Pp. 751. (London: Hutchinson and Co. (Publishers), Ltd., 1964.) 42*s*.

THE rapid growth of knowledge which has taken place in the past fifty years or so has also enlarged our conception of science. Gradually it is being recognized that science, like art, is a creative activity. This has directed our attention to investigating the nature of scientific creativity.

Mr. Koestler has attempted in *The Act of Creation* to explain the creative process. His explanation is based on Freud's theory concerning the relation of wit to the unconscious. It is described in detail in the first part of his book; in the second part, Mr. Koestler cites the scientific evidence in support of his view.

Laughter and humour are therefore the first topics discussed. The pattern which underlies the joke is 'bisociative'—we perceive an idea or a situation simultaneously in two contexts that are usually incompatible. 'Bisociation' is the term invented by Mr. Koestler to distinguish between routine thinking, which is on one, single level, and creative thinking, which always operates on more than one level.

The transfer of thought from one matrix to another governed by a different set of rules arises from conflicting feelings. The ambivalence of our basic emotions, the aggressive–defensive mode with which we react to every happening, sets the pattern of all our activities. Thus, the 'bisociative' shock of humour which makes reasoning perform a somersault also occurs in scientific discovery, according to Koestler. Solving a problem is very similar to seeing a joke. Just as the joke liberates us from a tension which is discharged in laughter, so the creative act, too, resolves tension and enables us to attain a higher, more integrated, level of thought.

The moment of truth—the *Eureka* of Archimedes—characterizes the act of creation. This is illustrated by Mr. Koestler in many examples. Gutenberg's invention of the printing press, Kepler's discovery of the laws of planetary motion, and Darwin's formulation of the theory of evolution are discussed in detail. 'Thinking aside'—letting unconscious thoughts come up into the open—is the secret. Logical and intellectual reasoning is superficial and unproductive: it is, in any event, needed only later for verbalization once the discovery has been made. We have to 'regress' into more primitive, pre-verbal, unconscious modes of thought in order to progress to higher levels of thinking. "*Reculer pour mieux sauter*" is the proverb Koestler uses for describing the process.

The various mechanisms, such as displacement, condensation, etc., which Freud found operating in the dream can also be shown to be at work in scientific discovery. Scientists, like Poincaré and Kekulé, have in fact claimed to have arrived at their results in a dream. Unconscious phantasy is the source of all creativity. This is what we would expect if we regard the evolution of ideas as a natural process; for the unconscious phantasies are the mental representatives of our biological–genetic drives. A little 'calculated regression' into the realm of primitive imagination is needed; but our conscious mind tends to forbid this because infantile wishes and fears are always involved in unconscious processes. We must learn to be spontaneous and able to relax our conscious control. The moment of truth, then, occurs when unconscious and irrational thoughts are turned into conscious and rational knowledge.

The scientist is not a pedantic plodder; rather, he is a dreamer or a sleepwalker, as Koestler calls him. The scientist is just as emotionally involved in his work and impassioned as the artist. The earlier stages are the same as can be seen from the history, or pre-history, of both art and science. The æsthetic experience aroused by a work of art is derived from the same, bisociative processes that cannot be rendered in verbal language. The artist exploits these unconscious processes and externalizes them by following the rules which the conventions of a period or of a school prescribe. His originality, however, consists in directing attention to aspects previously ignored or in bringing out new relationships between *motif* and medium.

In the second part of the book, Mr. Koestler presents the evidence from biology and psychology in favour of the theory he has outlined in the first part. Pre-natal skills, the development of the nervous system, the generation and regeneration of primitive organisms, instinctual behaviour, perception and memory, motor skills, the pitfalls of learning theory, behaviourism these are the topics into which the author plunges with zest and erudition. Koestler's onslaught on the behaviourists who deny all creativity as something supernatural is savage though substantiated. The stimulus-response and rat experiments cannot suffice to explain the higher, more complex processes which are involved in creative work. Abstraction and concept-formation are the central problems of symbolic thinking. We cannot explain them unless we follow the slow growth of abstract symbolism from the 'concrete', physical reactions of the infant. This is very far removed from any stimulus-response theory of learning.

There are two criticisms which, I think, must be made. The first is that, for Koestler, creation is merely the new arrangement of already existing parts: a different synthesis rather than the emergence of genuine novelty. Novelty, however, must occur; this is shown, for example, by the mutations of a gene. There is discontinuity; and, indeed, evolution as a whole exhibits it. On the biological level, there is the appearance of new species: on the level of mental development, new ideas arise that go beyond what has previously been known.

The second criticism I would make is that wit is not a sufficiently complex phenomenon to serve as paradigm for the creative act. Freud never intended his explanation to cover so wide a range. Moreover, since his theory was published, just about sixty years ago, a great deal more has been said about creativity in art and in science by psycho-analytically oriented writers. Mr. Koestler does not mention this literature.

The merit of Mr. Koestler's book lies in pointing the way towards a better understanding of science. If science creates new knowledge, we cannot forget the unconscious processes from which it springs. We must reject the view still widely held that science progresses through intellectual and logical thinking and, in consequence, revise the narrow, mechanistic criteria which are used for judging whether a theory is acceptable or not.

E. H. HUTTEN

A GUIDE TO TECHNICAL TEACHING AND INSTRUCTION

Technical Teaching and Instruction

By Alexander Maclennan. Pp. 187. 8 in. × 5¼ in (20 cm × 13 cm). (London: Oldbourne Book Co., Ltd., 1963.) 18*s*.

TECHNICAL Teaching and Instruction is a very practical book by the director of the Training College for Technical Teachers at Huddersfield, and represents the fruit of nearly twenty-five years' varied experience. For new teachers it will serve as a sound guide, and the complacent established lecturer should heed its critical comment and cautionary points.

Two chapters provide a brief survey of primary, secondary and technical education, and are followed by others dealing much more fully with the learning process, factors in learning, the scheme of work, the preparation

of teaching material, the structure of the lesson, less-formal methods of teaching, class management, homework, students' notes and teachers' records. If all teachers in technical colleges mastered the essentials of good teaching here set out in detail, standards would manifestly rise, to the continuing advantage of students in full-time and sandwich courses, in part-time day and evening classes alike.

With so important a task to be accomplished, some shortcomings in the book must perforce be noted with regret. The style is terse, often with one fact per sentence, one sentence after another. The writing is frequently reiterative, with many sentences beginning alike, and only in the chapter on "Liberal Studies" is there felicity of thought and expression. Perhaps this is too much to expect in an essentially practical manual, but it is difficult to believe that enthusiasm and imaginative insight will be greatly stimulated by reading its well-filled pages.

Errors of fact and interpretation also occur which cannot be overlooked. For example, the Higher National Diploma is described as the second main course in the colleges of advanced technology: in 1963 out of 11,800 students in full-time and sandwich courses only 231 students were in Higher National Diploma courses. Some statistical treatment would have added precision to other generalizations. Again, very misleading interpretations could very justifiably be made of the tree diagram of the "Organization of a Technical College" (p. 111), especially as to the relative importance of the academic and administrative functions, and the line—staff relationships between principal, vice-principal and heads of departments. It is stated that thirty-two regional colleges have been designated in the past six years—the official number is twenty-five.

Despite its shortcomings, the book will be of undoubted value to teachers of students in craft and technicians courses and at similar levels, and is to be strongly recommended accordingly. Beyond these, however, the effectiveness of the book will be much less, as it lacks the philosophical treatment and speculative enquiry appropriate to teaching at higher levels. This is not a criticism and it may be unreasonable to expect so wide-ranging a task to be accomplished in one book. Nevertheless, this represents a lost or at least a deferred opportunity with the publication of the Hale Committee Report *. The need for better teaching will scarcely be less with degree courses sponsored in the technical colleges by the new Council for National Academic Awards, than with degree courses in the universities surveyed by the Hale Report, and courses in the new universities including the former colleges of advanced technology.

P. F. R. Venables

* Report of the Committee (chairman Sir Edward Hale), appointed by the University Grants Committee, on *University Teaching Methods* (H.M.S.O., Nov. 1964).

SOCIAL CONTEXT OF EDUCATION

Education and Environment

By Stephen Wiseman. Pp. xiv+202. (Manchester: The University Press, 1964.) 37*s*. 6*d*. net.

In this significant book, Dr. Stephen Wiseman describes four separate investigations carried out by the staff of the University of Manchester School of Education. Tests of reading comprehension, mechanical arithmetic and verbal intelligence were constructed and a massive testing programme involving 14,000 children of 14+ in 273 schools was carried out in the Manchester area.

The results must have been of particular interest to local educationists. There was a very great variation in the attainment of children in different schools, and the amount of overlap in attainment in arithmetic and reading in selective and non-selective schools was marked. Forty per cent of the best readers were found to be outside the grammar schools. In the second investigation the relationship between the educational attainments and social and environmental factors was examined. The results appear to have been disappointing. There were difficulties in deciding on the most important factors in the environment, but questions were raised and further research was suggested.

Chapter 4 cuts into the report of the 1951 survey, but in this chapter Dr. Wiseman makes a very useful and interesting selection of relevant researches into education and environment. Material concerning family background in researches not directly investigating educational attainment is described, but Dr. Wiseman seems reluctant to concede that his clinical colleagues might be able to assist him in the choice and definition of family variables. Dr. F. W. Warburton's report on the third investigation, in which he examines the relationship between attainment and the school environment, is concise and factual. 1,700 children were tested in 48 secondary schools in Salford excluding grammar schools. He finds that a factor which he describes as socio-economic has higher correlations with intelligence than with attainment tests, an association which Dr. Wiseman also found between intelligence and environment. The second factor seems to represent school atmosphere. Progressiveness in schools was shown to be associated with ability in reading comprehension. This result is noted by Dr. Wiseman in his final chapter as one of the most significant findings in the book. A third factor represented good teaching conditions which, as Dr. Warburton anticipated, were associated with higher attainment in arithmetic.

Dr. Wiseman goes on to describe the 1957 survey. He was well aware of the limitations of his previous survey, but apart from including grammar school children and adding 12 new variables which were thought to have some connexion with a 'maternal care' factor, the 1957 survey is very similar. About 1,400 children were tested from 20 schools in Manchester. A major improvement was found in the standards of reading and arithmetic and the proportion of illiterates and semi-illiterates had been nearly halved. Apparently it was not thought necessary even in this second survey to include a non-verbal intelligence test or to attempt to broaden the basis of measurement and to assess the effects of environment on the more liberal aspects of the secondary school curricula.

One interesting fact emerges concerning the interpretation of results in these surveys. The intelligence test results seem to be more affected by environmental factors than are the results from the other two tests. According to Dr. Wiseman these unexpected results occur when the unit of measurement and the basis of the correlations is not the individual child but the school, neighbourhood or town. Dr. Wiseman stresses the importance of the interactions of attitudes of pupils, teachers and parents in the education of a particular child, and he emphasizes the need "to buttress ecological surveys with investigations of individual children and individual families".

Many readers may wonder whether Dr. Wiseman and his colleagues might not have presented a more penetrating contribution to educational research had they made intensive studies of individual children and their families the starting point of their investigations. Some readers, too, may be disturbed by the application of scientific rigour to the analysis of human attributes and to the analysis of indices which are not directly measurable and may be confused by the statistical virtuosity displayed in certain chapters.

This is not an easy book. It is a book which poses more questions than it answers. It is, however, an important book which will certainly repay close study and which will provoke discussion and controversy and stimulate further research.

John Bradley

SHORT REVIEWS

Corridors of Power

By C. P. Snow. Pp. viii+408. (London: Macmillan and Co., Ltd.; New York: Charles Scribener Sons, 1964.) 25*s*. net.

THE title of Sir Charles Snow's latest novel in the *Strangers and Brothers* sequence appears to have been first used in one of his earlier novels some eight years ago, and not, as the currency of the phrase might now suggest, in his Godkin Lectures, "Science and Government". The phrase almost inevitably turns the mind of a scientist to those Lectures, and the novel might be described as an attempt to express in fiction the essential conflict which Sir Charles discussed in them and his subsequent postscript. There is, of course, much else, and the particular political issue on which the book centres is one of the place of nuclear weapons in defence policy, and not those of the Second World War. The setting of the whole drama of power and influence is unfolded with the same skill and insight which characterize earlier novels in the series, the accuracy of which, from the point of view of the scientist, Lord Rutherford once acknowledged. Quite apart from its merits as a novel, the book could well contribute something to the deeper understanding of the Civil Service by the scientist, perhaps also, especially in one passage which recalls A. H. Compton's description of the heart-searchings of the nuclear physicists in *Atomic Quest*, to the understanding of the scientist by the administrator and politician.

Office Economy by O and M

(A Preliminary Text-book on Methods.) By G. E. Milward and P. H. S. Wroe. Pp. ix+140. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, 1964.) 21*s*.

THE Organization and Methods Training Council was established in 1957 by nine companies intent on developing advanced training courses and preparing and testing a text-book on simple office methods, incorporating their experience and intended for the use of college students and others. Such a text, called *Organization and Methods*, was produced and has been eminently successful. On the whole, however, it covered too wide a field for the preliminary training required by industry, and *Office Economy by O and M* has been designed to deal particularly with methods training. It would provide an admirable basis for such training courses and, after describing the context of methods work, shows the fundamental approach to simplifying processes involving the choosing of the most suitable methods, the design of forms, various ways for reproducing and copying documents and information, clerical aids, the conduct of enquiry and procedure charts, office machinery, and the effects and evaluation of changes in methods. The book itself is an admirable example of how words can be used simply, economically and effectively. On its merits it should repay close examination by all who wish to improve the quality and efficiency of their office administration.

T. H. HAWKINS

Rural Life and Urbanized Society

By Lee Taylor and Arthur R. Jones, jun. Pp. xiv+493. (London and New York: Oxford University Press, 1964.) 60*s*.

THIS American text-book is aimed mainly, I should imagine, at professional rural sociologists or those in training. But it differs from many forerunners in that it is readable—in the armchair as well as at the office desk—and because it adheres closely to its central theme, that is, the marked changes which have occurred in the relationships between town and country people—especially the urbanization of social organizations—during the present century.

The material is arranged in four parts. The first brings out the changes, in intensity and kind, of rural–urban differences. The second part discusses the influences of farm, non-farm and suburban peoples and their work, as well as the increasing use made of the countryside for 'vacationing' of all kinds. The last actually has increased remarkably during the past decade and is becoming highly organized in many parts of the United States. The third section concentrates on the social aspects of food and fibre production; the present-day American farm is revealed as primarily and necessarily a business organization or, to use a present but horrible piece of American shorthand, an 'agribusiness'. The fourth and final group of chapters bring out the increasing dependence of rural people on urban-inspired and directed social institutions.

Numerous book references and notes bring together research material and works of reference from all over the United States. At the end of each chapter is a list of selective readings; here also is a summary of the chapter. I would have preferred these summaries to have been assembled as a concluding chapter so that the book and its authors might have come to a dignified conclusion rather than, as at present, a full stop. The text is well written, and the material points to many trends which we can see, or will be seeing, in the United Kingdom as we approach the state of one family one car (at least).

H. E. BRACEY

Human Histology

By Bruce Cruickshank, T. C. Dodds and Dugald L. Gardner. Pp. vii+268. (Edinburgh and London: E. and S. Livingstone, Ltd., 1964.) 70*s*.

AS the title of *Human Histology* implies, the authors have set out to use human rather than animal material for the production of about 300 colour photomicrographs which illustrate the text. These photographs show excellent colour rendering; but the detail obtained is less than it would have been in black-and-white photographs. The text is limited to a description of these plates. References to the physiological and biochemical significance of structures have usually been avoided. The term histology has been taken in a strict sense and tissues from human diseases of physiological interest are not described, nor are many of the changes occurring in different physiological conditions. Within these limitations, the aims of the authors have been admirably achieved, and despite its price it will undoubtedly be popular with medical students.

The limitations are such that the dissociation of structure and function is more marked than in some nineteenth-century text-books of histology. This, in my opinion, is really undesirable. It might at an early stage of a medical student's career inculcate an approach which is the antithesis of all that he will be made to learn later. Now that, under the influence of pathologists such as Cameron and Florey, the teaching of pathology integrates structural changes so closely with functional and biochemical ones, it does seem unwise to start a new text-book of histology

which does not emphasize, or even over-emphasize, this correlation. Is it reasonable to ask a student to memorize the differences between the cell types of the adenohypophysis without mentioning that they secrete hormones and without explaining that the staining differences are due to the chemical nature of those hormones? Why omit reference to the function of RNA in nerve cells, plasma cells and hæmocytoblasts? Surely nothing can be duller to teach or to learn than the differences in structure of different parts of the nephron; but, taken in conjunction with the structure shown by electron microscope and with modern theories of urine formation, the same differences are understandable, fascinating and easy to remember.

E. H. Leach

Seals of the World

By Judith E. King. Pp. 154. (London: British Museum (Natural History), 1964.) 11*s*.

Miss King has performed a most useful task in bringing together in succinct form so much information on the Pinnipedes. This group has sustained more attack from man than any other order of mammals, and only in this century has any attempt been made to preserve this valuable animal resource. Work carried out by American, British, Canadian, French, Australian and Russian biologists has gradually built up a body of knowledge which, within the foreseeable future, will allow a policy of management to be applied to most of the threatened species (see also *Nature*, 204, 522; 1964).

In the first half Miss King gives an account of the thirty-two species, including their classification and interrelationships and their distribution both past and present. Such features as the breeding biology, food, social behaviour, longevity and seasonal movements are included where they are known, and estimates of the world population are also given where possible. This part forms a most valuable synthesis of our present knowledge.

In the second half, aspects common to the group as a whole are dealt with. There are chapters on: distribution and ocean currents; body form and locomotion; skin, fur, moult and temperature control; skull and skeleton; dentition and age determination; alimentary, respiratory, vascular, nervous and reproductive systems; senses; and diving abilities. Two final chapters on the scarce fossil history and on the parasites recorded complete a really comprehensive survey. I applaud the inclusion of the reasons (origins) of the scientific names which brings to life for the layman what is often regarded as an arid field of zoology.

The maps and line drawings are excellent; clear and unambiguous. It is pleasant to find all the places mentioned in the text shown on the maps. The photographs of species are good but could perhaps have been more plentiful, although this would have raised the very moderate cost. The literature list might also have been longer, but it includes enough to lead to the rest and that is the main object in such a work as this, which should certainly be on the shelves of the libraries of all departments of zoology as well as those of the public libraries.

H. R. Hewer

Comptes rendus du 3ème Congrès d'EUCARPIA

(Association Européenne pour l'Amélioration des Plantes), Paris, 21–28 Mai, 1962. (Third Congress of the European Association for Research on Plant Breeding.) Pp. 336. (Paris: Institut National de la Recherche Agronomique, 1964.) 37 francs.

The Association Européenne pour l'Amélioration des Plantes provides annually one of the few opportunities for European plant breeders to assemble and to exchange ideas and experiences. This report of its third congress in Paris in 1964 is a full description of the proceedings of the meeting including the complete texts, with tables and illustrations, of the papers, twenty-one in all, delivered there.

In the first of eight sessions, R. Mayer described, in a historical fashion, the progress and organization of plant breeding in France. The themes of six following sessions were: dry matter production as an objective in plant breeding; disease resistance in plants; the fate of the mutated cell; induction of mutation and plant breeding; present views on the gene centre theory; and physiological aspects of quality. In a final session, P. l'Héritier gave an account of present-day views on cytoplasmic inheritance. The final part of this report deals mainly with the activity of the Association and its various sections during preceding years.

This volume conveniently brings together some of the recent findings and concepts of plant breeders and, as such, it will be of interest to a wide audience. In an otherwise very complete congress report, the only omission is the absence of records of discussions of the papers, the inclusion of which might have enabled the outsider to share more fully the benefit of the meeting of the Association.

The Architecture of the Germplasm

By Prof. Verne Grant. Pp. xv+236. (New York and London: John Wiley and Sons, Inc., 1964.) 75*s*.

The Architecture of the Germplasm is primarily concerned with the way in which genes interact in development, and how their linkage or independence in inheritance is related to this. After an introduction to Mendelian heredity there are useful discussions of multiple gene systems and of structural changes in chromosomes, particularly in relation to the evolution of close linkage of adaptive gene combinations. Examples have been chosen, where possible, from the flowering plants. In view of this, the decision of Prof. Grant largely to omit discussion of polyploidy in the interest of brevity is perhaps unfortunate. The book is addressed primarily to students in pure and applied genetics and to advanced biology students, and provides a clearly written account of a difficult subject.

A criticism of the book is that it is not up to date. The literature appears to have been well surveyed up to about the year 1957, but only superficially after that. This is particularly serious for the chapters concerned with the nature of the gene and with gene action. Progress in these fields has been so rapid in the past few years that an account based on what was known 6 or 8 years ago is of little value. Indeed, there are so many errors or misleading statements in these chapters (2 and 6) that readers would be well advised to omit them. Fortunately, such omission does not greatly mar the work as a whole, since the structure of the chromosome and the mechanisms of control of gene functioning in higher organisms are not yet understood in molecular terms. The recent advances on the boundary between biochemistry and genetics have therefore had little impact as yet on the ideas about gene interaction which form the main theme of the book. For the same reason, these ideas cannot be regarded as more than interesting hypotheses until substantiated by a clearer understanding of the chromosome and how it is organized.

H. L. K. Whitehouse

Selected Works in Organic Chemistry

By A. N. Nesmeyanov. Translated from the Russian by Dr. Avraham Birron and Z. S. Cole. Translation edited by David P. Gelfand. Pp. xvi+1172. (London and New York: Pergamon Press; Jerusalem: Academic Press, 1963.) 200*s*. net.

It is noted in the preface that the complete works of A. N. Nesmeyanov were published by the Academy of Sciences, U.S.S.R., in 1959, on the occasion of his sixtieth birthday—in the form of four volumes, embracing all his scientific papers which have appeared on various

occasions since 1929. The first three volumes were concerned with his experimental research and the resulting generalizations and theories, and the fourth contained papers of more general concern, such as review articles and public discussions in chemistry.

The selection of representative papers for the present volume was difficult, but it was decided, with Nesmeyanov's help, to exclude Vol. 4, and to distribute the contents of Vols. 1–3 under the headings: Part 1, "Organo-metallic Chemistry"; Part 2, "Elemento-organic Chemistry"; Part 3, "Organic Chemistry".

The meaning of "Elemento-organic Chemistry" may not be clear: Part 2 contains first a number of papers on 'onium' salts, particularly diaryl-chloronium, -bromonium, and -iodonium salts, and triaryl-oxonium salts. These are followed by a larger number of papers on the synthesis and reactions of alkyl titanates and other related titanium derivatives. Finally there are a few papers on the reaction of various silanes with olefines.

The whole volume contains about 180 papers, which, it should be emphasized, are printed in full with the complete experimental detail. Such a collection of papers, covering a very wide field, excellently translated and clearly printed, forms an impressive tribute to Prof. Nesmeyanov's work; furthermore, almost all organic chemists will find in this collection some papers having a direct bearing on their own work or chemical interests.

F. G. MANN

Modern Developments in Electron Microscopy

Edited by Benjamin M. Siegel. Pp. xiii+432. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1964.) 96*s*. 6*d*.

ELECTRON microscopy is now so diversely applied to the two principal fields of metal physics and microbiology that the usefulness of a single volume devoted to both is limited; any one laboratory is likely to use only half this book. The techniques of specimen preparation are different in the two fields, and the vocabulary of interpretation so different as to make the biological results practically unintelligible to the physicist, and *vice versa*.

However, those articles which I am competent to judge (those dealing with metal physics) are particularly well written. Chapter 5, by Dr. Pashley, constitutes an up-to-date review of the application of electron microscopy and diffraction to the defect structure of crystals, and forms a good introduction to the subject for a research student. Siegel's opening chapter on the electron microscope seems to fall between the stools of elementary exposition and technical monograph; but still it will be useful to microscopists as a source of references, and as a background for the instruction manual accompanying their microscopes. The remainder of the book is good browsing value. It is interesting to see that the problem of obtaining a three-dimensional knowledge of structures by systematic sectioning is common to physics and biology. Fawcett's advice at the end of Chapter 6, to the effect that a sharp, beautiful image is likely to be a truer representation of Nature than one which is coarse and indistinct, also seems to be of universal validity.

In short, although one would not recommend that every electron microscopist should buy this book, one can recommend it as bedside reading: it is a good book to have available.

L. M. BROWN

Fundamental Particles

By K. Nishijima. (Lecture Notes and Supplements in Physics.) Pp. xi+408. (New York and Amsterdam: W. A. Benjamin, Inc., 1963.) 11.85 dollars.

IT is difficult to conceive of an essentially better introduction to the theory of fundamental particles than Dr. Nishijima's *Fundamental Particles*. The first chapter is a historical survey of progress up to and including the discovery of pions. Chapter 2 presents, in clarity and detail, the transformations of space and time inversion and charge conjugation; Chapter 3 deals with charge independence, iso-spin invariance and G-conjugation. Each transformation or principle is illustrated by its application to an important experiment, so that by the end of Chapter 3 the author has given the experimental basis of the established quantum numbers of the pion. Chapters 4 and 5 are concerned with the dynamics of the pion–nucleon interaction covering, *inter alia*, perturbation theory, S-matrix theory, fixed-angle dispersion relations, pion–nucleon scattering up to the first resonance, multi-pion resonances, and nucleon form factors; the author mentions, but does not enter, the field of partial wave dispersion relations. Not only is there a thorough explanation of principle, but also (as indeed throughout the book) there are sufficient examples to make it a useful guide in many practical calculations. Chapter 6 deals with strange particles (including resonances) establishing quantum numbers and some interaction properties, while the final chapter deals with the principal points in weak interactions, again with a wealth of applications.

As is necessary, Dr. Nishijima makes considerable use of the language of field theory, and thus a good knowledge of quantum electrodynamics is desirable for the fullest appreciation of the book. From the point of view of the beginner it is (perhaps) unfortunate that most works on quantum electrodynamics are more difficult than the present book and cover some of the same ground with less force and clarity. However, those who wish to use the book without knowledge of field theory will be able to do so.

To be a most excellent introduction to the subject is not the only function of *Fundamental Particles*; it should, for many years, be a valuable handbook to experimental and theoretical research workers in the field.

R. G. MOORHOUSE

Ancillary Mathematics

By Sir H. S. W. Massey and H. Kestelman. Second edition. Pp. xviii+1053. (London: Sir Isaac Pitman and Sons, Ltd., 1964.) 65*s*. net.

THIS massive compendium, first issued in 1959 at 75*s*., was tailored to the mathematical requirements of those taking the London special honours degree in physics or chemistry. Its success has led to a second edition, at a reduced price, with an additional chapter on matrices. In 60 pages, there is a fairly comprehensive account of linear algebra and matrix theory, up to the Cayley-Hamilton theorem, eigenvectors, quadratic and Hermitian forms, unitary and orthogonal matrices, as well as nearly 100 good exercises for the student. Such a concentration is achieved partly by a terse exposition, demanding close attention, and partly by placing the chapter at the end of the book and so being able to make use of ideas on vectors and algebraic geometry from the earlier chapters. The science student may find the topic difficult, but he should be helped by his knowledge of its importance in theoretical physics to-day, and by the care the authors have taken to slant the account towards applications in this field.

T. A. A. BROADBENT

The Electronic Structure of Molecules

A New Approach. By J. W. Linnett. Pp. vii+167. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1964.) 25*s*.

DR. LINNETT and his group have been working for some years now on a concept of valency which differs from that of G. N. Lewis, and in which pairing of electrons plays a subsidiary role to another concept, namely, the division of electrons into two sets of opposite spin. Although these views have been developed mathematically in the journals, this book makes no demands on the mathematical background of the reader. The views are presented qualitatively, reference being made

at various points to the results of quantal investigations. The ideas as such, therefore, have to be judged by their success in interpreting known phenomena of molecular structure. Starting with simple systems, the author then leads the reader through the more complex areas of organic and inorganic chemistry, ending with a discussion of the structures of excited states of molecules. The mechanism of certain organic reactions is also described within the framework of the theory.

The position of the theory is clearly stated by the author in his final paragraph: "To summarize, it seems not unfair to conclude from the contents of the first half of this book, and from the examination of the simple systems considered in Chapters 3, 4 and 5, that there are sound reasons for believing that the hypothesis is firmly based and that there are advantages in making use of it for formulating at least some molecular electronic structures. This, together with the examples presented in Chapters 6, 7, 8 and 9, provide justification for also believing that the hypothesis deserves further study and investigation".

The book should appeal to a wide selection of readers, from the intelligent sixth-former to those concerned at all levels with the teaching and investigation of the structure of molecules. ALLAN MACCOLL

Physics of Atomic Collisions

By Dr. J. B. Hasted. (Butterworths Advanced Physics Series: Monographs on Ionization and Electrical Discharges of Gases.) Pp. ix+536. (London: Butterworth and Co. (Publishers), Ltd., 1964.) 130*s*.

PHYSICS of Atomic Collisions, the author states, is intended to aid the young experimental physicist entering into the investigation of ionized gases, or of other phenomena involving atomic collisions. This aim will be achieved admirably, provided the young scientist is willing to study with some intensity the very comprehensive data and theory given by Dr. Hasted. Indeed, the book will be valuable to the young physicist for many years, and no less to the worker already established in the field.

In recent years there has been a considerably increased interest in the investigation of atomic collision processes and allied subjects, so that there exists a large amount of published research which requires collation and unified presentation. Dr. Hasted has attempted this task with success.

In the book the author presents first a brief but careful survey of the basic concepts of swarm phenomena in gases and of the classical and quantum theory of collisions. This is followed by an extensive survey of experimental techniques used in collision physics, and this section is particularly valuable. Sources of molecular and atomic beams are described, as also are electron, ion and photon sources. Velocity selection and particle detection methods are surveyed. The major portion of the book is concerned with the description of the experiments and data available on some important collision phenomena. Chapters are given on electronic excitation of atoms and molecules; ionization by electrons; positive ion recombination; electron attachment and detachment; photon emission and absorption; elastic collisions between atomic particles; ionization and excitation by atomic particles; charge transfer processes; collisions of excited atoms and particles; and ionization interchange. In all these chapters the author presents, in a lucid manner, an up-to-date review of the subject-matter, giving the reader clear guidance on the importance of the data under examination and indicating the theoretical implications. There are many useful diagrams of modern data on collision cross-sections, excitation functions, potential functions, etc. Extensive bibliographies are given and should prove most helpful. There is a useful appendix of tables of atomic constants, ionization and excitation levels, selection rules and potential functions. In the text there are helpful review tables. The book can be recommended to all serious students of atomic collision processes and gas discharge physics. H. EDELS

The Nucleon–Nucleon Interaction

Experimental and Phenomenological Aspects. By Prof. Richard Wilson. (Interscience Tracts of Physics and Astronomy.) Pp. ix+249. (New York and London: Interscience Publishers, a division of John Wiley and Sons, 1963.) 45*s*.

A STAGE has been reached in the study of the nucleon–nucleon interaction where it is possible to give a fairly complete picture of the interaction up to nucleon energies of 300 MeV. All the general features seem to fit together, and it is natural therefore to seek a comprehensive review which can at the same time point the way to future experiments. This book sets out to discuss the nucleon–nucleon interaction from the "experimenter's point of view". On the theoretical side, a companion volume by H. P. Noyes is promised, and one by M. J. Moravcsik has already appeared.

The author is in an advantageous position to present the experimental side, having been engaged for the past fourteen years both in research and teaching in this field. However, this familiarity has led in a few instances to the presentation of a personal point of view, to a neglect of material, and to a greater number of mistakes in text and references than is permissible in a book aimed at the teaching of graduate students. It would also have been better to restrict the book to energies below a few hundred MeV, since data in the GeV range are accumulating so rapidly and their interpretation is so tentative that their inclusion adds nothing to the main purpose of the book. The 50 pages of experimental values, most of which have appeared in graphical form, can only be aimed at those who wish to make their own computer (phase shift ?) analysis of the data. Such serious students always refer to the original work and form their own independent assessments. This space could well have been devoted to a fuller development of the topics discussed, and in particular to a critical assessment of the points remaining to be resolved or tested, such as the application of charge independence.

In spite of these criticisms the book largely supplies a need in presenting the relevant data and its interpretation ranging from the ground state of the deuteron to the scattering of nucleons by light nuclei. It provides a useful starting point to be followed by reading the books stressing the theoretical side and the review talks given at annual conferences. A. E. TAYLOR

The Theory of Rings

By Neal H. McCoy. Pp. x+161. (New York: The Macmillan Company; London: Collier–Macmillan, Ltd., 1964.) 25*s*.

THE Carus monograph, *Rings and Ideals* (1948), by N. H. McCoy, has served as a good introduction to this branch of modern algebra, but the purpose of the Carus Foundation was to present mathematical topics to non-specialists. *The Theory of Rings*, however, is strictly professional, though only a minimum amount of previous knowledge is assumed. The main properties of rings, ideals and radicals are set out lucidly but tersely, with a good supply of exercises for the reader. The young student will find the book an excellent introduction to, say, the more detailed Jacobson classic, *Structure of Rings* (1956), and some account is also given of the more recent advances. The honours undergraduate with a taste for abstract algebra has now a number of valuable texts available; but if he wishes to proceed from a broad survey to deeper penetration of this narrower field, he should profit from this somewhat austere, but invigorating and up-to-date, account. T. A. A. BROADBENT

LETTERS TO THE EDITOR

ASTROPHYSICS

Two Sources of Cosmic X-rays in Scorpius and Sagittarius

We have observed two separate and intense sources of cosmic X-rays in the region of the constellations Scorpius and Sagittarius during a rocket experiment launched on August 28, 1964. This is the same general region of the sky from which non-solar cosmic X-rays were first detected in June 1962 by Giacconi *et al.*[1]. In that earlier work a Geiger tube detector of large area and wide angular response was mounted, looking out of the side of a spinning rocket. A strong maximum in the counting rate was observed when the detector pointed in a southerly direction. A detailed discussion of the results led to the conclusion that the X-rays were of non-terrestrial origin, and that they emanated from a source close to, but apparently not coincident with, the galactic centre. These conclusions were confirmed in two later rocket flights, also employing wide-angle detectors[2]. In April 1963 Bowyer *et al.* conducted a rocket experiment using a detector with a field of view 10° wide at half maximum intensity[3]. At the time of that flight the galactic centre was below the horizon. They gave a location for the source in Scorpius at about 16 h 15 min right ascension and −15° declination and stated that its angular diameter is less than 5°.

The results reported here are based on an analysis of data received from one of several detectors in a payload carried aloft by an *Aerobee* rocket from White Sands, New Mexico (latitude, 32·4°, longitude, 106° W.) at 05: 30 G.M.T. (sidereal time, 20 h 56 min). This particular detector was a bank of argon-filled Geiger tubes with 0·002 in. thick beryllium windows, and a total sensitive area of 70 cm². The X-ray sensitivity of the detector extends from 1 to 9 Å. A rectangular honeycomb collimator with a field of view of 15° × 21·5° at half maximum intensity was mounted in front of the detector, with its long dimension coplanar with the rocket spin axis. The normal to the detector made an angle of 80° with the rocket axis. The orientation of the rocket during the flight was established from data obtained by two star sensors which registered the passage of stars across narrow rectangular fields of view. During the observations the rocket motion was a rapid spin about its long axis, and a slow precession of the spin axis around a yaw cone of small opening angle.

The presence of two sources in the band of directions scanned by the X-ray detector is evident from the data presented in Fig. 1. In this figure the number of counts is plotted as a function of angle around the spin axis for each of several intervals around the yaw cycle. Fig. 2 shows the traces of the normal to the detector across the sky at the mid-point of each of the time intervals for which the data were compounded to give the results given in Fig. 1. The numbers along the traces correspond to the angle around the spin axis as shown in Fig. 1. The left-hand peak (between angles 175° and 200°) appears to be due to the source in Scorpius. The other peak (between 200° and 225°) is due to a source in Sagittarius and may be coincident with Sgr *A*, the radio centre of the galaxy. The shape of the double peak can be accounted for entirely in terms of the angular response of the detector, which implies that the angular widths of the sources are smaller than 5° in the scan direction.

The maximum counting rates recorded when the normal to the detector came closest to the two sources were 12·6 counts cm^{-2} sec^{-1} for the Scorpius source and 5·5 counts cm^{-2} sec^{-1} for the Sagittarius source. If we tentatively assume an effective wave-length of 3 Å (that is, a wave-length near the peak of the spectral response curves of the detectors) we compute for these rates energy fluxes of 1·0 × 10^{-7} and 0·44 × 10^{-7} ergs cm^{-2} sec^{-1}, respectively.

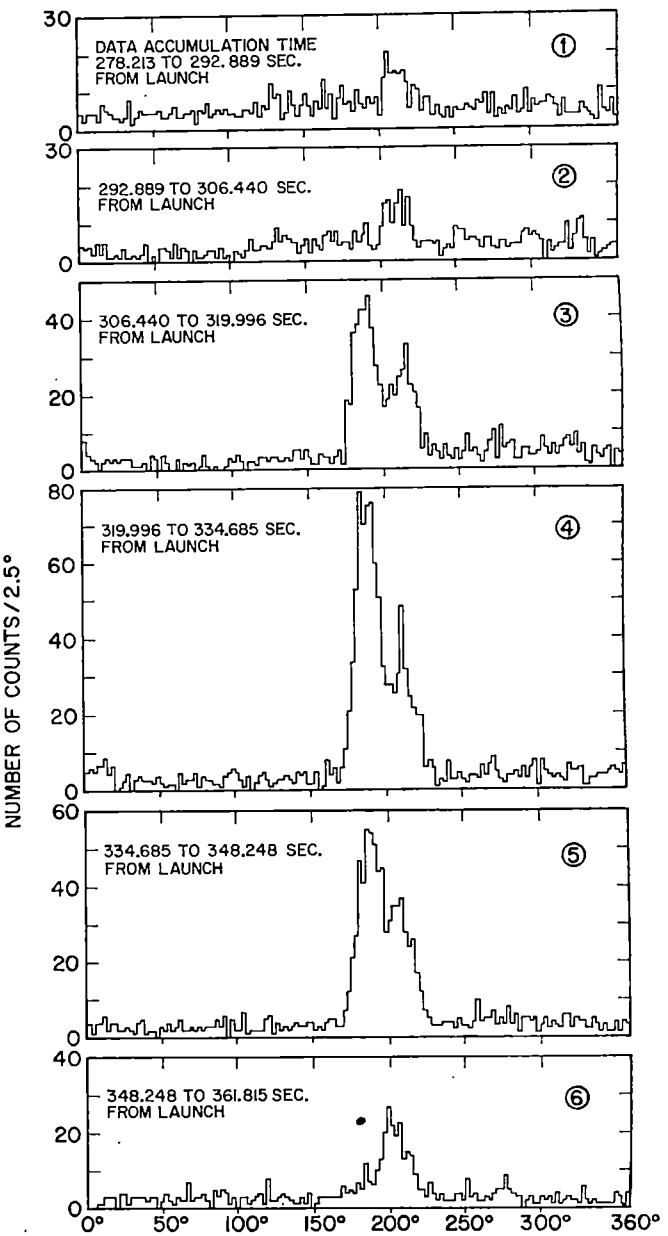

Fig. 1. Number of counts obtained in six time intervals plotted as a function of the angle around the rocket spin axis

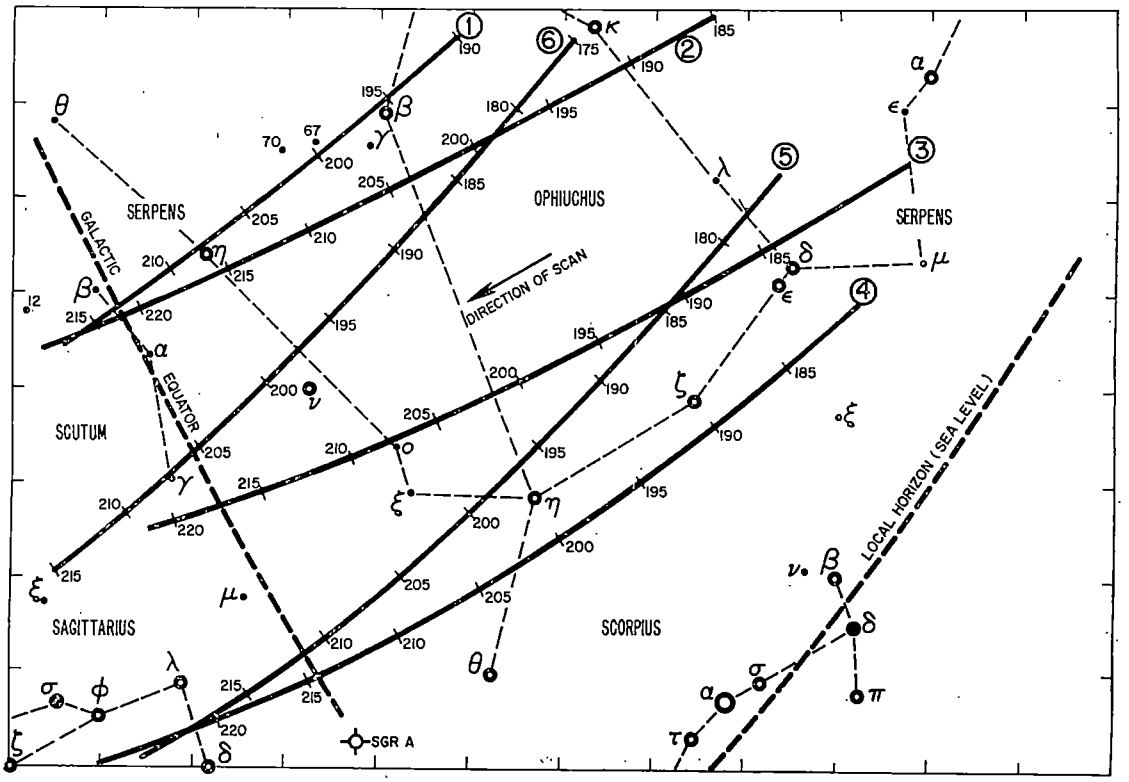

Fig. 2. Traces of the detector axis are shown in the region of the celestial sphere containing the two sources. The circled numbers refer to correspondingly numbered distributions in Fig. 1. The angles given along the traces correspond to those in Fig. 1

Upper Limit to Jupiter's X-ray Flux on September 30, 1962

During a search for celestial sources of X-ray emission, several opportunities arose to detect X-rays associated with Jupiter's radiation belts. The observations presented here were obtained from three successive scans of Jupiter made by a proportional counter flown on an *Aerobee* rocket launched from Wallops Island, Virginia. Although significant X-ray fluxes (which were time-dependent and apparently associated with or led to horizon effects) were observed, no X-ray flux from Jupiter was detected. The observations given in Fig. 1 below led to a conservative upper limit of $2{\cdot}4 \times 10^{-8}$ ergs/cm^2 sec for the flux of 4–8 keV (3–1·5 Å) photons from Jupiter between 0603 U.T. and 0605 U.T. on September 30, 1962.

The proportional counter employed had an effective aperture of 8 cm^2 provided by a beryllium window 0·005 in. thick set into the side of the counter. A sweeping magnet prevented electrons less energetic than 50 keV from impinging on the counter window. Collimation was provided by a simple aluminium baffle used to fix the field of view at (maximum widths of) 60° × 85°. The rocket rolled at a rate of 15°/sec and precessed in such a manner that the 60° dimension of the field of view scanned past Jupiter on three successive occasions early in the flight. Results related to galactic X-ray sources and details concerning instrumentation may be found in Fisher and Meyerott[1], and Fisher, Meyerott, Grench, Nobles and Reagan[2], respectively.

Fig. 1 gives the detector (labelled *K*–O–115) counting rate in two adjacent energy intervals for three complete rolls of the rocket as a function of time. A universal time of 0603 corresponds approximately to 100 sec after launching the rocket. The detector's field of view was inclined at an angle of 65° with respect to the rocket's nose, which was tipped down to the east by some 30° with respect to local vertical. As a result, the centre of the counter's field of view scanned along a path which rose above the northern horizon, passed approximately midway (near Cygnus) between zenith and the western horizon, descended to the southern horizon, and then scanned from south to north along the eastern horizon. The shaded areas in Fig. 1 separate regions in which the long (85°) dimension of the counter's field of view was completely above or below the rocket's horizontal horizon. Corrections made for counter dead time are such that instantaneous counting rates, for the combined energy intervals, greater than some 20 counts/cm^2 sec are not very precisely known. The 4–8 keV (3–1·5 Å) background of 9 photons/cm^2 sec (7·2 counts/cm^2 sec) was found by averaging data from the first two of the three available scans when the (85°) long central field of view dimension was completely above the horizon. The third scan was not used because Jupiter fell so near the edge of the counter's field of view that the detection sensitivity was only one-half that of the preceding two scans. Allowing for the 2 sec/scan that Jupiter fell within the counter's field of view at greater than 50 per cent detection efficiency, the upper limit for the 4–8 keV

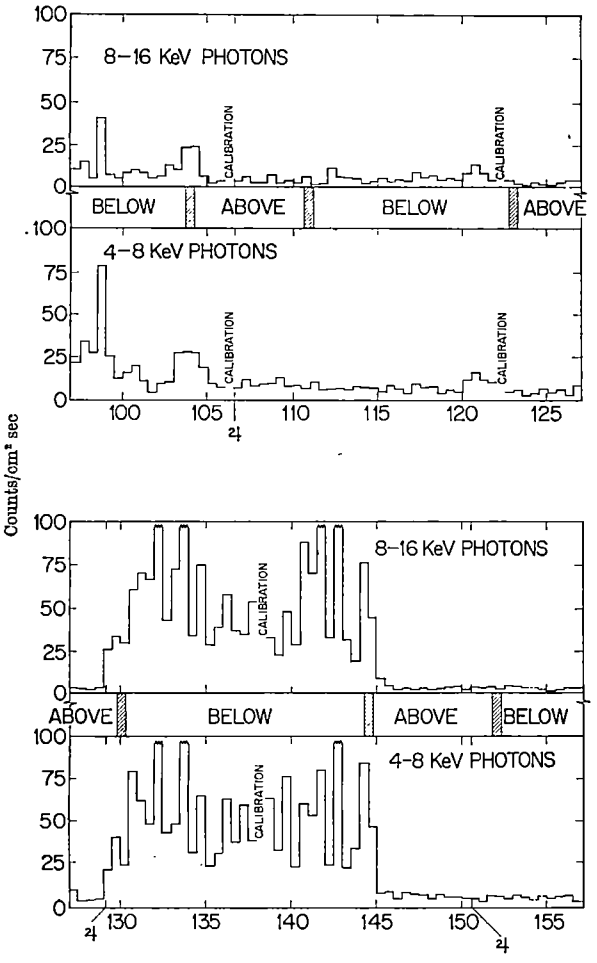

Fig. 1. Variation with time after launch of detector count rate in two adjacent energy-intervals

(3–1·5 Å) flux from Jupiter is 2·4 photons/cm² sec. This value corresponds to a signal three standard deviations above the average background level. Warwick[3] has estimated that Jupiter's X-ray flux might be of the order of 1/5,000 of the limit quoted here.

Further inspection of Fig. 1 establishes the fact that, during this part of the flight, instantaneous count rates significantly above the night sky background only occur when the detector's field of view includes some portion of the horizontal horizon. The complete northern auroral zone could be observed at one instant by the detector and measurements in that direction appear to produce the highest counting rate found during the whole flight. The time sequence given in the figure indicates a weak source near 104 sec of flight time, which was not present one roll later near 122 sec. However, at 145 sec, after the next complete revolution of the rocket, a source intense enough to jam the counter's electronics was found at approximately the same azimuth as the 104-sec source. The latest revolution indicates a source or sources extending along the whole eastern horizon, although the detected X-ray flux appeared to be most intense near the northern and southern extremities of the eastern horizon. Because of the rocket's precession, maximum sensitivity to the northern horizon source occurs at times separated by less than the 22-sec roll period of the rocket. No attempt has been made to associate the observed X-rays with the standard indicators of non-local ionospheric or auroral activity.

While significant and time-varying horizon related X-ray sources were found, no X-ray flux from Jupiter was observed. The upper limit to the 4–8 keV (3–1·5 Å) photon flux for the particular epoch investigated was 2·4 photons/cm² sec.

GEOPHYSICS

Downward Electron Flux at 1,000 km Altitude from Electron Content Measurement at Mid-latitudes

In a previous paper[1], describing diurnal variation of ionospheric electron content during November–December, 1961, at mid-latitudes, we reported the existence of a secondary maximum of ionization content below 1,000 km altitude for a period shortly after midnight. The data used in that paper were based on measurements of maximum inflexion Doppler slopes of simultaneous signals using high elevation orbits of the multiple-frequency navigational satellite 1961 *Omicron* I. Great care was taken to include in the statistics only those orbits for which the propagation paths of the various involved frequencies were nearly identical, that is, close to the overhead position. This reduces the available results considerably but increases the confidence in the correctness of the evaluation which assumes identical straight-line propagation. It could be seen that the diurnal contour of the content had some oscillations which need not indicate the presence of actual diurnal behaviour. Since the variation is based on two months of results the contour could include seasonal effects.

For this communication we have smoothed the obtained diurnal variation curve by normalizing each single observation of it with respect to the corresponding 10·7-cm radiation[2], $S_{10.7}$, which is an indicator of solar activity. The mean daily variation of the 10·7-cm flux for the period during which our observations were made is given in Fig. 1. This technique was previously used by Bauer and Blumle[3] for removing the seasonal effect superimposed on the diurnal variation of the topside ionosphere at fixed altitudes. Our curve is normalized to the average condition of $S_{10.7} = 92{\cdot}8 \times 10^{-22}$ W/m² (c/s) during observation time, making a proportional correction of the electron content to the corresponding (in date) variation of the 10·7-cm flux. The normalized curve is shown in Fig. 2. Although the diurnal curve was appreciably smoothed (indicating the correlation of the two quantities), the normalization failed to remove the midnight ionization content enhancement. This indicates that the content increase in regions below 1,000 km is real and deserves attention as to the mechanisms contributing to its production. At first, the correspondence of the content contour to the diurnal variation of the $h_{max}F_2$ for a similar period[4], as well as the approximate 12-h separation between the absolute content maximum (1400 E.S.T.) and the post-midnight maximum (0200 E.S.T.), suggested the influence of the semidiurnal solar tidal effects and the atmospheric natural mode of thermal oscillation whose period is close to 12[5] h in the creation of the midnight enhancement.

However, tidal and oscillatory effects cause vertically upward electron motion at noon and at midnight, whereas interpretation of the content curve must be described as

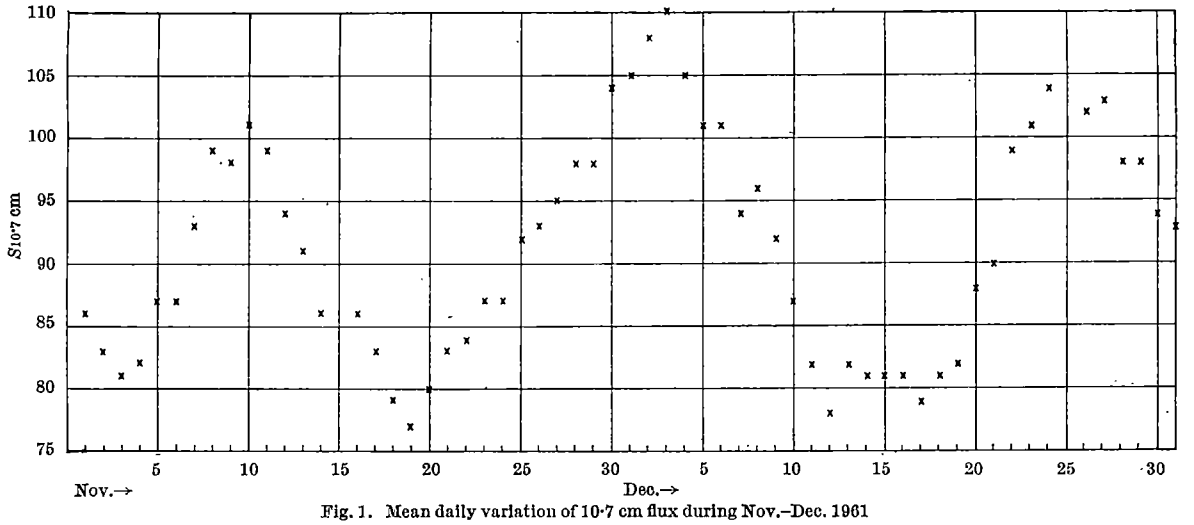

Fig. 1. Mean daily variation of 10·7 cm flux during Nov.–Dec. 1961

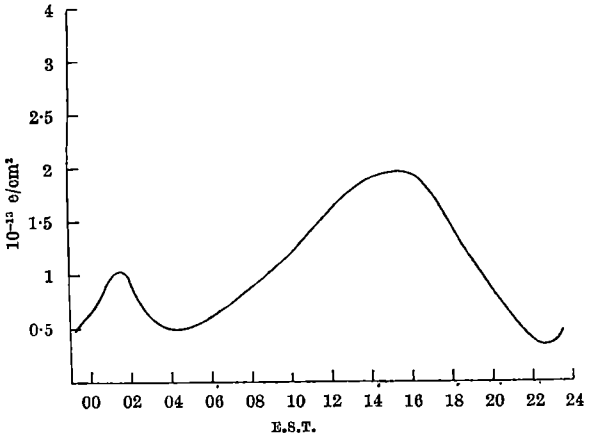

Fig. 2. Normalized diurnal variation of ionospheric electron content under 930 km during Nov.–Dec. 1961. (Note ionization content enhancement past midnight)

ionization drifts from ionospheric regions above the satellite (1,000 km) into ionospheric regions below it. In other words, the downward electron flux which is necessary to create the post-midnight maximum must be over and above the electron upward drift caused by tidal and oscillatory effects. (An analysis of the diurnal variation of the topside ionosphere electron density data at fixed altitudes (up to 1,000 km) points to a similar downward electron flux at night-time[6].)

The downward electron flux measured at the satellite's altitude is of the order of 5×10^8 electrons/cm^2/sec. The statistical uncertainties due to the lack of a great number of usable data (subject to the above-mentioned requirements of path equality, etc.) permit us to give only orders of magnitude rather than exact values. Using a value of 6×10^3 e/cm^3 at the satellite's average altitude, the above flux means that each second 1-km column of ionization of 1 cm^2 cross-section moves downward at the time of the post-midnight enhancement. It must be remembered, however, that the enhancement is over and above recombination and upward moving tidal and oscillatory motion. This consideration should increase the value for the downward flux by a factor of about two.

The flux seems to decrease substantially when the content contour reaches its secondary maximum at about 0130 E.S.T. From then on the content decreases with a rate which is equal to the decrease after sunset. (Note the parallelism of the content decay slopes after sunset and after the post-midnight enhancement.) The rate of decay at a certain time is proportional to the content value at that time, indicating a β-type attachment process for the two decreases. The secondary minimum (at 0400 E.S.T.) is slightly above the absolute minimum (2300 E.S.T.), indicating that not all the content-enhancement electrons recombined before the illumination of the topside ionosphere and the beginning of solar ionospheric ionization.

The mechanism responsible for the observed downward drift at high altitudes is not known. The possibility of horizontal ionization drifts from low latitudes into our latitude could also account, at least in part, for the observed ionization enhancement.

We thank Drs. S. J. Bauer of the National Aeronautics and Space Research Administration, Goddard Space Flight Center, and G. Goubau of our Institute for their advice. We also thank Mr. R. Silberstein of the U.S. Army Radio Propagation Agency for the 10·7-cm flux values, and Mrs. Myrna H. Meisner for performing the calculations leading to Figs. 1 and 2.

Some Irregularities observed simultaneously in the Upper and Lower Ionosphere at Middle Latitudes

Results from a ground network of fast ionosondes over western Europe, together with simultaneous topside soundings from the satellite *Alouette*, have revealed the existence of irregularities extending to both the upper and lower ionosphere.

The ionograms (kindly communicated by Dr. J. W. King, Radio Research Station, Slough) on Fig. 1 correspond—on the left-hand side—to *Alouette* observations recorded by the telemetry station at Winkfield, Bucks (England), and—on the right-hand side—to a panoramic sequence taken from the ground station at Garchy (Nièvre, France). The date was April 1, 1963, and the time 11.30–11.50 U.T. at ground-level, and 11.09–11.11 U.T. for the satellite, which covers 3 geographical deg/min.

On the last three topside ionograms, a series of oblique propagation traces are visible. In a previous publication, Du Castel[1] has shown that such traces could be interpreted as due to ducted propagation, the ducting surface being the lower edge of an irregularity, characterized by an

increase of ionization along a magnetic line of force. The kind of abnormal trace present on the second ionogram, where both a lower and an upper frequency limit appear, as compared with the normal trace, corresponds to the satellite moving towards the outer, convex face of the ducting irregularity.

The kind of trace visible on the 3rd and 4th, which show only an upper frequency limit, corresponds to the satellite moving towards the inner, concave face of the duct. As the two types of traces occur on several ionograms running, it is possible to evaluate the position as well as the characteristics of the irregularities themselves (Fig. 2).

Calculation[2] shows these three sheets of ionization are 8 km thick transversally to the magnetic field, with maxima of 0·4 per cent in excess over the ambient plasma.

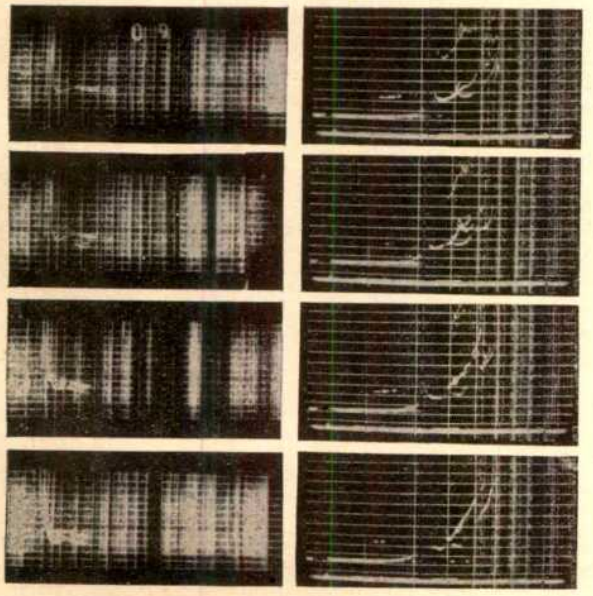
On the ground-based simultaneous ionograms, a fork appears at the upper end of the F_2 trace. This fork moves gradually downwards, first along the F normal trace, then along the E region trace, to disappear finally in a weak, short-lived sporadic E ionization.

These irregular traces are generally considered to be moving disturbances[3]. The simultaneous existence of such perturbations, on ground-based as well as topside ionograms, has already been mentioned[4]. When they are observed by ground-based network of ionosondes, the front is usually moving southwards, with an apparent speed over the ground of 100–200 m/s^{-1}. In the present case, three perturbations have been effectively observed (Fig. 2), with certain time-lags between the stations: Breisach (Bade, Germany), Garchy (Nièvre, France), Poitiers (Vienne, France) and Tortosa (Spain), from which it has been possible to deduce an apparent speed of 180 m/s^{-1}, and a direction at right-angles to the lines of isomagnetic inclination.

Thus the dimensions of these irregularities have been deduced from their special guiding effects on topside ionograms, and their movement from the ground-based network. Notice that their speed cannot be observed by the satellite, which travels more than 30 times faster.

Further, the irregularity corresponding to the first ducted echo on the *Alouette* ionograms has been very clearly observed, simultaneously at the stations Garchy and Poitiers, and 45 min later at Tortosa; it does not appear at Breisach. This shows that the longitudinal extension of such perturbations can be limited, and that they can be local in character.

The hypotheses which can account for such ionization irregularities at middle latitudes have recently been



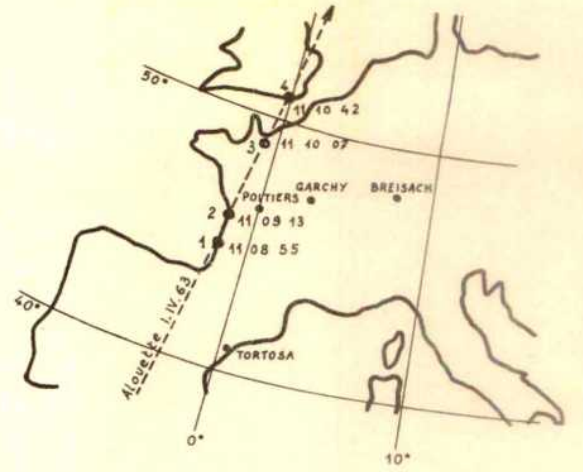


Fig. 1

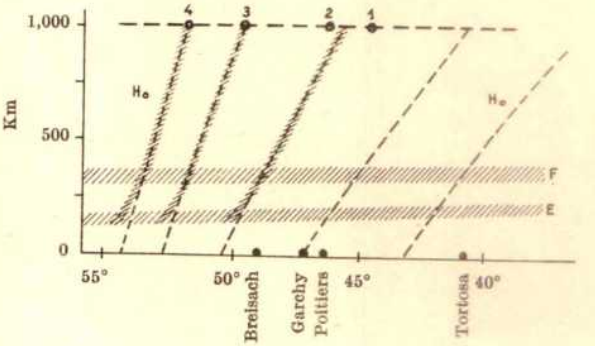

Fig. 2

examined[5]. It is reasonable to suppose that these irregularities originate at high latitudes, and then move towards equatorial regions under the influence of the S_q (currents) circulation. However, it seems impossible as yet to decide whether they have a magnetospheric origin from incident particles, or whether they are generated by this ionospheric S_q system.

Better understanding of these irregularities, obtained through further ground-based and topside observations similar to those mentioned in this communication, would be a help towards the interpretation of upper atmosphere phenomena.

PHYSICS

Quadruple Frequency Multiplication of a 1·06-μ Neodymium-pulsed Laser

The fourth harmonic of a Q-spoiled high-intensity neodymium-in-glass laser was produced using the non-linear optic effect in two KDP (potassium dihydrogen phosphate) crystals. The laser output pulse at 1·06μ has been converted successively to 5300 Å and 2650 Å. The purpose of the communication is to report these experimen-

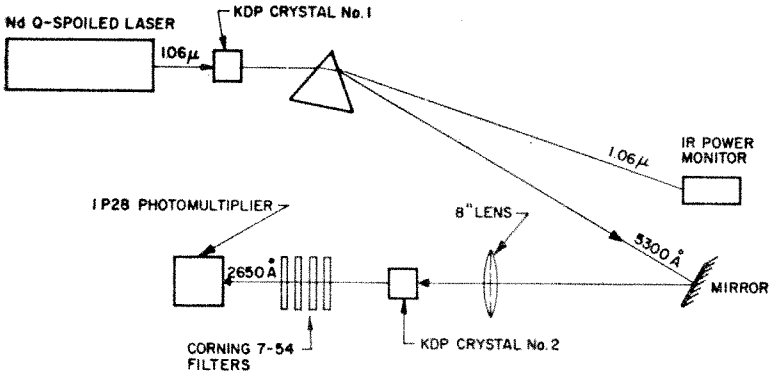

Fig. 1. Schematic diagram of experimental arrangement

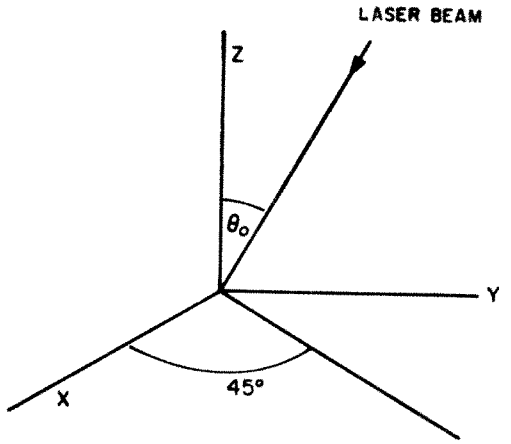

Fig. 2. Critical angles for harmonic generation

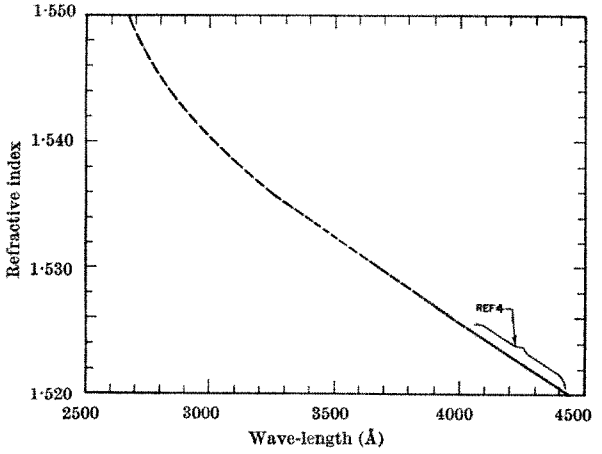

Fig. 3. Ordinary refractive index of KDP derived from the second harmonic generation results

tal results and to point out the potential importance of this high-intensity spatially coherent radiation at 2650 Å.

The experimental arrangement used is shown schematically in Fig. 1. The unfocused 10-MW output from the neodymium, *Q*-switched laser was passed through KDP crystal No. 1, which was properly index matched[1,2] for maximum energy conversion from 1·06μ to 5300 Å. A dispersive prism separated the 1·06μ and the green 5300 Å radiation. The green radiation was then reflected from a high-quality mirror and focused with an 8-in. lens on to KDP crystal No. 2. This crystal was again orientated in such a manner that the index matching the condition was satisfied for optimum energy transformation from 5300 Å to 2650 Å.

Table 1. Summary of Data on Frequency Quadrupling

Wave-length	Power	Pulse-width (nsec)	Index matching angle θ_o experimental
1·06 μ	10 MW	15	40° ± 1°
5300 Å	200 kW	10	
2650 Å	2·4 kW	—	77° 20′ ± 1°

In addition to choosing the appropriate polar angle, θ, and the azimuthal angle, Φ, proper care had to be taken so that the incident electric field components of the laser pulses were correctly polarized[3], that is, they were in the *xy* crystallographic plane and perpendicular to the bisector of the *xy* axis. Note the various changes in polarization. As the beam enters the crystal it is vertically polarized at 1·06μ. It then emerges as the extraordinary ray in crystal No. 1 at 5300 Å horizontally polarized, and again emerges as the ordinary ray vertically polarized at 2650 Å.

The results of power measurements at the respective wave-lengths are shown in Table 1. There was a noticeable pulse shortening at higher harmonics due to the quadratic nature of second harmonic generation. The conversion efficiency from infra-red to green is about 2 per cent and about 1 per cent from green to ultra-violet. It should be noted, however, that the laser beam is focused on KDP crystal No. 2 only, and not on No. 1, hence the apparent comparable conversion efficiencies. Higher conversion efficiencies, that is, 20 per cent, from infra-red to green would be expected if focusing were to be used in the first conversion. This was not done to avoid damage to the KDP crystal.

The critical angle, θ_o, which represents the angle subtended by the incoming laser beam and the optic axis, *z* (Fig. 2), and which allows the primary and second harmonic beams to travel at the same phase velocity[1,2] is given by the expression:

$$\sin^2\theta_o = \left(\frac{{}_en_2}{{}_on_1}\right)^2 \frac{({}_on_2 + {}_on_1)({}_on_2 - {}_on_1)}{({}_on_2 + {}_en_2)({}_on_2 - {}_en_2)} \qquad (1)$$

where the subscripts *e* and *o* refer to the extraordinary and ordinary index respectively and the subscripts 1 and 2 to the primary and second harmonic.

Equation (1) can be re-written to a good approximation for the region 2500–5000 Å:

$$\sin\theta_o = \left(\frac{{}_on_2 - {}_on_1}{{}_on_2 - {}_en_2}\right)^{\frac{1}{2}} \qquad (2)$$

Substitution of representative values of *n* in equation (2) shows that uncertainties in the index of refraction of one part per thousand causes an error in θ_o of the order of 1 per cent. Since θ_o can be measured to a precision of 10′, obviously more accurate values of *n* are obtainable by this technique. The quoted errors in θ_o arise because of experimental uncertainties in the X-ray crystallographic determination of the optic axis. We have measured the second harmonic generation in KDP over a wide range of wave-lengths, as shown in Table 2.

Table 2. Table of Wave-lengths and Refractive Indices

	Primary wave-length (Å)	Second harmonic wave-length (Å)	θ_o exp.	θ_o calc.	${}_on_1$	${}_on_2$	${}_en_2$
a	10,600	5300	40° ± 1°	40°	1·495$_5$	1·513	1·470$_5$
b	6943	3472	50° ± 1°	49° 44′	1·506	1·533	1·487
c	6328	3164	55° 40′ ± 1°	56° 6′	1·508$_8$	1·537	1·495$_5$
d	5300	2650	77° 20′ ± 1°	77° 12′	1·513	1·552	1·511

Note: All the experimental results in Table 2 were taken on a single crystal of KDP. The second harmonic generation of *a* and *b* has been reported also by other workers[1–3]; however, *c* and *d* represent new results[4].

All the second harmonic generation data were found consistent with the refractive index data[4], provided a small correction in the last significant place of the published refractive index data was made (which is well

within the stated error of their measurements). However, since recently two new measurements[5] on the second harmonic generation extending to the ultra-violet were made, it is possible to extrapolate values of the ordinary index of refraction to 2650 Å with a precision which is comparable to the published values in the visible region. See Fig. 3 for the results of the values of the refractive index.

The importance of these results points out the possibilities of new coherent optical sources with powers in the kW region and wave-lengths in the ultra-violet spectral region. A number of new experiments suggest themselves with such a source. The 2650 Å wave-length, for example, lies in the region of strong absorption for purine and pyrimidine[6] and other related compounds which are contained in living tissues. Thus, damage done to living cells may now be probed with this source.

I thank Drs. G. R. White, P. C. Fletcher and D. E. Rounds for their advice, W. C. Goss and M. J. Weinberg for their assistance, and J. W. Burns for performing the X-ray analysis.

Ionization of Mercury by Alkali Positive Ions

A NUMBER of workers have investigated ionization of gases by positive ions of low energies[1–5]. They have measured ionization electron current produced by positive ions by their impact with gas atoms. The greatest uncertainty in these investigations is due to the emission of secondary electrons from metals by positive ions and is an inherent weakness in most of these methods. The sensitivity of the apparatus used for detecting very small ionization electron current is another important consideration in these measurements. Disagreement in the results obtained by different workers may be ascribed mainly to these two factors. Values for ionization cross-sections and for on-set potentials vary from one observer to the other, but there is a general agreement concerning the belief that ionization of gases by positive ions of low energies is not caused by direct collisions between incident ions and electrons of the target atom. Satisfactory theory to explain the mechanism of this phenomenon in this energy-range is still lacking.

Accurate data for ionization on-set potentials and on cross-section measurements for slow ions in different gases are useful in understanding this process and are of importance and interest in plasma physics.

It has been observed[6] that K^+ ions of 220-V energy ionize mercury vapour. The ionization was detected by a photosensitive Geiger counter. In some earlier experiments[7] it was reported, however, that mercury atoms are not ionized by K^+ ions of energy less than 300 V.

In the work recorded here a much more sensitive device is used for detecting the radiation resulting from ionization of mercury. The object is to investigate if a lower on-set potential exists for this process to occur in this gas.

The ions are supplied from a Kunsman source. A 'Pyrex' ground-glass joint fused to a quartz chamber through a 'Pyrex'-quartz graded seal carries the K^+ ion source which is deposited on a directly heated tungsten filament. The ions are accelerated from the filament to a collimating slit system, carefully adjusted to be coaxial with the chamber, by low-voltage Exide batteries. The defined ion beam travels a distance of about 10 cm in the quartz chamber where collisions of K^+ ion occur with mercury vapour contained in it. The positive ion current is collected in a Faraday cup placed at a distance of about 16 cm from the source and is measured by a moving coil galvanometer of the sensitivity of 10^{-10} amp/mm. The collimating slits and the Faraday cup are held firmly in position by 'Pyrex'-tungsten seals fused into the body of the 'Pyrex' glass component of the apparatus. The interior of the chamber containing vapour of distilled mercury is well covered by a metal shield to check the scattered ions from striking against the quartz walls.

The apparatus was continuously pumped out through a liquid air trap by a two-stage mercury diffusion pump backed by a rotary oil pump. It was proved to be leak-tight before observations were made. The vacuum inside the apparatus was 10^{-6} mm mercury during the course of experiments and the vapour pressure of mercury in the chamber was maintained at $2–3 \times 10^{-3}$ mm mercury.

The radiation emitted by mercury vapour, excited and ionized by the impact of K^+ ions, was detected and measured by a quartz photoelectron multiplier, type E.M.I. 6255, which 'peeped' into the chamber through a wide window provided in the metal shield. The radiation was examined using ultra-violet interference filters supplied by Messrs. Barr and Stroud of Glasgow, the peak transmission of which varied from 14 to 23 per cent and band-width ranged between 150 Å and 200 Å.

The apparatus and the photomultiplier were placed in a closed light-tight enclosure in which a steady temperature was maintained, a condition which is necessary to keep mercury vapour pressure constant as well as to obtain reproducible observations with the photo-tube.

The photomultiplier pulses were fed through a cathode follower to a high gain amplifier the output of which was read in a scaler. A stabilized power unit provided the high voltage to the photo-tube.

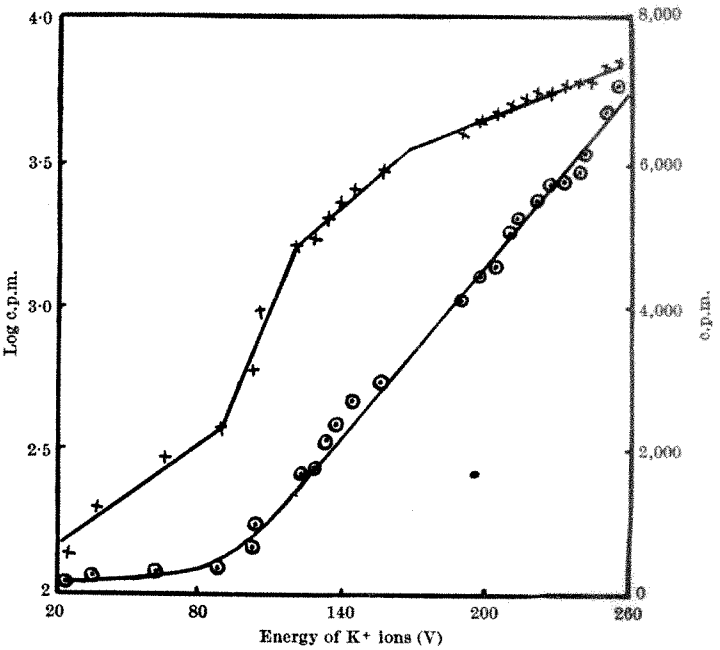

Fig. 1

Curve ⊙ of Fig. 1 shows the variation of the intensity of the radiation with ion energy for a constant K^+ ion current to the Faraday cup for mercury line 2537.

It is observed that the radiation is first emitted at an energy as low as 60 V; its intensity rises gradually with ion energy but there is an abrupt increase at 89–90 V. The rise in the intensity of the radiation is rapid above this energy.

We believe that the radiation detected by us at ion energies of 89–90 V and above is the recombination spectrum emitted by ionized mercury vapour. It is found that the strongest line in this radiation is 2537 and all other lines are comparatively very faint. This is what is observed in a low-pressure mercury arc spectrum[8].

The electric field distribution in the apparatus does not permit secondary electrons to gain a velocity high enough to produce excitation and ionization of mercury atoms. The fact that the radiation is emitted when the accelerating voltage is applied to ions and not without it ensures that photo-ionization due to ultra-violet radiation from heated filament carrying the source is negligible and beyond our detection. It was also observed that by putting a pad dipped in liquid air on the quartz chamber the counts of the photo-electron multiplier dropped to normal background.

Relation between the total intensity of radiation emitted by the ionized gas and the energy of K^+ ions is quite identical with curve ⊙, Fig. 1. A semi-log curve for this relation shows discrete kinks curve ×, Fig. 1.

It is probable that there are different modes of ionization of mercury atoms which may be excited at varying energies of K^+ ions. New groups of ionization electrons have, however, been detected[4] in ionization of argon, neon and krypton by K^+ ions of increasing energies, which support this assumption.

We thank Sir James Chadwick, Sir John Cockcroft and Sir Mark Oliphant for their advice, and CENTO administration for a fresh supply of ultra-violet filters.

Identification of Free Radicals in Flash Photolysis

McGrath and Morrow[1] have recently reported on a spectrum near 3290 Å obtained in the flash photolysis of fulminic acid which they ascribe to the free CNO radical. It appears that this spectrum is the same as that found independently by Jennings and Linnett[2] and ourselves[3]. The spectrum has recently been analysed in detail and shown to be due to the free NCN radical[4]. All the strong bands listed by McGrath and Morrow agree with strong NCN bands listed in our paper and relative intensities are roughly the same. We believe that on the basis of the observed intensity alternation and the observed triplet splitting, there can be no doubt that our identification of this spectrum is correct.

The occurrence of the spectrum of NCN in the flash photolysis of fulminic acid is an example of the need for caution in the assignment of observed spectra on the basis of excitation conditions or chemical considerations only. The history of spectroscopy abounds in such examples. We only need to mention the spectrum observed in the flame produced by active nitrogen when BCl_3 is introduced into it. From the excitation conditions this spectrum was first believed to be due to BN until Mulliken[5] showed conclusively by observation of isotope shifts that it is due to BO. Similarly, in more recent years, the 4050 Å group of cometary spectra, since it occurs in a discharge through CH_4, was first thought[6] to be due to CH_2. However, isotopic investigations[7] showed it to be due to C_2. The observation of the same spectrum in the flash photolysis of diazomethane is equally surprising if one bases expectation on photochemical arguments. Many similar examples could be quoted.

It is indeed interesting that the spectrum of NCN appears in the flash photolysis of fulminic acid as well as in the flash photolysis of diazomethane and in the action of active nitrogen on hydrocarbons. This information may now be used to draw conclusions about the kinetics of these various reactions, but we feel it is not possible to draw definite conclusions about the nature of the carrier of a spectrum from photochemical evidence alone.

In our previous communication[1] we gave an account of experiments on the flash photolysis of cyanogen/oxygen and cyanogen/ozone mixtures in which a new transient band system was obtained in absorption in the wavelength region 3250–3330 Å. Although the rotational structure of the band system could not be resolved because of the low dispersion used, the chemical and kinetic evidence obtained from these and related experiments indicated that the most likely absorbing species was the free fulminate radical (C—N—O). This same spectrum has recently been obtained by Herzberg and Travis[2] also by flash photolysis, using diazomethane and diazomethane/cyanogen mixtures. These authors were able to carry out a vibrational and rotational analysis of the band system and from their observations have concluded that the absorbing species is NCN. This conclusion of Herzberg and Travis is substantiated by their carbon isotope experiments showing the presence of one carbon atom and the observation of an intensity alternation indicating the presence of two identical nuclei of non-zero spin. The observed triplet splitting is also consistent with the assignment of the absorber to NCN. However, these workers have not attempted to give any kinetic mechanism for the formation of the NCN radical in their systems and did not carry out any isotopic experiments to disprove the presence of oxygen.

Although the spectroscopic evidence in favour of CN_2 is very strong, particularly the observation of the intensity alternation, it is not so easy to reconcile this assignment with the chemical kinetics of the systems in which it has been observed, and it would seem almost as dangerous to rely solely on spectroscopic evidence and not consider the possible chemical processes which could lead to the formation of the postulated absorber.

The most significant fact to emerge from the flash photolysis experiments on cyanogen mixtures which we have carried out is that oxygen must be present in the

reaction mixture in order to obtain the 3290 Å system, and that the intensity of this system is strongly dependent on the oxygen concentration. Unless rigorous precautions are taken to ensure total exclusion of oxygen from the reaction mixture the 3290 Å system can be detected when cyanogen/inert gas mixtures are flashed. The most intense spectrum was obtained when the oxygen concentration was 1/100 per cent that of the cyanogen concentration. Since it is easy to attain this if the cyanogen is insufficiently degassed or if high swamping concentrations of inert gas containing a few tenths of a per cent air or oxygen are used it would be easy to overlook the important function of oxygen in obtaining the spectrum. With higher concentrations of oxygen the 3290 Å system is weakened, being totally suppressed in a $(CN)_2/O_2$ mixture of ratio 4/1.

The kinetic mechanisms postulated for the production of the fulminate radical in these experiments and in the flash photolysis of fulminic acid have already been discussed[1]. If the radical responsible for the 3290 Å band system is actually NCN, as suggested by Herzberg and Travis, it is not so easy to provide a convincing reaction scheme, since it must satisfy the following conditions.

(1) A variety of cyanogen mixtures were investigated, including those containing oxygen, ozone, nitrogen dioxide, nitrous oxide, carbon disulphide, carbonyl sulphide, halogens, nitric oxide, carbon dioxide and carbon monoxide. Only in the cases of oxygen, ozone and nitrogen dioxide was the 3290 Å system observed.

(2) The 3290 Å system was not observed when pure cyanogen was flash photolysed. This latter fact indicates that if the 3290 Å spectrum is due to CN_2 it cannot arise by the reaction:

$$CN + N \equiv C - C \equiv N \rightarrow NCN + C_2N \qquad (1)$$

which is in any event to be expected from thermochemical and kinetic considerations. It is also in agreement with condition 1.

When a cyanogen/oxygen mixture is flashed only the cyanogen dissociates to give two CN radicals. These react with the oxygen to give the observed NCO radical according to:

$$CN + O_2 \rightarrow NCO + O \qquad (2)$$

For the production of NCN the most feasible process would be the further reaction of NCO with a CN radical.

$$CN + NCO \rightarrow NCN + CO \qquad (3)$$

In the cases of cyanogen/ozone/argon and cyanogen/nitrogen dioxide/argon experiments, in which the cyanogen was prevented from direct dissociation in the photolytic flash and only the ozone and nitrogen dioxide broke up to yield respectively ^1D and ^3P oxygen atoms, the reaction scheme would then be:

$$O(^3P \text{ or } ^1D) + (CN)_2 \rightarrow NCO + CN \qquad (4)$$

followed by (3).

If the observed 3290 Å system is, in fact, due to NCN then it must be concluded that reaction (3) is responsible for its production and that it is a very fast reaction. It is interesting to observe here, however, that the analogous reaction (5) in the case of the sulphur analogue NCS, produced in the flash photolysis of cyanogen/carbonyl sulphide mixtures, does not occur, that is:

$$CN + NCS \rightarrow NCN + CS \qquad (5)$$

since no sign of the 3290 Å system appeared in any of the cyanogen/carbonyl sulphide experiments. Reaction (5), however, would undoubtedly not be as thermochemically favoured as reaction (3).

Recent work in this laboratory using cyanogen/ethyl isocyanate mixtures was inclusive as regards the occurrence of reaction (3) because of the insufficient concentration of NCO obtainable. Mass spectrum analysis of the final products from flash photolysed cyanogen/oxygen/argon mixtures, however, did show the presence of a small concentration of a stable product of mass 80, which would correspond with $(NCN)_2$ along with the expected CO and N_2. This result is indicative of the presence of NCN in the reacting system but is not conclusive proof for the assignment of the 3290 Å absorber to NCN.

A final point of difficulty with the NCN hypothesis is how it can be fitted into a reaction scheme for the combustion of cyanogen which results in only CO_2, CO and N_2 as end-products.

A General Expression for the Isentropic Stagnation Temperature of a Fluid

The stagnation temperature of a fluid is commonly represented by the expression:

$$T_0 = T_\infty + \frac{U_\infty^2}{2c_p} \qquad (1)$$

where T, U and c_p denote the temperature, velocity and specific heat at constant pressure, and the subscripts 0 and ∞ refer to the stagnation point and free stream, respectively.

It must be remembered, however, that this expression is true only for a perfect gas. For general application it is recommended that equation (1) be presented in the general form:

$$T_0 = T_\infty + \frac{T}{v}\left(\frac{\partial v}{\partial T}\right)_p \times \frac{U_\infty^2}{2c_p} \qquad (2)$$

where v denotes the specific volume.

This equation is valid for mono-phase fluids, liquids or gases, and is obtained by correlating the changes of pressure, kinetic energy and temperature in the assumed isentropic process of stagnation.

The steady flow energy equation applied to an isentropic flow gives the isentropic change of enthalpy,

$$(\mathrm{d}h)_s = v\,(\mathrm{d}p)_s = -U\mathrm{d}U \qquad (3)$$

From Maxwell's relations and the definition of specific heat at constant pressure:

$$\left(\frac{\partial T}{\partial P}\right)_s = \frac{T}{c_p} \times \left(\frac{\partial v}{\partial T}\right)_p \qquad (4)$$

By substituting for $(\mathrm{d}p)_s$ from equation (3), and rearranging, equation (4) becomes:

$$(\mathrm{d}T)_s = -\frac{T}{v} \times \left(\frac{\partial v}{\partial T}\right)_p \times \frac{U\mathrm{d}U}{c_p} \qquad (5)$$

Equation (2) is then obtained by integrating equation (5) between the free-stream and stagnation conditions, and assuming that $\frac{T}{vc_p} \times \left(\frac{\partial v}{\partial T}\right)_p$ is a constant (or adopting an average value).

For a fluid obeying the perfect gas law the stagnation coefficient $\frac{T}{v} \times \left(\frac{\partial v}{\partial T}\right)_p$ is equal to unity; only then is equation (1) applicable.

For water at atmospheric pressure, the coefficient varies from about 0·04 at 14° C to about 0·12 at 50° C, but at high pressures and temperatures it may exceed that of a perfect gas. For example, at 200 atmospheres and 300° C the coefficient reaches 1·43. An even more interesting fact is that, at temperatures between 0° C and 4° C and low pressures, the stagnation coefficient for water is negative (because $\left(\frac{\partial v}{\partial T}\right)_p$ is negative). Thus, contrary to expectation, the stagnation temperature is less than that of the free stream.

MINERALOGY

Structure of Opal

Since the work of Flörke[1] it has generally been accepted that natural opaline silicas fall into two broad categories: (1) specimens which give X-ray patterns indicative of an obviously, although in some cases poorly, crystalline structure; (2) specimens which give X-ray patterns showing only a few diffuse bands. Earlier work by some of us[2] supported these conclusions, and a comprehensive re-examination of natural opals has confirmed that the structure can vary from almost perfect α-cristobalite to apparently amorphous or near amorphous material. The X-ray diffractometer traces shown in Fig. 1 illustrate the variations encountered; it should be noted, however, that, of the diffuse bands visible on powder photographs, only that at about 4·1 Å is recorded in traces *G* and *H*. Most specimens which would be termed 'common opal' by mineralogists are crystalline. Rarely, these may be well crystallized, as in sample *B* (which may be compared with *A*, a synthetic α-cristobalite), or very poorly crystallized, as in *F*. Most samples, however, give traces similar to *C*, *D* and *E*. Most precious opals and their associated 'potch', as well as hyalite, give patterns like *G* and *H*.

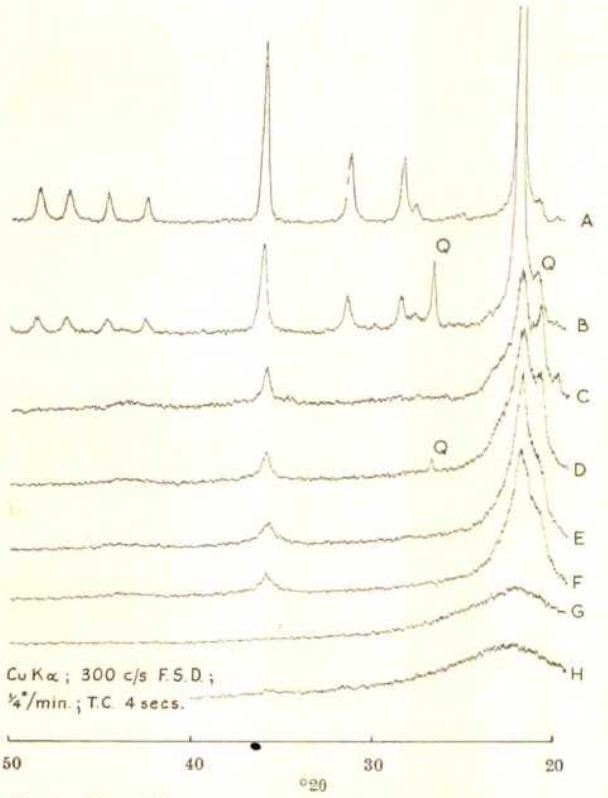

Fig. 1. X-ray diffractometer traces. *A*, α-cristobalite, prepared by heating opal from Coober Pedy, South Australia, at 1,200° C for 30 h; *B*, jasp-opal, Guanjuato, Mexico, No. 1664; *C*, common opal, Sunbury, Victoria, No. 19023; *D*, common opal, Kalgoorlie, Western Australia, No. 4680; *E*, common opal, Stony Creek, Victoria, No. 19020; *F*, jasp-opal, locality unknown, No. 2225; *G*, milky opal, locality unknown, No. 19000; *H*, precious opal, Coober Pedy, South Australia, No. 17015. Peaks marked *Q* are due to quartz. Numbers refer to specimens in the Geology Department Museum, the University of Adelaide

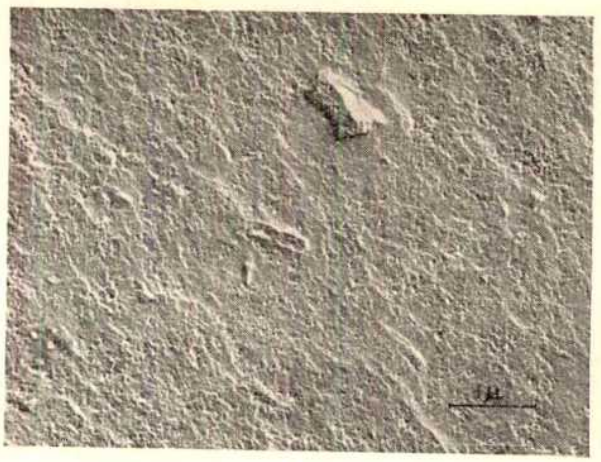

Fig. 2. Replica of fresh fracture surface of a transparent wood opal from Lake Eyre, South Australia. X-ray pattern of this sample is similar to *D*, Fig. 1, No. 1445

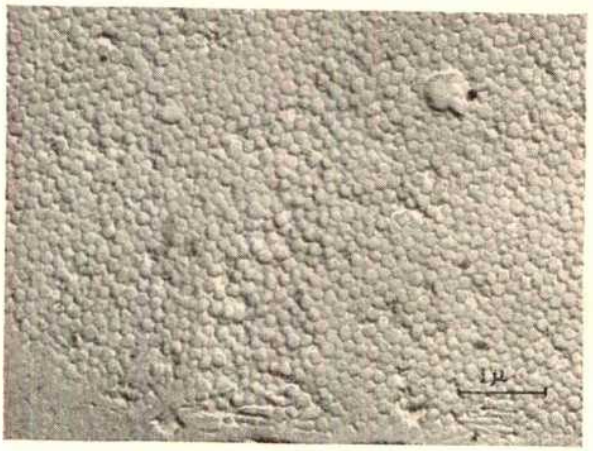

Fig. 3. Replica of transverse section of opalized wood, showing cell filled with silica spheres. Polished and lightly etched sample from White Cliffs, New South Wales. X-ray pattern similar to *H*, Fig. 1, No. 4662

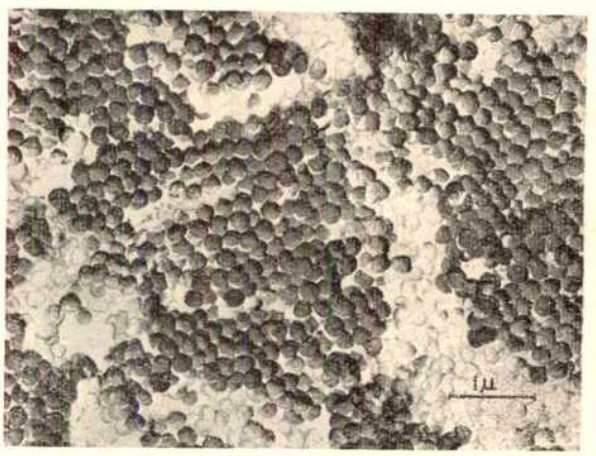

Fig. 4. Replica of etched surface of precious opal from Coober Pedy, South Australia. X-ray pattern *H*, Fig. 1, No. 17015

Although electron diffraction patterns of powdered samples generally confirmed the X-ray results, transmission electron micrographs showed only minor differences between the two groups of opal. By contrast, electron micrographs of surface replicas of freshly broken surfaces showed quite different gross structures. 'Crystalline' opals showed a relatively fine-grained uneven surface, the nature of which is still uncertain (Fig. 2). 'Amorphous'

opals, apart from glass-clear hyalites of low water content, showed discrete areas composed of close-packed aggregates of silica spheres of uniform size (Figs. 3 and 4). The diameter of the spheres is commonly in the range of 1500 Å–3500 Å.

The evidence presented here indicates a distinct break in structural properties between the two major groups of opals. It is believed that sufficient samples have been examined to indicate that this division is real, and may reflect differences in the genesis of the opals.

CRYSTALLOGRAPHY

$TiAs_2$-type Phases

The structure of $TiAs_2$, which is of a new type, has recently been determined by Wenglowski *et al.*[1]. The orthorhombic unit cell contains eight formula units which comprise two kinds of titanium and four kinds of arsenic atoms. The co-ordination of Ti_I and Ti_{II} is very similar. Both have six As neighbours forming a trigonal prism and three more neighbours lying at the corners of a triangle perpendicular to the prism axis. The corners of this triangle are occupied by 3As in the case of Ti_I and by 2As + $1Ti_{II}$ in the case of Ti_{II}. As_I is located at the centre of a tetrahedron formed by $1Ti_{II} + 2Ti_{II} + 1As_I$. As_{II} and As_{III} lie at the centre of a distorted tetrahedron of $3Ti_I + 1Ti_{II}$. Finally, As_{IV} is placed at the centre of a trigonal prism of $2Ti_I + 4Ti_{II}$, a co-ordination which is also found in α-TiAs (TiP type) and β-TiAs (NiAs type). This co-ordination immediately reveals that $TiAs_2$ must be metallic though its composition would suggest the possibility of a semi-conductor of ionic formula $Ti^{4+}(As_2)^{4-}$. However, only one of the four different arsenic atoms forms pairs, but half the cations are connected as well. Assuming single bonds between Ti_{II}–Ti_{II} and As_I–As_I, we are left with 44 anion valence electrons per unit cell for the cation–anion bonds which cannot be balanced by the 28 available cation electrons and thus induce metallic conductivity. My resistivity measurements in fact confirm these conclusions.

$TiAs_2$ seems to be the only arsenide of this structure type, $ZrAs_2$ (ref. 2) and $HfAs_2$ (ref. 3) crystallizing in the *C*23 type of structure. We found this structure, however, in two antimonides, $ZrSb_2$ and α-$HfSb_2$ (low-temperature modification). Their lattice constants are listed in Table 1 together with the data derived for $TiAs_2$. Though Wenglowski *et al.*[1] deduced from their tensimetric analysis the existence of a broad homogeneity range for $TiAs_2$, we could not detect a difference in the X-ray patterns of different samples of all three compounds. $ZrSb_2$ and $HfSb_2$ also show metallic conduction and a small *p*-type thermoelectric power. Since no localized *d* electrons are left on the cations, a temperature-independent dia- or para-magnetism is to be expected in these compounds.

There is little doubt that $ZrBi_2$, the lattice constants of which have been reported by Bykov and Kazarnikov[4], also crystallizes in this structure. Our bismuthide samples did not allow a determination of the lattice constants but Guinier patterns give some indication that $HfBi_2$ is isostructural with $ZrBi_2$.

Table 1. Lattice Constants of $TiAs_2$-type Phases

	a (Å)	*b* (Å)	*c* (Å)
$ZrSb_2$	14·974 ± 14	9·968 ± 5	3·878 ± 3
α-$HfSb_2$	14·981 ± 12*	9·869 ± 5	3·848 ± 3
$TiAs_2$	13·220 ± 8	8·915 ± 4	3·478 ± 2
	13·27 (ref. 1)	8·96 (ref. 1)	3·50 (ref. 1)

I thank Mr. H. U. Boelsterli for assistance in sample preparation and X-ray work.

Note added in proof. For $HfBi_2$, which in powder form is as strongly pyrophoric as $ZrBi_2$, I obtained the following lattice constants: $a = 15{\cdot}7$ Å, $b = 10{\cdot}1$ Å, $c = 3{\cdot}93$, which are nearly the same as those of $ZrBi_2$ (ref. 4).

CHEMISTRY

Chlorine Hyperfine Splittings in Phenoxy Free Radicals

Hollocher *et al.*[1] have presented evidence for chlorine hyperfine splittings of the electron spin resonance spectrum of 2-hydroxy-1,4-naphthosemiquinone chloro-derivatives. The observed splitting was quite small (0·28 gauss) and no attempt was made to present a value for a chlorine splitting constant. In order to obtain a larger splitting from the chlorine nuclear spin and perhaps also to obtain an estimate of the splitting constant, an electron spin resonance investigation of the chloro-derivatives of phenoxy radicals was made. The electron spin resonance spectrum of the unsubstituted phenoxy radical has been obtained by Stone and Waters[2], using a flow apparatus[3] in order to detect this short-lived free radical. The electron spin resonance spectra of the free radicals of phenol, *p*-chlorophenol, 2,6-dichlorophenol and 2,4-dichlorophenol have been detected using a similar system and are reported here.

The compounds were obtained from K. and K. Laboratories and from Eastman Kodak, and were used without further purification as 10^{-3} molar aqueous solution. Free radicals were generated by oxidizing these compounds with an acidic solution of ceric ammonium sulphate, and detected with a Varian 4,500 *X*-band spectrometer.

The electron spin resonance spectra obtained are shown in Fig. 1, and the hyperfine splittings assigned to these spectra are listed in Table 1.

Table 1. Hyperfine Splittings (Gauss)

Radical	Doublet	Triplet	Sextet
Phenoxy	10·1	6·6	
		1·8	
p-Chlorophenoxy		6·6	1·9
2,6-Dichlorophenoxy	9·7		
2,4-Dichlorophenoxy	7·9		1·9

A comparison of the hyperfine splittings enables us to assign them to specific protons or chlorine atoms in the different ring positions. For example, the large doublet splitting (~ 10 gauss) occurs in the electron spin resonance spectra of the phenoxy, and 2,6-dichlorophenoxy, radicals but not in the other two. Hence, we can assign the 10 gauss splitting to the 4 position proton of the phenoxy radical.

Similarly, in the phenoxy and *p*-chlorophenoxy radicals, we have triplet splittings of 6·5 gauss, but in the splittings for the 2,4-dichlorophenoxy radical we have a doublet of 7·9 gauss. Although these are somewhat different, we feel that it is reasonable to assign this splitting to the 2 and 6 position protons.

We have then assigned splittings to each of the ring protons in the phenoxy radical; the next step is to evaluate

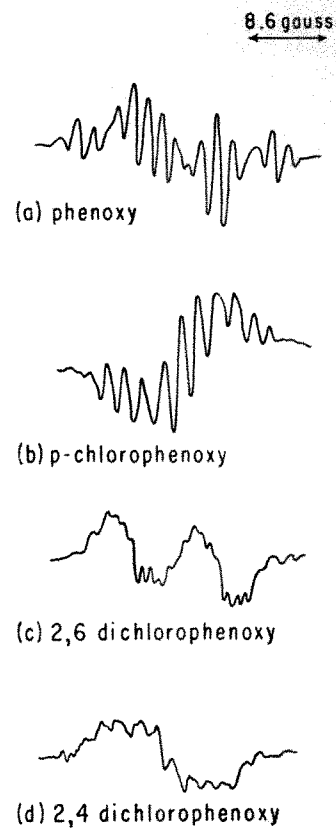

Fig. 1. Electron spin resonance spectra of (*a*) phenoxy, (*b*) *p*-chlorophenoxy, (*c*) 2,6-dichlorophenoxy, (*d*) 2,4-dichlorophenoxy radicals

the chlorine splittings. Comparing the splittings for phenoxy and *p*-chlorophenoxy radicals, we see that a doublet of 10·1 gauss and a triplet of 1·8 gauss in the phenoxy electron spin resonance spectrum are replaced by a sextet of 1·9 gauss in the *p*-chlorophenoxy radical spectrum. The sextet is due to an effective nucleus of spin quantum number 5/2, which it is reasonable to assume, to be made up of two equivalent protons (I = 1) and one equivalent chlorine nucleus (I = 3/2). This would mean that a chlorine in the 4 position of a phenoxy type radical produces a splitting of 1·9 gauss. A similar comparison with the electron spin resonance spectrum of 2,4-dichlorophenol shows the 4 position chlorine to give a splitting of 1·9 gauss. If we now made an assumption that the substituting of a Cl for an H does not change the distribution of the unpaired electron in the phenoxy radical drastically, we may make an estimate of the value of the ring chlorine splitting constant.

Using the equation[4]:

$$\Delta H_p = Q_p \rho$$

where ΔH_p is the splitting due to a ring proton, ρ is the unpaired electron density on the adjacent carbon atom, and Q_p is the ring proton splitting constant. We assume a similar relationship:

$$\Delta H_c = Q_c \rho$$

where Q_c is the ring chlorine coupling constant and ΔH_c the splitting it produces.

We may write then:

$$Q_c = Q_p \times \frac{\Delta H_c}{\Delta H_p}$$

$$Q_c = 0{\cdot}19\ Q_p$$

If we take Q_p to be 24·2 gauss[5], then:

$$Q_c = 4{\cdot}6 \text{ gauss} \pm 0{\cdot}6 \text{ gauss}$$

This value has been arrived at assuming there is no effect of the A on the π electron distribution.

Chemiluminescent Reactions of SO with O and with O_3

The spectrum of the sulphur dioxide afterglow was first investigated in detail by Gaydon[1], who reported that it appeared to be continuous over its entire range from 2400 Å into the visible, apart from some weak bands above 3800 Å which are now known to arise from the (0,0,0) and (0,1,0) levels of the $^3B_1$ state of SO_2 (refs. 2 and 3). More recently, Herman *et al.*[4] have investigated the afterglow at low pressures and found no evidence of banded structure; they confirmed Gaydon's view that the afterglow was due to the chemiluminescent combination of O and SO, but did not establish whether it required a third body.

Recently, we have used a fast flow system to examine the reactions occurring in the products of a radiofrequency discharge through sulphur dioxide in an argon carrier, and have shown that the intensity (I) of the sulphur dioxide afterglow obeys the relation:

$$I = I_0[\text{O}][\text{SO}]$$

It has not, however, been possible to determine whether the quantity I_0 depends on total pressure. This alone might not establish that the luminescent reaction requires a third body since for the analogous air-afterglow reaction involving the chemiluminescent combination of O and NO to form electronically excited NO_2, the quantity I_0 is independent of pressure over a considerable range[5,6]. In this case, kinetic evidence[5] and the presence of banded structure near the high-frequency limit of emission[7] support the view that a third body is involved.

We have observed weak but definite banded structure near the short wave-length limit of the sulphur dioxide afterglow at room temperature. In separate experiments we have established that sulphur dioxide does not absorb significantly in this region until the product of concentration and path length is twenty times the maximum that could have been present in our experiments. This provides clear evidence that a third body is required for the chemiluminescent combination reaction O + SO and that the 'continuum' which reaches its maximum intensity at about 2700 Å is a mass of overlapping bands arising from many vibrational levels in the excited state.

The origin of the triplet bands is of interest. Gaydon[1] observed that they were more intense at higher pressures; in addition, we find that they are greatly enhanced when additional sulphur dioxide is added downstream from the discharge. This establishes that these bands are not due to long-lived triplet SO_2 formed in the discharge. The observation that this enhancement is not accompanied by any detectable shift in the overall spectral distribution from the ultra-violet to the visible suggests that the effect of added SO_2 is to increase the rate of vibrational relaxation in the triplet state of SO_2, since the appearance of the bands from the lowest vibrational levels would then be accompanied by a matching reduction in the intensity of that part of the 'continuum' which has a

maximum near 4500 Å (ref. 4) and which presumably consists of transitions from higher vibrational levels of the triplet state. This interpretation is supported by the observation that the triplet bands are enhanced, albeit to a lesser extent, by the addition to the discharge products of CO_2 or SF_6, both of which normally have high efficiencies for vibrational quenching. Molecular oxygen does not show this effect.

At relatively high pressures, oxygen atoms decay much more rapidly than SO, the reactions of which can then be examined readily beyond the point at which the sulphur dioxide afterglow has faded out. Under these conditions, added ozone undergoes a rapid reaction accompanied by blue and ultra-violet chemiluminescence. This reaction can only be:

$$SO + O_3 = SO_2 + O_2 + 106 \text{ kcal/mole} \qquad (1)$$

since the spectrum consists of strong emission from the $^3B_1$ state of SO_2 (minimum excitation energy 74 kcal/mole) and weaker emission from the $^1B_2$ state (threshold energy 85 kcal/mole). The emission from the $^3B_1$ state comes mainly from vibrational levels (0,0,0)and (0,1,0), although transitions from the (1,0,0) level appear weakly.

The $^1B_2$ emission is very different in distribution from the SO_2 afterglow. It consists of a series of bands commencing near 3000 Å which under low dispersion merge into a pseudo-continuum at about 3300 Å. This 'continuum' reaches its maximum at about 3500 Å and extends to 4000 Å. The bands observed cannot be due to self-reversal; they correspond to those which appear in absorption in this region. This is to be expected, since the highest frequency bands must be transitions to the lowest levels of the ground state. The highest energy band so far observed corresponds to (3,6,0), (4,3,0) or (5,0,0) in Metropolis's scheme[8], and it seems clear that the pseudo-continuum at longer wave-lengths arises from overlapping bands mainly involving lower vibrational levels of the excited state.

A strict proportionality was always observed between the intensities of the singlet and the triplet bands; we therefore conclude that both states are populated by the same reaction and that the $^1B_2$ state is not populated in the collision of two $^3B_1$ molecules by a mechanism analogous to that of delayed fluorescence[9].

There is a clear similarity between reaction (1) and the chemiluminescent reaction[10,11]:

$$NO + O_3 = NO_2 + O_2 + 48 \text{ kcal/mole} \qquad (2)$$

which has recently been shown to populate lower vibrational levels of the excited state of NO_2, which is also responsible for the air-afterglow emission[11].

Reaction (2) has been shown to have a higher activation energy when it yields electronically excited NO_2 than when ground state NO_2 is formed[11]. On this basis[12], reaction (1) would be expected to have successively higher activation energies to yield SO_2 in its ground ($^1A_1$), $^3B_1$ and $^1B_2$ states. This would explain why the $^3B_1$ emission is roughly ten times more intense than the $^1B_2$ emission in the $SO + O_3$ reaction, while the reverse is true in the O + SO reaction, which is expected to have zero activation energy. The latter situation would be predicted from the radiative lives, which the relative intensities of the absorption spectra show to be much greater for the $^3B_1$ state than for the $^1B_2$ state.

For this reason it is unlikely that the observed vibrational energy distribution of molecules in the $^3B_1$ state resembles that with which they are formed. The radiative lives of the $^1B_2$ state[13] and of the emitting state of NO_2 (ref. 14) are much shorter; the vibrational energy distribution of the emitting states is therefore probably similar to that with which the excited molecules are formed. This distribution of energy together with Franck–Condon factors will determine the spectral distribution of the emission. To judge by the corresponding absorption spectra, the Franck–Condon factors make a large contribution to the observed spread of the emission, but these factors are unlikely to vary greatly from level to level in the upper state. Thus the difference in energy between a particular vibrational level and the most probable transition from it should be almost constant for a given excited state. Table 1 shows that, for the same emitter, the difference between the most probable energies of emission is equal to the difference between the exothermicities of the reactions forming it. This suggests that the difference between the exothermicity of the reaction and the most probable excitation energy is roughly constant.

Table 1

Reaction	Exothermicity (kcal/mole at 298° K)	Wave-length of max. emission (Å)	Energy of max. emission (kcal/mole)
$O + NO \rightarrow NO_2^*$	73	6000	48
$O_3 + NO \rightarrow NO_2^*$	48	12,000	24
$O + SO \rightarrow SO_2^*$ ($^1B_2$)	131	2700	106
$O_3 + SO \rightarrow SO_2^*$ ($^1B_2$)	106	3500	82

The general similarities between the four chemiluminescent reactions discussed here, the similarity of Franck–Condon factors suggested by the constant difference between columns two and four in Table 1, and the closeness of the measured radiative lives[13,14] and of the integrated absorption coefficients all suggest that the main visible and near ultra-violet absorption spectrum of NO_2 is analogous to the $^1B_2$–$^1A_1$ transition of SO_2, that is, that it is a $^2B_2 \leftarrow {}^2A_1$ transition (presumably $2b_1 \leftarrow 1a_2$) (ref. 15). The formation of $^1B_2SO_2$ molecules in reaction (1) is clearly accompanied by anomalous vibrational excitation. Detailed investigations of this and reaction (2) are being carried out since the examination of vibrational excitation in reactions which yield electronically excited species has advantages over the method of infra-red chemiluminescence[16]. These include the wider choice of detectors and the shorter radiative lives of the species involved, which makes it possible to work at higher pressures.

Structures of Polymyxin *B2* and Polymyxin *E1*

In a previous communication[1], from the analysis of a partial acid hydrolysate, the structure of polymyxin *E1* was shown to be limited to two alternatives, the so-called 7α and 8γ formulæ. By applying the enzyme method of hydrolysis as devised by Suzuki *et al.* in their determ-

inations of the structures of polymyxin $B1$ (ref. 2) and colistin A (ref. 3), the problem has now been resolved.

We have isolated the peptides Ipel$\xrightarrow{\alpha}$DAB$\rightarrow$Thr and Ipel$\xrightarrow{\alpha}$DAB$\rightarrow$Thr$\xrightarrow{\alpha}$DAB from the hydrolysate of polymyxin $E1$ with the enzyme Nagarse (supplied by Teikoku Chemical Industry Co., Ltd., Osaka, Japan). The presence in particular of the second peptide eliminates the 8γ variant, and the structure of polymyxin $E1$ is therefore concluded to be (I; $R=(+)$ 6-methyloctanoyl, $X=$ D-Leu) and is therefore identical with that of colistin A (refs. 3 and 4).

(I)

Bands having the same electrophoretic mobilities as the two peptides described above are found in a comparable enzymatic hydrolysate of polymyxin $B2$ and therefore, in conjunction with the previous results of partial acid hydrolysis[1], this antibiotic is assigned the structure (I; $R=$ 6-methyl-heptanoyl, $X=$ D-Phe).

BIOCHEMISTRY

Release of Carbohydrate from Fibrin Monomer during Clotting

Human fibrinogen contains a small amount of carbohydrate, consisting of about 3·2 per cent hexoses, about 1 per cent glucosamine and about 0·8 per cent sialic acid[1–4]. In the transition from fibrinogen to fibrin in clotting, a decrease in the carbohydrate content has been reported[1–4]. Thrombin, which catalyses the proteolytic cleavage of the fibrinopeptides at arginyl-glycine linkages[5], is not known to have any glycolytic function, although the release of carbohydrate is reported to parallel thrombin action during clotting[2]. Laki and Mester[6] showed that selective oxidation of the carbohydrate moiety of fibrinogen resulted in concomitant loss of clottability, although no changes in the fibrinogen molecule other than the oxidation of carbohydrate occurred. Recently, Laki and Chandrasekhar[7] found that selective enzymic alteration of fibrinogen by sialidase altered the ability to form 'insoluble' fibrin, but not the clottability of fibrinogen. 'Insoluble' fibrin, differing from 'soluble' fibrin by urea solubility as well as other characteristics[8], is formed through the reaction of a fibrinogen-like, plasma protein, fibrin stabilizing factor (FSF)[9], which in the presence of Ca^{++} converts what would otherwise be a 'soluble', weakly bonded gel into a covalently bonded, insoluble clot. Laki and Chandrasekhar[7] postulated, therefore, that the activity of FSF was related to sialic acid and the carbohydrate moiety of fibrinogen.

In order to investigate the proposed role of FSF activity in the release of carbohydrate from fibrinogen, preliminary experiments have been done in which the supernatant has been analysed for released carbohydrates after clotting a solution of purified fibrin monomer in the presence of FSF and Ca^{++} but in the absence of thrombin.

Human fibrinogen was fractionated by the method of Laki[10] and further purified by the procedure of Bergström and Wallén[11]. Fibrin monomer was prepared from this fibrinogen by the method of Donnelly *et al.*[12] as modified by Latallo *et al.*[13], keeping a constant concentration of 0·01-M EDTA in all solutions to prevent FSF activity during preparation of the pure material. The resultant preparation formed soluble clots even in the presence of Ca^{++}. Pure FSF was prepared by the method of Loewy *et al.*[14] and assayed at about 50 per cent of the activity of his preparation. An indole-sulphuric acid method for assaying hexoses and pentoses was used[15]. The method was found to be sensitive to 5 μg of sugar in the standard samples, giving a change of optical density 480 mμ = 0·035. The initial monomer concentration was 61 mg/ml. dissolved in 1 M sodium bromide in 0·05 M acetate buffer at *p*H 5·2. This was diluted 20-fold with 0·067 M sodium phosphate buffer at *p*H 6·1 to obtain a concentration of 3·05 mg/ml. in the clotting mixture.

Table 1. Analysis of Supernatant for Carbohydrate* after Clotting of Fibrin Monomer with Added FSF and Ca^{++}

Incubation time after dilution of monomer and initiation of clotting (min)	*O.D.* 480 mμ (corrected for blank with water)	Variation from baseline *O.D.* after dilution and before FSF addition
0 (before add. of FSF)	0·176	
0 (just after add. of FSF)	0·170	−0·006
5	0·157	−0·019
15	0·193	+0·017
30	0·179	+0·003
45	0·172	−0·004
75	0·180	+0·004
360	0·186	+0·010

* Indole-H_2SO_4 method of Ashwell (ref. 15).

Ten ml. aliquots of the clotting solution and clot supernatant were removed before addition of FSF (final concentration of 0·01 mg/ml.) and 0·75 mM Ca^{++}, immediately after the addition, and subsequently at 5, 15, 30, 45, 75 and 360 min. Each aliquot was mixed with absolute ethyl alcohol to stop any enzymatic process and to denature all protein. The mixture of test supernatant and alcohol was reduced to a 2-ml. volume in a negative-pressure desiccator to concentrate any sugar present, thus giving a final protein concentration (now denatured) of 15·25 mg/ml. This solution was centrifuged and 1 ml. of it used for carbohydrate determination.

As shown in Table 1, there is a random fluctuation of $\pm 0{\cdot}017$ $O.D._{480\ m\mu}$ during the time of incubation of the clots, but no significant increase in sugar is noted. A release of 1 mole of sugar per mole of fibrin should give, at the concentration used, a definite increase outside the limits of error. Our inability to find any hexoses or pentoses in the supernatant of a clotted solution of fibrin monomer (in the presence of FSF and Ca^{++}) is negative evidence for the function of FSF as an amylase. The carbohydrate lost from fibrinogen in clotting may be difficult to analyse due to absorption on to the clot, not lost as hexoses or pentases but as other carbohydrates, or lost from the fibrinogen molecule during its transformation into fibrin (despite the lack of glycolytic activity of thrombin) and thus presumably not cleaved by FSF.

Clotting in this work did occur at *p*H 6·1, perhaps not the optimum *p*H for FSF activity in the formation of insoluble clots under the same conditions and within the same time period. It would be of interest to analyse for differences in carbohydrate content between fibrinogen and fibrin monomer, as well as between fibrin monomer, soluble fibrin and insoluble fibrin in order to further elucidate the problem of the nature of FSF activity and the manner of the release of carbohydrate. Specific analysis of clot supernatant for sialic acid and for glucosamine must also be carried out.

Chromatographic Identification of Lysins in Normal Tissues and Tumours of Mice

THE two hæmolytic materials found in the normal tissues of the mouse and man, and also in mouse and human tumours, have been partially identified as being higher fatty acids (or their soaps) and lysolecithin; the former give a characteristic ultra-violet fluorescence, and the latter are soluble in ethanol but not in cold ether[1,2]. This communication concerns their more complete identification by silica-gel thin-layer chromatography.

The separations were carried out on glass plates, 20 × 5 cm, coated with silica-gel according to standard procedure. Small quantities (0·01 ml.) of known solutions of fatty acids or lipids, or of unknown solutions (1 gm tissue in 5 ml. ethanol) of the ethanol soluble material of mouse tissues or tumours, are spread across the lower end of the plate; after drying, the plates are placed vertically in methanol–chloroform, which is allowed to ascend for about 18 cm. The plates are made in duplicate, so that one of each can be developed with iodine vapour to show the position of the unsaturated fatty acids, etc., and these positions are marked on the duplicate plates. Transverse strips, each 5 mm wide, are scraped off the plates at various levels, for example, at regions to which the fatty acids have migrated, and also at regions in which there is no reaction with iodine (blanks). The scraped-off material is received in test tubes, one for each scrape; 1 ml. of redistilled ethanol is added to each, and after 15 min the tubes are centrifuged and the supernatant fluid of each is poured off into porcelain cupels, one for each test-tube. The cupels are dried for 60 min at 60° C; 1 ml. of a suspension of washed red cells (the cells of 50 mm³ of blood to 10 ml. of saline) is added to each, and they are transferred to hæmolysis tubes. These are kept in a water-bath at 37° C, with hourly shaking, and the time for complete hæmolysis is determined for each.

The difficulty lies in avoiding the appearance of irregular lytic regions on the plates. Control plates (blanks) must show no hæmolytic regions, regions which do not stain with iodine should be negative, and many regions which stain with iodine are also not lytic. Avoidance of the appearance of irregular hæmolytic regions requires a standardization technique in which the samples do not come into contact with hands, a cell suspension buffered at *p*H 7, and redistilled ethanol for extraction.

The chromatographic plates usually show 6–8 components which stain with iodine vapour, but the only regions which produce hæmolysis in 10 h or less are: (*a*) a region which corresponds to the position of oleic acid; and (*b*) a region which corresponds to the position of lysolecithin.

Comparing plates of ethanol extracts of normal mouse tissue (liver, lung) with those of ethanol extracts of C_3H mouse tumour in the same concentration (g tissue/g extraction medium), the number and position of the regions which stain with iodine vapour are the same, and the same regions are hæmolytic, but the intensity and size of the regions corresponding to oleic acid and lysolecithin are greater for the extracts of liver and lung than for the extracts of tumours; measurement of fluorescence also shows the concentration of fluorescent material to be two to six times greater in the mouse liver and lung (male or female) than it is in the female breast tumour. The hæmolytic activity of the mouse tumour, however, is usually several times greater than that of normal mouse tissue[3,4]. That the lysin-inhibitor complex[5,6] in normal mouse tissues is more strongly bound than that in tumours is a possibility to be investigated.

Electrophoretic Patterns of Lysed Fibrin formed by Homologous and Heterologous Thrombin

THROMBIN[1] and fibrinogen[2] have been shown to exhibit species specificity. Recently attention has been directed to the possible removal of intravascular clots by fibrinolytic agents. Since high concentration of thrombin produces lysis of fibrin[3], it was of interest to investigate the effect of homologous and heterologous reagents.

In each of 2 tubes, equal volumes of fibrinogen (1 g/100 ml.) and thrombin (500 units/ml.) were quickly mixed and incubated at 37° C. Lysis was prevented in the control by the immediate addition of equal volume of 10 M urea (dissolves fibrin) in 0·1 M sodium acetate/acetic acid buffer *p*H 4·85, while in the test this reagent was only added after lysis had occurred, usually in 2½–4 h. In order to minimize the precipitation of fibrin and its lysed products, paper electrophoresis was carried out using 0·1 M sodium acetate/acetic acid buffer *p*H 4·85 (no final polymerization of fibrin at *p*H 4). For reasonable separation of components a potential of 260 V was applied for 28 h. After staining with azocarmine *B*, the strips were scanned with a chromoscan.

There was no demonstrable difference between the electrophoretic patterns of lysed and unlysed fibrin in urea on using homologous thrombin and fibrinogen (Table 1). On the other hand, the use of heterologous reagents resulted in the appearance of a new band moving towards the anode. This band was well illustrated on using bovine thrombin and human fibrin (Fig. 1). Increasing the concentration of thrombin did not alter the

Fig. 1. Change in electrophoretic pattern on using heterologous thrombin (bovine) and fibrinogen (human). (*a*) Unlysed fibrin dissolved in urea; (*b*) lysed fibrin mixed with urea

results. These findings prompted the following investigations:

(*a*) Thrombin–fibrinogen interaction without fibrin clot formation: this was achieved by maintaining the reaction at *p*H 4·85 throughout the experiments, thus allowing thrombin to act on fibrinogen but preventing the final formation of fibrin mesh[4]. The same concentrations of reagents mentioned here were used; urea being added after 48 h in order to compensate for the slowing of the thrombin–fibrinogen interaction occurring at *p*H 4·85. No electrophoretic changes could be elucidated on using heterologous reagents. It would therefore appear that the formation of fibrin is essential for the development of the new band.

Table 1. The Effect of Thrombin Species on the Electrophoretic Pattern of Lysed Fibrin

Species		
Thrombin*	Fibrinogen*	New band
Bovine	Human	Present
Human	Bovine	Present
Human	Human	Absent
Bovine	Bovine	Absent

* Freshly prepared solutions used after being clarified by centrifugation at 3,000 r.p.m. for 10 min.

(*b*) Other methods of lysis: for these, clotting of fibrinogen was induced by a lower concentration of thrombin, 10 units/ml. The lysis of this fibrin by the addition of streptokinase (activating plasminogen in fibrinogen solution) or by human plasmin 'Ortho-Actase' gave electrophoretic results similar to those described for the lysis of fibrin clot by thrombin. These findings indicated that the new electrophoretic band, appearing in case of heterologous reagents, was not related to the lytic agent used but rather to the molecular configuration of formed fibrin.

The exact nature of this electrophoretic band remains to be investigated. However, this variance in the electrophoretic pattern of lysed fibrin, depending on the source of thrombin, should be borne in mind when applying experiments on, or using reagents of, different species.

I thank Ortho Pharmaceutical, Ltd., for a gift of 'Actase'.

PHYSIOLOGY

Simple Separation of Rabbit Marrow Myeloid Cells from Erythroid Cells

Mel has recently reviewed the sedimentation properties of nucleated and non-nucleated cells in normal rat bone marrow[1]. The complex nature of the factors that are involved in the separation of marrow cells by sedimentation technique are emphasized in his comprehensive paper. Tsuji reported a method for separation of guinea-pig bone marrow cells by using layers of gum acacia solutions of varying densities[2]. Myeloid cells were obtained in practically pure state. Gradient techniques involving several kinds of solutions, such as sucrose and bovine plasma albumin, have been used by others[3].

Procedures for separating bone marrow cells of the rabbit have been investigated in this laboratory for a number of months. Approximately 2 ml. of cells are obtained from the femurs, tibiae and humeri of one animal and suspended in isotonic NaCl solution. They are then filtered through a nylon filter (No. 9331, The MacBick Co., Cambridge, Mass.). After centrifugation and removal of buffy material the cells are placed in 10 ml. of 6 per cent sucrose solution and gently layered on top of seven other layered sucrose solutions, in concentrations from 15 per cent to 75 per cent, with an increment of 10 per cent in successive layers from above downwards. Each of these solutions is 10 ml. in volume and the test-tube is 6 in. in length and 1¼ in. in diameter. The cells in solution are spun at 350*g* for 6 min. The non-erythroid elements are distinctly banded in the lower 3–4 density zones. They can be reconstituted in isotonic NaCl solution and are practically free of erythroid forms. The latter, which are in the top layers, can be obtained by similar reconstitution.

Our most successful method, however, and one which does not involve subjecting the cells to distortion by hypertonic solutions is the simple procedure of adding 6 ml. of isotonic saline to 1·5–2·0 ml. of marrow cells in a 10 ml. centrifuge tube, mixing, and allowing the tube to stand undisturbed at 6° C for 1 h. Under the influence of 1*g* there is marked sedimentation of predominantly myeloid cells. The erythroid cells are almost entirely restricted to the top solution. The time is fairly critical since after 1 h the erythroid cells begin to settle on top of the myeloid cells. Similar successive resuspensions of the bottom section will result in practical isolation of non-erythroid and erythroid elements. This can be accomplished in about four such treatments.

Presynaptic Inhibition induced by Muscle Stretch

The existence of a powerful inhibitory mechanism acting at the level of the primary afferent fibre has been well demonstrated[1]. The method by which this presynaptic inhibitory pathway acts is generally accepted to be through a prolonged depolarization of the central terminals of the primary afferent fibres with, as a consequence, depression of the amount of excitatory transmitter substance liberated by their synaptic terminals. This depolarization of the central terminals of a particular group of primary afferent fibres is effected in a rather specific manner by afferent impulses from some types of receptors and not from others. For example, the group I afferent impulses entering the spinal cord through the sensory fibres of the nerve to a flexor muscle (but not an extensor) will produce a prolonged depolarization of the central terminals of the primary afferent fibres from annulospiral endings of muscles of that limb, both flexors and extensors.

So far, presynaptic inhibition has been tested by electrically stimulating a given afferent nerve and noting the effects on the central terminals of other primary afferent fibres and on the excitatory synaptic action by

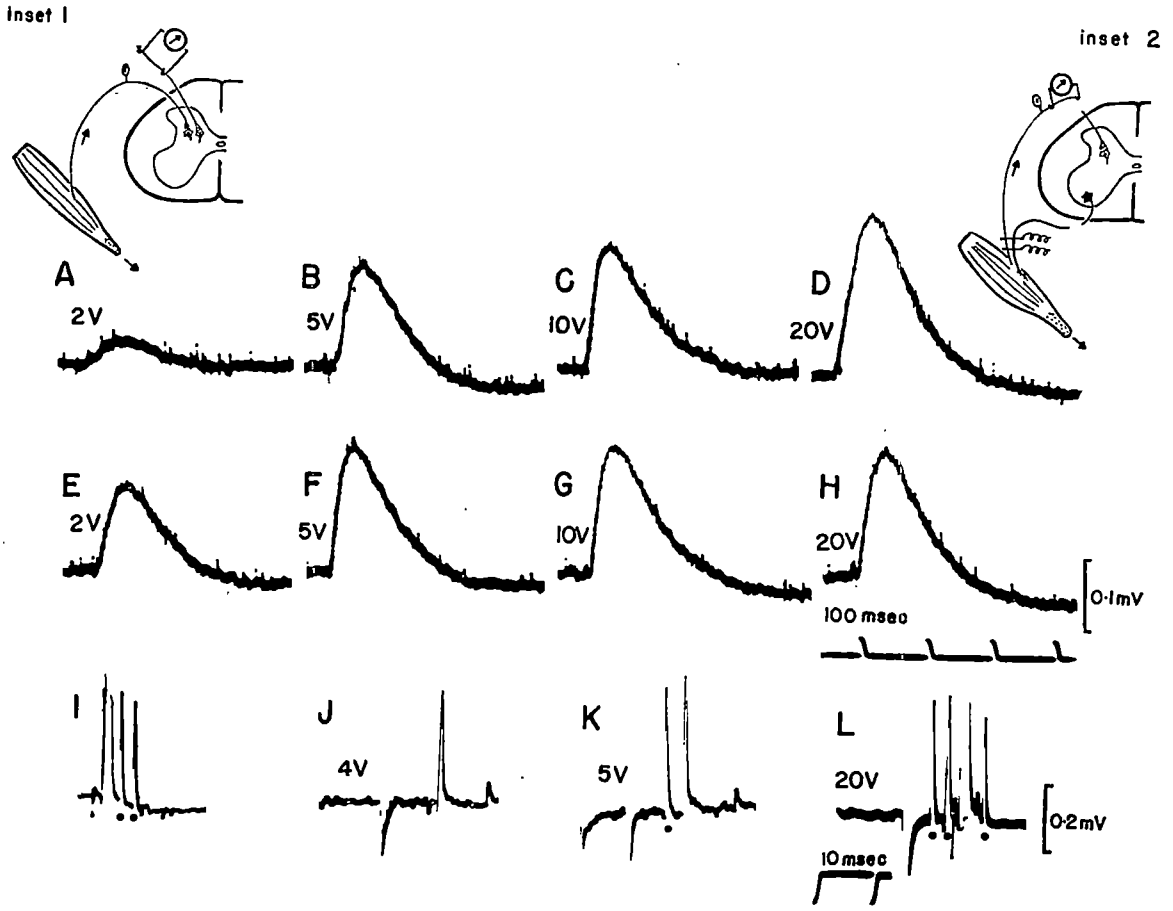

Fig. 1. *DRP*s recorded from an *L6* dorsal rootlet, as illustrated in inset 1. *A*, *B*, *C* and *D* show the *DRP*s produced when the *P* muscles were stretched, and *E*, *F*, *G* and *H* the *DRP*s when the *DP* muscles were stretched. The amplitude of the square pulse driving the vibrator is given in volts at the end of each *DRP*. *I* shows the impulses recorded in an *L7* dorsal root filament when the *DP* muscles were made to contract isotonically. *J* shows the beginning and end of the pull-artefact, using a 4-V pulse. In *K* and *L*, impulses (marked by dots) in the dorsal root filament, generated by a stretch of 5 V and 20 V respectively, are shown. Recording conditions are illustrated in inset 2

those fibres. These tests have thus employed conditioning by synchronous volleys and not the asynchronous repetitive discharges produced naturally by receptor organs. The present investigation has approximated much more closely to natural physiological conditions by investigating the presynaptic inhibitory action that is produced by the discharges of muscle receptor organs excited by brief stretches to the deep peroneal (*DP*) and peroneal (*P*) muscles.

Adult cats were anæsthetized with 'Nembutal', and the spinal cord was transected at the first lumbar segment. Both hind limbs were completely denervated except for the nerves to the peroneal and deep peroneal muscles on the left side. The muscles were pulled, using an electromagnetic vibrator, Goodman's model 390*A*, which was driven by a transistor d.c. power amplifier. The intensity of the stretch was determined by the amplitude of the square pulse driving the vibrator.

The depolarization of the central terminals of primary afferent fibres was recorded by two accepted techniques. In Fig. 1 (inset 1) it was recorded as an electrotonic spread into the dorsal rootlets, that is, the dorsal root potential (*DRP*)[2]. *A*–*D* show the *DRP*s produced when the *P* muscles were stretched, and *E*–*H* when the *DP* muscles were stretched. The intensity of the pull was progressively increased in each case, as shown by the amplitude of the square pulse used to drive the vibrator which is specified for

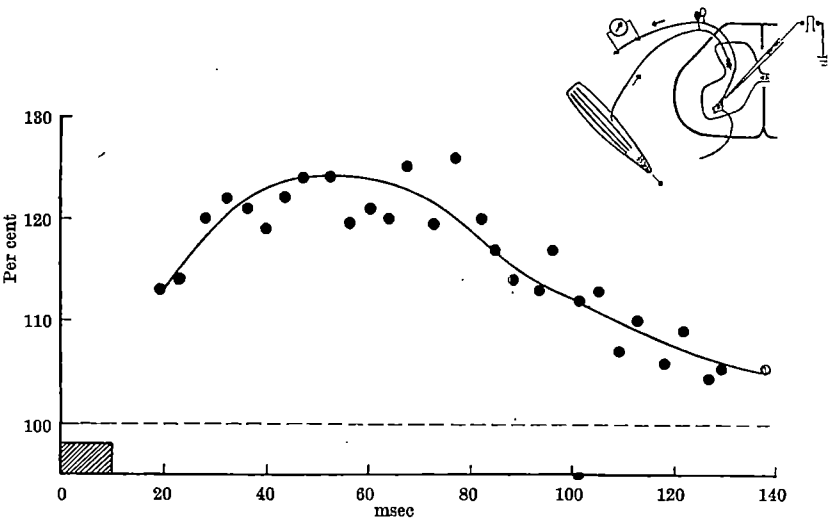

Fig. 2. The changes in excitability of the central terminals of the *Iα* afferent fibres of the gastrocnemius muscle were recorded as shown in the inset. The microelectrode is inserted near the *Iα* terminals of the *GS* nerve and connected to the square-pulse generator. The conditioning stimulus was an applied pull to the *DP* muscle setting up activity in the afferent fibres as shown by the arrow on the nerve into the cord; the other arrows indicate stretch of muscle and the direction of activity in the *GS* afferent nerve fibres. The time course of the change in excitability is plotted as a percentage (normal, 100) against time. The hatched rectangle denotes the duration of the pull (10 msec)

each *DRP*. To obtain a physiological measure of the pull intensity, small rootlets (inset 2) were dissected from the peripheral end of the cut upper *L*7 dorsal root so that they included only one large fibre from the muscle under examination. This fibre was identified as originating from a muscle spindle or a tendon organ by noting the discharge pattern when the muscle was allowed to contract isotonically. This identification was checked by application of a single stimulus to the peripheral nerve and by the measurement of the conduction velocity[3]. In I, the discharge of the I*b* fibre due to contraction of the *DP* muscles evoked by stimulation of the muscle nerve is shown, and in *K*, when the amplitude of the driving pulse was 5 V, the impulses in the I*b* fibres were just elicited by this pull. Correspondingly, the *DRP* showed a considerable increase when the pulse was increased from 2 V to 5 V, which indicates that the depolarization of the central terminals of primary afferent fibres was progressively increased as the muscle was stretched in order to stimulate the tendon organs in addition to the spindles. This agrees well with previous results[4].

In Fig. 2, another method of testing was used (inset). The change in excitability of the primary afferent fibres was recorded as described by Wall[5]. Since the stimulating microelectrode was placed at the motor nucleus of the gastrocnemius muscle, the primary afferent fibres tested were the I*a* fibres of the gastrocnemius nerve[6]. The figure illustrates that stretching of the *DP* muscle, using 10-V pulse to drive the vibrator, led to an increased excitability of the *GS* I*a* fibres which had a maximum at 50 msec and a duration of more than 140 msec. This excitability change indicates that the central terminals of the I*a* fibres of the gastrocnemius nerve were depolarized by impulses in the I*a* and I*b* fibres of the deep peroneal nerve. Again the present results are in agreement with those published previously[7].

It has also been observed that applied stretches to muscle diminished the size of intracellular monosynaptic EPSPs from motoneurones and were even more effective inhibitors of monosynaptic reflexes.

It is therefore concluded that stimulation of muscle receptors by stretch is an effective method of producing presynaptic inhibition.

We thank the Aeronautical Research Laboratories, Fisherman's Bend, Victoria, Australia, for the loan of the vibrator, Goodman's model 390*A*.

Body Surface Area in Human Beings

Halliday and Hugo[1] reported on a new method for the determination of the radiation surface area of the human body. They concluded that "measurements on a conventionalized model of a human being have shown that a human subject in the spread-eagle position presents the largest radiation area that can be presented, and that this area is approximately 95 per cent of the true geometrical area". We were interested in testing this postulate.

A full-scale model of the integrating sphere proposed by Halliday and Hugo was constructed and calibrated for the Applied Physiology Laboratory. By the end of 1963 six Caucasian and four Bantu men had been extensively tested for body surface area. The spread-eagle position was used, and in Table 1 the results obtained are compared with those of a direct measuring technique in which the subjects' bodies were coated with a removable substance of which the true geometrical area could be determined by ordinary physical methods. Also included are the calculated surface areas using the conventional du Bois formula.

Table 1. Surface Area in m²

Subject*	Coating method	Photometric method	du Bois formula
1	1·81	1·73	1·70
2	1·82	1·72	1·70
3	1·96	1·89	1·81
4	1·85	1·75	1·72
5	2·55	2·42	2·38
6	2·07	1·94	1·95
7	1·89	1·77	1·77
8	1·85	1·77	1·75
9	1·94	1·86	1·78
10	1·96	1·87	1·85
Av.	1·97	1·87	1·84
S.D.	0·208	0·207	0·204

* Subjects 1–4 were Bantus.

It is obvious that the radiation surface determined by the new method with the men in a spread-eagle position is always less than the true geometrical area by ±5 per cent. This is in accord with the postulate of Halliday and Hugo[1]. Of more significance, though, is the large discrepancy between the geometrical surface area and those obtained by the du Bois formula. The latter underestimates the true surface area by 6·6 per cent, which is significant at the 5 per cent level. There is no difference between Bantu and European men in this regard. The finding is in agreement with those of Banerjee and Sen in India[2].

The error variances of the photometric and du Bois methods compared with the geometrical surface area obtained from coating the body are 0·000322 and 0·000306 respectively.

These results need to be validated in bigger samples but they direct attention to a probable systematic bias between the true geometrical surface area and that obtained from the du Bois formula which could be serious in the computation of basal metabolic rates, especially for primitive peoples. Also the actual radiation area is found to be larger than the du Bois surface area. Therefore, computations of radiation energy exchange for human beings using 95 per cent of the du Bois surface area, which is the usual procedure, are questionable.

Microdroplet Assay of Human Serum Cytotoxins

Attempts to define leucocyte groups in man serologically have been hampered by the scarcity of immune human antisera and the capriciousness of the leucoagglutination reaction[1]. The method recorded here for assaying lymphocyte cytotoxins in a microscale was developed to circumvent these difficulties. Its extreme sensitivity permits performance of 1,000 or more tests with 1 ml. of antiserum. Furthermore, lymphocytes obtained from one finger-prick sample of blood are sufficient for 100 separate tests. The basic innovation in handling these small quantities of serum and cells and in gaining a greater than ten-fold increase in sensitivity over present-day methods is the performance of the reaction in microdroplets submerged under oil. This permits reduction in numbers of target cells to as few as 500 cells

in contrast to the 50,000 or so cells required for previously described cytotoxicity tests[2-4]. Since the sensitivity of cytotoxicity is inversely proportional to the number of cells used[2,3], an increase of sensitivity in the range of 10–100 times may be expected. Unlike the usual de Fonbrune oil chamber employed in micromanipulation, use of a 'dish' with a cover-glass bottom facilitated rapid addition of reagents and cells with a microsyringe.

Blood lymphocyte preparations containing less than 5–10 per cent granulocytes were isolated from fingertip blood in the following manner. Blood taken into 4–6 heparinized capillary tubes (1·4 mm diam.) was spun in a hæmatocrit centrifuge at 500*g* for 2 min, the supernatant plasma containing platelets was removed, and the tubes were spun at 12,000*g* for a further 2 min. After pipetting off the plasma, the tubes were cut just below the buffy coat layer under a dissection microscope. The buffy coat was then transferred to a polystyrene Petri dish together with about 0·1 ml. of fresh, type AB serum previously adjusted to *p*H 7 with carbon dioxide gas. A 45 mm × 50 mm cover-glass was put over the cells, which were enclosed by a rim of 'Vaseline' on the dish. For optimal adherence of polymorphonuclear leucocytes, a suspending medium containing either fresh serum or serum stored in liquid nitrogen was essential. Also maximal adherence could only be obtained in slightly acidic media of *p*H 6·5–7·0. Following incubation at 37° C for 15 min, the cells on the dish were examined under phase contrast microscopy to determine whether platelets, granulocytes and monocytes had firmly adhered. Granulocytes and monocytes should appear as large, flattened, dark granular cells. When in this condition, they will not wash off even with the most vigorous pipetting of solution over the surface of the dish. If the granulocyte contamination was greater than 10 per cent of the lymphocyte count in the wash, the sediment from centrifugation at 1,000*g* for 2 min was incubated either on another Petri dish or a glass slide. To remove contaminating erythrocytes which were present in a ratio of about 10 red blood cells to 1 lymphocyte at this stage, the cells were spun in narrow bore capillary tubes (1·0 mm diam.) at 12,000*g* for 2 min. Cutting off the buffy coat under a dissection microscope yielded the final suspension of cells which contained about equal numbers of erythrocytes and lymphocytes. Alternatively, erythrocyte contamination can be reduced to levels below 5 per cent of the lymphocytes by differential lysis in hypotonic solutions. As described earlier[5], 10–30 sec exposure to 1/3–1/5 isotonic Hanks's balanced salt solution was simple and effective. The hypotonic solution must be acidic (about *p*H 5) to lyse erythrocytes adequately. Water or hypotonic saline used by others[6,7] often resulted in formation of clot-like gels which could be prevented by trace amounts of Mg^{++} and Ca^{++} ions (we thank Prof. P. B. Medawar for this suggestion). Although lymphocytes treated in this manner were shown to yield almost exactly comparable results as the non-osmotically stressed cells, the latter were used exclusively for the present investigations. Similar principles of isolation were applied to larger volumes of blood following careful removal of only the uppermost layer of buffy coat cells as recommended by Jago[8].

For the test, oil chambers are prepared by affixing a 45 cm × 50 mm cover-glass to a 60 mm square 'picture frame' with ordinary cellophane tape. If the outside frame is made out of heavy aluminium foil, the foil was crimped at the corners to form a dish of 3 mm height. A stainless steel frame of similar construction was preferred for rigidity. After filling the chamber with mineral oil, antisera were placed on the cover-glass with a flat-tipped needle from a microsyringe of 0·01 ml. or 0·001 ml. capacity (Hamilton Syringe Co., Anaheim, California). To antiserum dilutions of 0·003–0·00001 ml., 0·003 ml. of pooled rabbit complement (*C′*) and 2,000 lymphocytes (in 0·001 ml.) were added. Rabbit *C′* was previously absorbed twice with 1 : 10 washed human erythrocytes and once with human leucocytes (10,000 per ml.) at 0° C for 5 min and separated by centrifugation at 0°–3° C. The *C′* was stored at −196° C since activity declined rapidly within a few days at −20° C. Though the numbers of cells added to each droplet can be as low as 500 cells, for routine work 2,000 cells provided a more readily countable number of cells per high-power observation field. Since the temperature of the microdroplet could not be easily maintained at 37° C because of excessive fluctuations in the temperature of the oil, the chambers were incubated at room temperature for 4 h.

Cell viability was assessed by the morphological appearance of lymphocytes when examined with an inverted phase contrast microscope at 620 or 820 times magnifications. Comparisons of viability by dye exclusion methods with time-lapse cinematography have shown that one prominent morphological change occurs on death of the cell. With phase contrast the cell nucleus, which is not visible in a living cell, becomes unmistakably recognizable in dead cells. Presumably injury to the cell membrane followed by leakage of intracellular substances reduces the refractility of the cytoplasm. Though this criterion of viability cannot be used for all types of cells (for example, monocytes, granulocytes, and fibroblasts), it appears to be applicable to a few other cell types besides lymphocytes (epidermal cells and certain tumour cells). It was found that the morphology of living and dead cells could be permanently fixed by the addition of 0·002 ml. of 37 per cent formalin. This provided a means of stopping the reaction at standard times for later thorough examination.

In confirming our earlier observation that normal human sera, even across ABO incompatibilities, are not cytotoxic[5], tests of 70 normal sera with lymphocytes from a type *B* and two type *A* individuals were entirely negative in the 210 combinations tested. In the course of other experiments, roughly a similar number of combinations used as controls were also negative. In contrast, many sera obtained from women with multiple pregnancies were cytotoxic. Though only a relatively few sera have thus far been tested, antibodies were detected in 49 per cent of sera (30 out of 61) from women with five or more pregnancies. A lesser proportion (16 per cent) of sera from women with 1–4 pregnancies was found in the 38 serum samples tested. In this limited series, the correlation of cytotoxic activity with number of pregnancies was better than with number of abortions. The high incidence of positive sera from multigravid women provides an abundant 'natural' source of allogeneic antibodies, obviating the need for deliberate immunization of human volunteers. Payne[9], van Rood[10] and Jensen[11] have earlier uncovered this source of allogeneic antisera as measured by leucoagglutination. However, the incidence of positive leucoagglutinating sera in these investigations ranged from 6 per cent[10] to 20 per cent[9].

The sensitivity of the present microdroplet assay can be gauged from the fact that out of the 49 antisera tested, 11 reacted to a maximum titre of 0·00001 ml. (50 per cent or more of cells killed). Further, the maximum titre was 0·0001–0·00001 ml. for 34 antisera and 0·001–0·0001 ml. for 15 sera.

The frequency with which each antisera reacted positively (50 per cent cytotoxicity) is given in Table 1. Based on the reactions of lymphocytes from 10–35 persons, the number of sera reacting at different levels was somewhat evenly scattered. Two antisera were cytotoxic to all lymphocytes thus far tested. The antisera which were cytotoxic to a high proportion of lymphocytes also tended to be those which acted to high dilutions. Therefore, frequency data with this type of sera must be interpreted with caution since the frequency may be dependent on concentration. Though non-specificity of cytotoxicity may therefore be suspected, it should be noted that often a serum highly toxic to

Table 1. Frequency of Cytotoxicity of 52 Antisera, each tested with Lymphocytes of 10–35 Individuals

Per cent of positive reactions	0–10	11–20	21–30	31–40	41–50	51–60	61–70	71–80	81–90	91–100
Total No. of antisera in each category	2	2	11	5	7	4	7	6	3	5

lymphocytes of one individual was not toxic to those of another with a 300-fold increase in antiserum volume.

To test reproducibility, lymphocytes of three individuals were reacted with 48 antisera in six dilution steps (by 1 : 3·3). The percentages of viable cells were estimated in multiples of 10 and duplicate titrations on a second day were compared by noting the difference in number of dilution steps ('tubes' or 'droplets') by which an equivalent degree of cytotoxicity was attained. Only deviations in multiples of 1/2 'tube' were counted in this rough estimation. Totalling up the differences obtained, which was never more than 1·5 dilution steps, the average dilution step variation for the 48 antisera was 0·16, 0·23 and 0·39. Duplicate tests with lymphocytes from one individual isolated with and without osmotic lysis and tested on one day resulted in an average discrepancy of 0·08 dilution droplet. Actual counting of 200 cells and dilution of sera by 1 : 2 or by 1 : 1·5 would increase the precision and accuracy obtainable, but was not deemed necessary for this initial investigation.

In summary, the microdroplet method has most of the features necessary for a practical human lymphocyte typing test. It is reproducible, rapid, and extremely sensitive. Since only semiquantitative data can be obtained, the principal future refinement needed will be a quantitative assay similar to the Coulter Counter method[4], which would be effective at this sensitivity range.

Results of using this assay in matching lymphocytes of long-term kidney homograft survivors and their respective donors have been described[12]. Evidence that the actual donor possessed less incompatible antigens than other random hypothetical donors was obtained.

PHARMACOLOGY

Release of Adenine Nucleotide from Nerve Axons

Recent experiments have shown that adenine nucleotides antagonize the neural effects of calcium deficiency[1] and procaine[2]. These findings suggest that adenine nucleotides play some part in normal axon physiology and, specifically, a nucleotide-protein complex in the excitable membrane of the axon has been postulated[1,3]. Nerve stimulation and certain alterations of the ionic environment may affect axon function by causing dissociation of this complex and, consequently, an increased rate of nucleotide release. In this communication we present evidence in support of this hypothesis.

The sciatic nerve of the frog, *Rana pipiens*, was isolated and immersed with the cut ends tied in buffered Ringer's solution (*p*H 7·2) at room temperature (22°–24° C). The nerve was then soaked for 2 h in 1 ml. Ringer containing 8×10^{-5} M tritium-labelled adenosine-5′-monophosphate (^{3}H-AMP), 50 μc./ml. After rinsing for 20 sec in 50 ml. of non-radioactive Ringer's solution, the time course of ^{3}H-AMP efflux into normal Ringer was determined for a period of 6 h. During this time the nerve was successively immersed into a series of scintillation sample vials, each containing 2 ml. Ringer, for intervals of 5–20 min. The total radioactivity in each vial, and that of the acid extract of sonicated nerve obtained at the end of the experiment, was measured in a liquid scintillation counter. The scintillation solvents and fluors were added directly to the collection fluid in each vial just prior to counting. Immediately after the collection procedure, and before sonication, the nerve was stimulated with supramaximal square wave shocks and action potentials recorded in order to evaluate the functional state of the nerve. To measure the efflux of ^{3}H-AMP from the epineural connective tissue sheath, the procedure was the same as already described here. The efflux of AMP labelled with carbon-14 from the nerve was also studied, and the results were the same as those obtained from the experiments with ^{3}H-AMP.

A curve describing the time course of decline of nerve ^{3}H-AMP is shown in Fig. 1. An initial rapid phase of loss of nucleotide is followed by a slower exponential loss. The rapid phase probably represents mainly the emergence of nucleotide from the extra-axonal spaces, and the slow component is assumed to represent mainly the efflux from axonal membranes. Although some of the nucleotide emerging from the nerve after 240 min comes from the epineural sheath, this comprises a relatively small fraction of the total. Comparison of the desaturation curves for nerve and sheath shown in Fig. 1 reveals that both the

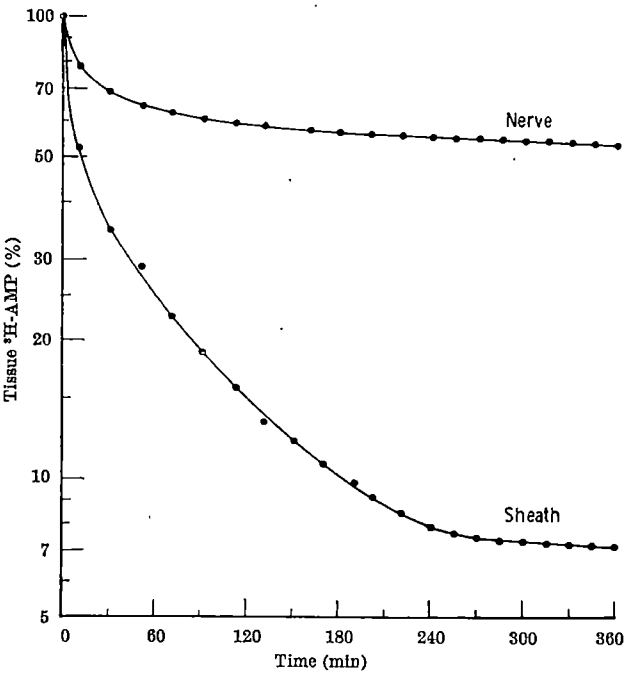

Fig. 1. Time course of decline of ^{3}H-AMP content of whole nerve and of epineural sheath during immersion in normal Ringer's solution. Nerve and sheath desaturation curves become exponential at 180 and 280 min respectively

ucleotide and the actual amount lost to the are much greater in the sheath. Even after normal Ringer's solution for 48 h, about 10 e initial radioactivity is present in the nerve, elatively tight binding of AMP to cellular

ct of $2{\cdot}5 \times 10^{-3}$ M ethylenediamine tetraacetic TA) was ascertained on the rate of loss of during its exponential phase of emergence. ent for 1 h with this concentration of EDTA was to have no effect on electrophysiological parameters n function. We showed that electrical stimulation ve causes increased rate of nucleotide release into al Ringer (Fig. 2) and, therefore, it was desirable to d a concentration of EDTA which causes depolariza- n or spontaneous discharge during the test period. Immediately after the immersion of a nerve into the DTA–Ringer's solution, the rate of nucleotide loss in- reased, and the total amount lost during the test period was a large fraction of the initial uptake (Fig. 3). The EDTA also caused an increase in rate of nucleotide release from the epineural sheath but the effect was no greater in magnitude than that obtained with the whole nerve. This is interesting because the results shown in Fig. 1 indicate relatively weak binding of AMP to the sheath. Although the striking effect of $2{\cdot}5 \times 10^{-3}$ M EDTA on nucleotide release is unrelated temporally to measurable changes in axonal electrophysiological parameters, the effect is probably related to molecular events in the excitable membrane which lead ultimately to spontaneous discharge (after about 75 min treatment) and axon depolarization.

The effect of calcium deficiency is not limited to the release of adenine nucleotide. Other experiments[3] indicate,

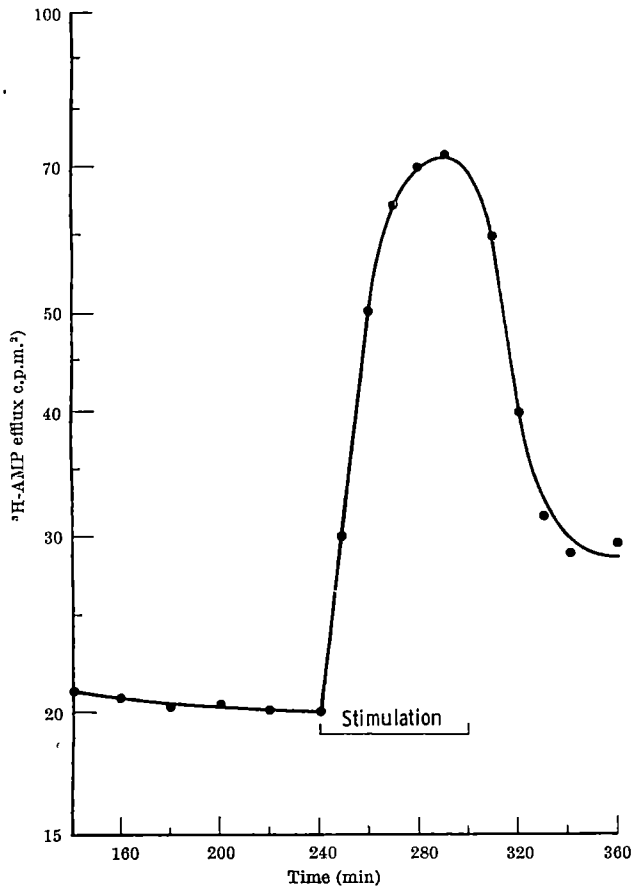

Fig. 2. Effect of electrical stimulation on rate of efflux on ^{3}H-AMP from nerve into normal Ringer's. Stimuli were applied at frequency of 50 per sec through bipolar platinum electrodes; voltage was supramaximal for the α-A fibres

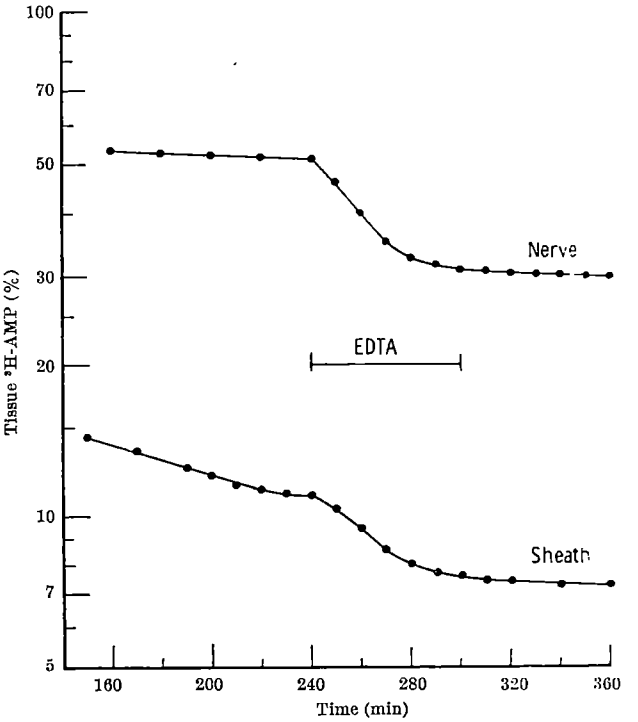

Fig. 3. Effect of $2{\cdot}5 \times 10^{-3}$ M EDTA on the rate of loss of ^{3}H-AMP from whole nerve and from epineural sheath

for example, that phosphocreatine is released to a much greater extent than nucleotide during exposure of a nerve to EDTA–Ringer's. Also, we have shown that EDTA causes a marked increase in the rate of loss of ^{3}H-adenosine. The fact remains, however, that neither phosphocreatine nor adenosine antagonizes the axonal effects of calcium deficiency, whereas the adenine nucleotides do. Thus, the effect of EDTA on the release of nucleotide from axons is probably related to a primary effect of calcium depletion.

These results are interpreted to indicate: (1) that extracellular AMP binds to receptors presumably located in the excitable membrane; (2) that this AMP binding is weakened by conditions which affect axon function. Other experiments in this laboratory have shown that ATP behaves in a similar way and, in fact, exchanges freely with axonal AMP. By reporting only the AMP results, we emphasize a role of adenine nucleotide in axon function which does not involve hydrolysis of pyrophosphate bonds. The conditions which affect nucleotide release also increase the rate of calcium efflux from the membrane[4], suggesting that nucleotide binding to membrane receptors depends on the presence of calcium. Conceivably, the configuration of a protein receptor in the excitable membrane is regulated primarily by the degree of binding to nucleotide and calcium; conditions which affect this binding will, accordingly, alter protein configuration in a manner which leads to changes in axon function.

HÆMATOLOGY

Xg Blood Groups of Chinese

SAMPLES of blood from 64 normal unrelated Chinese people, mostly from Singapore, were tested for the X-linked blood group antigen Xg^a with the following results:

	Xg(a+)	Xg(a−)	total
Males	16	19	35
Females	20	9	29

The number is small because the supply of anti-Xg^a plasma is being used mainly for the investigation of X-linkage and of abnormalities of sex, but the results are sufficient to show that the antigen is less common in Chinese than in Europeans.

Chinese gene frequencies calculated from the male and female results are: Xg^a 0·46 and Xg 0·54. These gene frequencies re-applied to the 64 show the male and female results to be mutually concordant (Table 1), and this suggests that the gene frequencies may be about right despite the small number of tests.

Table 1. MUTUAL CONCORDANCE OF THE CHINESE MALE AND FEMALE PHENOTYPE FREQUENCIES IN THE SAMPLE OF 64

	Expected proportion	Expected absolute	Observed
Males Xg(a+)	0·46	16·1	16
Males Xg(a−)	0·54	18·9	19
Females Xg(a+)	0·71	20·6	20
Females Xg(a−)	0·29	8·4	9

Estimates of the gene frequencies of people so far tested with anti-Xg^a are given in Table 2. The Bombay Indian frequencies are recalculated from the male and female figures in Bhatia's results[1]. The Chinese sample differs significantly from the Caucasian and almost significantly from the Indian, but it is too small to show whether it differs significantly from that of the Negroes.

Table 2. Xg GENE FREQUENCIES IN VARIOUS PEOPLE CALCULATED FROM THE MALE AND FEMALE RESULTS

	No. tested	Xg^a	Xg
Caucasians (ref. 2)	2,000	0·662	0·338
Bombay Indians (ref. 1)	100	0·65	0·35
Negroes (ref. 3)	219	0·55	0·45
Chinese	64	0·46	0·54

We thank Dr. A. Cahan of Knickerbocker Biologics, New York, and Dr. J. D. Mann of Butterworth Hospital, Grand Rapids, for gifts of the anti-Xg^a plasma.

Dose-response Curve of Phytohæmagglutinin in Tissue Culture of Normal Human Leucocytes

PHYTOHÆMAGGLUTININ (PHA) stimulates division of normal lymphocytes from venous blood *in vitro*[1]. Little or no cell division occurs when it is omitted from culture[2]. Other workers[3] have suggested a relationship between the amount of protein in the culture and the rate of cell division, but have not reported a systematic study. The relationship between a single dose of phytohæmagglutinin and the kinetics of cell division has been d
communication reports the effect of various

blood from six normal human subjects was in
with dextran (Abbott Laboratories, 6 per cent dex
normal saline) in a final concentration of 1 per cent
blood was allowed to stand 45 min at room temper
Two ml. of leucocyte-rich supernatant plasma wer
moved and mixed with 8 ml. tissue culture Medium
Varying concentrations of PHA-*P* were added in appr
mately 0·2 ml. buffered saline. Fifty aliquot cultures w
made. Cultures were incubated at 37° C and uniform
terminated at three days. Colchicine 10^{-7} M was added fo
2 h prior to death of the culture and air-dried metaphas
preparations made. From each culture 1–10 × 10^3 cells
were counted and the number of mitoses tabulated. The
mitotic index was expressed as percentage mitoses per hour exposure to colchicine.

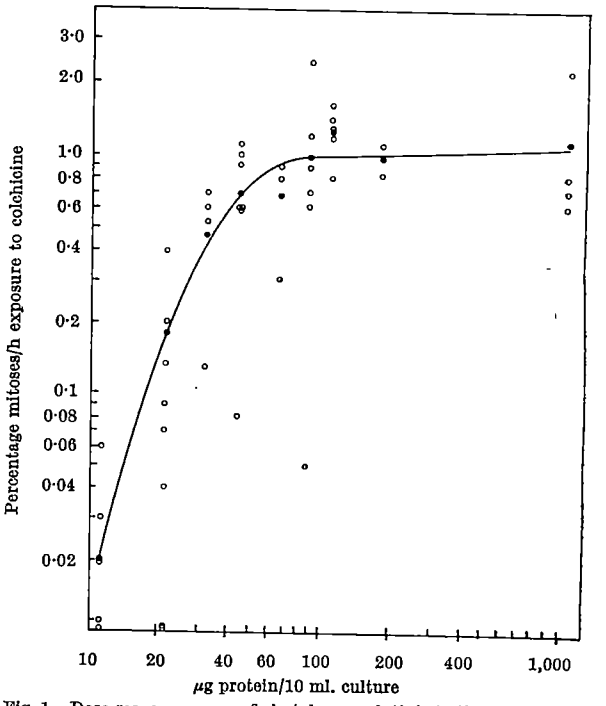

Fig. 1. Dose-response curve of phytohæmagglutinin in tissue cultures of human peripheral blood. Open circles represent individual mitotic indices at various concentrations of PHA; solid circles represent mean values. Log_{10} log_{10} plot

The lower four points were linear using probit analysis. The curve shows that the concentration of the protein and the proportion of cells which divide are directly related. The maximum response was obtained with 85 μg, and a half-response with 30 μg protein. One per cent mitosis was the maximum response which could be obtained by varying the concentration of protein. There was no detectable threshold of mitosis-stimulating activity. Fig. 1 shows the mitotic index plotted against the dose. The variations in mitotic index were attributed to large deviations from the mean which occur at low percentages[4], and variations among normal subjects.

The measurement chosen did not involve gradation. Either the cell was dividing or it appeared dormant. The assay resembles pharmacological investigations in which mortality or other single event is measured. It differs from the mortality investigations because cell division rather than death is its end-point.

work suggests that PHA-*P* may function as an Cells are known to divide in the presence of *ivo*[7]. PHA is not unique in its ability to induce in tissue culture. A wide variety of heterologous ave been demonstrated to stimulate mitosis HA has several unusual features: ribonuclease tes it[8]. Its activity is associated with a leucoag utinating property or substance[9]. Primary immunization to PHA has not been proved necessary to leucocyte proliferation. The precise mechanism by which PHA stimulates cell division is still uncertain.

PATHOLOGY

Establishment of a Turkey Flock Free of 'N' Strain *Mycoplasma*

Mycoplasma of the 'N' strain are frequently isolated from turkey poults affected with airsacculitis but free of *Mycoplasma gallisepticum*[1]. Research on the 'N' strain has been impeded by the presence of a high proportion of turkey poults with airsacculitis in all breeding flocks examined[1,2,4,5], by the difficulty of culturing and identifying the *Mycoplasma* strains, and by the lack of a practical serologic test. This communication describes the establishment of a small nucleus of 'N'-free turkeys from a commercial breeding flock known to carry 'N' *Mycoplasma*. Hens and toms for the production of 'N'-free poults were selected from the parent flock by serology and culture.

An antigen was prepared from an 'N' *Mycoplasma* designated 'strain 529'. This strain was isolated from the sinus exudate of a turkey negative to *Mycoplasma gallisepticum*. Unlike other 'N'-type isolates which grew poorly and on agar medium only, this isolate grew readily in broth, facilitating antigen production.

Virgin female and male turkeys were screened serologically at 14 and 6 days prior to the first insemination. Swabs of the mucosa from the female oviduct taken by eversion of the cloaca, and semen from the males, were also collected for culture. In a test pen, 12 females diagnosed as negative by serology and culture were inseminated artificially with semen from males which were also negative. In a control pen, 19 females diagnosed as positive by serology or culture were mated to males which were positive.

Because a previous experience indicated that airsacculitis possibly caused by 'N' *Mycoplasma* was lowest in the poults from early hatches[3], only the first hatches were considered. All 'dead-in-shell', pipped eggs, cull poults and half the normal poults from the first hatch from each group were killed and dissected, and specimens taken for culture. Ten eggs candled out at 14 days, four cull poults, six pipped eggs, and 21 normal poults were examined from the negative test pen. No evidence of airsacculitis was found in the poults, and all cultures were negative for *Mycoplasma*. The remaining 19 birds in the hatch were raised in isolation and serologically tested at frequent intervals with 'strain 529' antigen. At 27 weeks of age, and after 11 separate bleedings, nine females and six males were negative. The four birds which died or were culled from this group were free of airsacculitis and 'N' *Mycoplasma* as diagnosed by examination and culture.

The culture of ten eggs candled out at 14 days incubation from the positive control pen revealed one isolation of an 'N' strain *Mycoplasma*. Four cull poults examined were found negative for airsacculitis and *Mycoplasma* on culture. Twenty 1-day-old poults were examined; one had airsacculitis from which 'N' *Mycoplasma* was cultured. Of 17 additional poults held for further investigation, one of nine that died within a 21-day period had airsacculitis from which *Mycoplasma* was recovered. The remaining 8 poults killed at 21 days of age were all negative for airsacculitis and *Mycoplasma* of the 'N' strain.

The fertility of the eggs in the second hatch from the negative test females was compared with that of the positive controls. The percentage of eggs candled out as infertile at 12 days incubation was 4·5 for those laid by the negative hens and 13·2 for those from the positive hens. In 'break out' examination of these, 1/11 from the negative hens was considered truly infertile, compared with 12/37 from the positive group. The remaining eggs were considered to be cases of early embryonic death.

Inhibition of a Transplantable Murine Leukæmia by a Lymphocytopenic Virus

IN our laboratory the isolation of a viral agent with lymphocytopenic action *in vivo* directed our attention to its possible anti-leukæmic action. Anti-tumour properties of this virus are briefly described herein.

We have described the physical and chemical properties and the pathology of this lymphocytopenic virus which was isolated from a non-tumorigenic tissue culture line of Ehrlich's ascites carcinoma[1]. Parenteral introduction of this virus into adult mice of Swiss and several inbred strains (*C_3H*, *DBA/1*, *A/He*, *$C_{57}Bl/6$* and *Balb/c*) produces an acute infection within 7–10 days, involving primarily a reduction of lymphocytes in lymph node, thymus and spleen, secondarily some fatty degeneration of the liver, and is accompanied by the development of small amounts of ascitic fluid. The most susceptible Swiss strain usually develops both ascitic and pleural fluids and was chosen for routine passage of this virus in its 28th passage on August 18, 1964. The transplantable lymphoid leukæmia[2] in its 166th passage, on August 18, 1964, was used as a source of leukæmic cells. This lymphoid leukæmia was originally induced by 3,4,9,10-dibenzpyrene treatment to *Balb/c* mice in 1960. The concentration of leukæmic cells was determined with a Coulter Counter, followed by serial dilution with sterile phosphate-buffered saline (*p*H 7·4) to reach the desired number of cells in a 0·25-ml. inoculum.

Each experimental group was concurrently injected with a standard dose of the lymphocytopenic virus. A standard dose of lymphocytopenic virus was arbitrarily set as 0·25 ml. of a filtrate obtained from a 1 : 5 dilution of liver homogenate with phosphate-buffered saline (*p*H 7·4) obtained on the 7th day of infection in Swiss mice. Experimental mice were compared with control groups

receiving leukæmic cells only. A control group receiving virus only was also included.

Treatment of leukæmic mice with the viral agent resulted in complete remission in some mice (Table 1), still alive. They are grossly normal 60 days after the start of the experiment. Survival times were extended when the viral agent was administered to the leukæmic mice. All the control groups receiving leukæmic cells died within 7–12 days. Each group contained 12 mice to start, equally divided among males and females. Some mice from each group were killed during the course of the experiment to verify that infective action of the viral agent was occurring and to follow the course of the infections. These pathological and histological data support the gross observation; no evidence of the presence of leukæmic cells was found in the surviving mice, and 100 per cent survival after viral infection was observed in the viral control group.

In a similar experimental design, administration of a standard dose of lymphocytopenic virus concurrently with counted numbers of Ehrlich's ascites carcinoma cells intraperitoneally in *Balb/c* mice resulted in inhibition of tumour growth (Table 2). This Ehrlich's ascites carcinoma was obtained from Dr. K. Sigiura in November 1960 and is carried routinely in C_3H mice.

Law and Dunn[3] have described a lymphocytopenic virus isolated from *L*1210 leukæmia carried in *DBA*/1 mice which produced a statistically significant lengthening of the life of mice bearing subcutaneous implants of the infected *L*1210 sub-line and suggested that more striking results in survival time would be expected by titrating the dose of virus.

The lymphocytopenic virus in the present study has demonstrated an inhibition of the growth of both transplantable lymphoid leukæmia and Ehrlich's ascites carcinoma. Additional experiments currently under way will determine the condition under which increases in the titre of this virus may have further inhibitory activity against more concentrated tumour challenges for both lymphoid leukæmia, and Ehrlich's ascites carcinoma and other tumours.

Oncolytic viruses have been reported previously, and were reviewed recently by Southam[4] and Love[5]. The virus described in this article has the interesting properties of inducing complete remission of a transplantable lymphoid leukæmia and Ehrlich ascites carcinoma. The mice also recover from the viral infection, and are immune to further infection with the lymphocytopenic virus. These immune mice, however, do not have the ability to inhibit the growth of subsequent transplants of Ehrlich's ascites or leukæmia (Table 3). This suggests that the viral agent directly affects the tumour cells *in vivo*.

This virus can be repeatedly isolated from the tissue culture line of Ehrlich's ascites carcinoma. Feulgen-stained smears of tissue culture cells reveal a few lymphoid-type cells distributed among the predominant spindle-shaped cells containing large nuclei typical of Ehrlich's carcinoma[1]. The virus is non-cytopathic for these tissue culture cells. On injection into mice, the virus caused reduction of lymphocyte population during the acute phase of the infection and necrotic foci were secondarily induced in liver cell parenchyma. The inhibition of lymphoid leukæmia and Ehrlich ascites carcinoma are probably produced by similar cytopathic activity of this virus.

This virus for the two tumours tested so far demonstrates significant inhibition of the growth of the tumour graft. Pilot investigations now being evaluated have shown viral infection in suckling rats. Adult rats show reduction in spleen size.

The investigations described herein were supported in part by the National Institutes of Health, research grant *CA*–07114-01, and by Mrs. John E. Nicholson and family of Manhasset, New York.

Partial Protection by an Ox Liver Extract against Rat Liver Carcinogenesis by 4-Dimethylaminoazobenzene

The fraction of ox liver which contains those components soluble both in water and in acetone was found by Maisin and Lambert to have a powerful prophylactic effect against the liver carcinogen 4-dimethylaminoazobenzene (DMAB) when both were given in the diet[1]. It has been found in these laboratories that a diet supplemented with copper acetate affords a good degree of protection against this carcinogen[2] and it was decided to test the ox liver fraction under our conditions so that the efficacy of the copper salt could be compared with that of the fraction.

The fraction, prepared as described[1] and stored in a stoppered dark bottle at 4° C, was added to a diet of maize meal containing 0·09 per cent DMAB at the level of 5 ml. per rat per day. In a preliminary experiment, this diet was given to 6 female rats for 5 days each week, proprietary rat cube being given on the other 2 days of the week to provide the vitamins and other growth factors deficient in maize.

Only poor protection resulted, and the rats all developed tumours after an induction time of 10·5 months, com-

pared with 8·5 months for control animals given maize plus DMAB only.

The material utilized in this experiment was prepared in batches every 12 weeks, and it was observed that during this time the content of glucose, as measured by the specific glucose oxidase test, fell from an initial value of 2·93 to 0·16 mg/100 ml. Bacteriological examination showed the presence of large numbers of yeasts and some Gram-negative bacilli.

The original work had been carried out on such a large scale that fresh batches of liver extract were prepared daily[3], and accordingly our fraction was thereafter stored in 15-ml. quantities in sealed vials in the deep freeze before use. Under these conditions, contaminating organisms would be prevented from metabolizing the fraction by the low temperature.

When the feeding experiment was repeated using liver extract stored in this way, a much better degree of protection (mean tumour induction time 14 months) was observed although: (1) each of the 6 rats eventually developed tumours; (2) the protection was not so pronounced as that given by copper acetate, where tumours only develop in rare cases (in about 10 per cent of rats after 500 days on a diet containing 0·09 per cent DMAB + 0·5 per cent cupric oxyacetate).

Copper acetate and the two liver fraction preparations are compared as protective agents in Table 1. The criteria are the reductions in changes in three parameters which are affected by DMAB carcinogenesis. These are the decreases in the ratio of body-weight to liver-weight, liver protein content and liver succinoxidase activity, after an arbitrary time of 350 days.

Table 1. Ratio of Body-weight to Liver-weight, Liver Protein Content and Liver Succinic Dehydrogenase Activity after 350 Days

Diet	Weight ratio	Liver protein (mg/100 mg pulp)	Liver enzyme activity (manometric units/ 100 mg pulp)
M	26·5	3·41	115
M + DMAB	7·6	1·59	27
M + DMAB + F_1	11·5	2·16	53
M + DMAB + F_2	15·9	2·69	79
M + DMAB + CuAc	19·8	2·96	91

M, maize; DMAB, 0·09 per cent carcinogen; F_1 and F_2, first and second beef liver fraction preparations, 5 ml./rat/day; CuAc, 0·5 per cent cupric oxyacetate hydrate; pulp, minced whole rat liver filtered through a 1-mm stainless steel mesh to retain connective and vascular elements.

Maisin and Lambert found that their preparation contained about 1 per cent protein and 0·8–1 mg per cent riboflavin. FAD is known to give partial protection against DMAB carcinogenesis but the protective effect of the liver extract was much greater than could be accounted for by its riboflavin content. The fraction was also found to retain some activity after deproteinization.

From the results of the experiments reported here, it would seem that the growth of bacterial contamination lowers the activity of the fraction. Chemical changes observed during this process were: (1) glucose fell from 2·93 to 0·16 mg per cent; (2) protein fell from 1·34 to 1·17 g per cent; (3) riboflavin fell from 1·43 to 1·27 mg per cent.

The original concentration of all these components were higher than those reported by the earlier workers, and when fraction F_2 was given our animals presumably received the unknown protective agents also at a higher dosage-level.

The slight falls in riboflavin and protein may be discounted as reasons for the loss of activity. There was no change in the free amino-acid content, and two-dimensional paper chromatograms showed further that no particular amino-acids were selectively decreased or increased.

Glucose was the only sugar which could be detected in the fraction by paper chromatography and by paper electrophoresis, both in the freshly prepared fraction and after storing. It may be postulated either that glucose is a contributory factor to the protective mechanism or that its metabolism products, mostly alcohol and acetic acid, inhibit the process, possibly by the change in *p*H.

Alternatively, the loss of efficacy may be concerned with some other necessary factor being destroyed by the yeasts or by some substance being formed which opposes the protective mechanism against DMAB.

My thanks are due to Dr. D. L. Woodhouse for advice given during this work, which was carried out during the tenure of a Medical Research Council training scholarship and supported by the Birmingham Branch of the British Empire Cancer Campaign for Research.

RADIOBIOLOGY

Sensitization of Anoxic Bacteria to X-rays by Di-t-butyl Nitroxide and Analogues

Few compounds are known to sensitize living organisms to the lethal effects of ionizing radiation. Since those that do include oxygen[1] and nitric oxide[2,3], both of which are stable free radicals, it was considered of interest to see if certain substituted nitroxides[4], which are water-soluble stable free radicals, would exhibit similar properties.

Escherichia coli B/r were grown with aeration to stationary phase in nutrient broth and then diluted to approximately 2×10^6/ml. in ice-cold buffered saline (0·13 M sodium chloride, 0·02 M phosphate; *p*H 6·8) for irradiation. The radiation vessels were shallow 'Pyrex' cylinders equipped with inlet and outlet tubes to permit the flow of gas over the bacterial suspension, which was stirred magnetically to promote equilibration of the dissolved gases throughout the experiment. Anoxia was

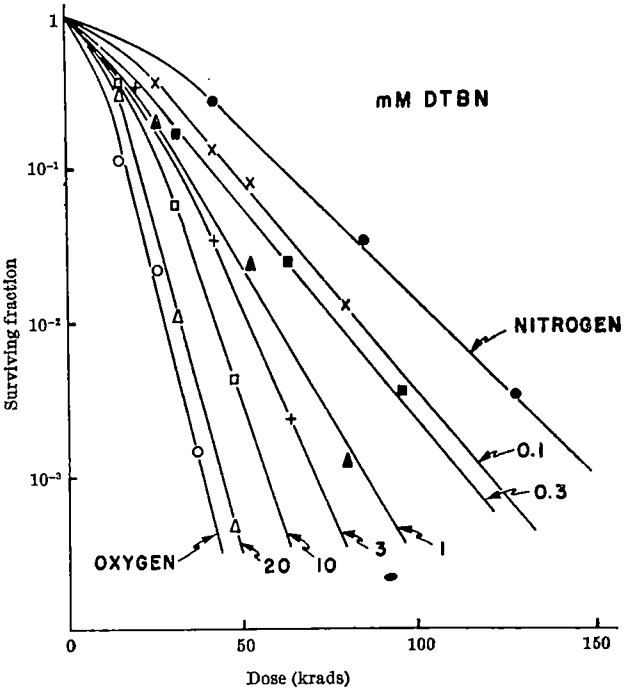

Fig. 1. The fraction of *E. coli B/r* that retains the capacity for colony formation when plated on nutrient agar, as a function of the X-ray dose delivered in the presence of various concentrations (mM) of di-*t*-butyl nitroxide under anoxia

maintained by passing nitrogen (containing less than 8 parts per 10^6 of oxygen) at a flow-rate of 12 ml./sec over the bacterial suspension for a period of 30 min prior to, and also during, irradiation. Irradiations were carried out at ice temperature with a 250-kV X-ray tube operating at 15 m.amp with a 1-mm aluminium filter. The mean dose-rate, determined by ferrous sulphate dosimetry, was $5{\cdot}4 \times 10^3$ rads/min. Samples were withdrawn after suitable X-ray doses, and after appropriate dilution the number of surviving bacteria was determined by plating on nutrient agar and counting the number of colonies produced on incubation overnight at 37° C.

Typical survival curves obtained for anoxic bacteria irradiated in the presence of various concentrations of di-*t*-butyl nitroxide (DTBN) are shown in Fig. 1. For comparison the survival curves under pure oxygen and pure nitrogen are also shown. Under the conditions of the experiment the free radicals showed no toxicity in the absence of radiation. It can be seen that there is a progressive increase in sensitivity to X-rays with increasing free radical concentration. At 2×10^{-2} M, the sensitivity is comparable with that in 100 per cent oxygen.

Similar results were obtained when the experiment was repeated with tetra-methyl-penta-methylene nitroxide (TMPMN). A third substituted nitroxide, *t*-butyl-2,6-dimethoxyphenyl nitroxide (TBDMPN), showed the same sensitizing action within the limits of its rather low solubility. The dose-reduction factors for various concentrations of the three nitroxides are shown in Table 1.

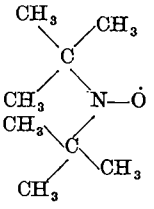

Table 1. X-ray Dose Reduction Factor for Anoxic *E. coli B/r* irradiated in the Presence of Various Concentrations of Substituted Nitroxides

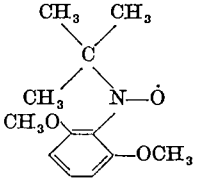
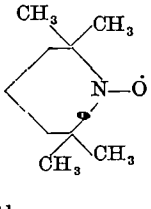
Conc. (M)	Dose reduction factor* DTBN	TMPMN	TBDMPN
10^{-4}	1·3	1·2	1·2
3×10^{-4}	1·4	/	/
10^{-3}	1·9	2·0	/
3×10^{-3}	2·0	2·2	/
10^{-2}	2·4	2·4	/
2×10^{-2}	3·2	/	/

* Defined as the ratio of doses required to kill 99 per cent of the cells in the absence of and in the presence of the nitroxide.



The structures of the substituted nitroxides are as follows:

DTBN



Di-*t*-butyl nitroxide

TBDMPN

t-Butyl-2,6-dimethoxy-phenyl nitroxide

TMPMN

Tetra-methyl-penta-methylene nitroxide

Chemically, these compounds resemble nitric oxide by virtue of the unpaired electron associated with the nitrogen–oxygen bond, but differ in that the nitrogen co-ordination number is two higher, which presumably explains the failure of the compounds to react with oxygen to form the peroxides. In comparison with nitric oxide or oxygen, much higher concentrations of the nitroxides are required for any given increase in sensitivity to X-rays, 1 mM DTBN being roughly as effective as 5 μM of oxygen in this system. The need for a higher concentration may reflect steric hindrance at the site of reaction or a lower rate of reaction, or—less likely—a difficulty in penetration into the cell. Nevertheless, the substituted nitroxides appear to be an important new class of substances for sensitizing anoxic cells to X-rays and may be of particular interest because of their stability to oxygen[4] and their apparent lack of toxicity.

We thank Dr. A. K. Hoffmann of the American Cyanamid Co. for the gift of the substituted nitroxides, and Dr. Ivar Johansen for advice.

Gamma Emitters in a Fin Whale

Baleen whales are prodigious collectors of marine zooplankton. Zooplankton in turn concentrate radionuclides. Both fission products from fall-out, and neutron-induced radionuclides (mostly zinc-65) from Hanford Laboratories, Washington, have been reported in marine zooplankton off Oregon[1,2]. An opportunity to measure the same radionuclides in various tissues of a plankton-feeding mammal occurred when a fin whale, *Balaenoptera physalus* Linnaeus, was captured west of Depoe Bay, Oregon, on September 19, 1963.

Tissue samples of a 55-ft. (16·8 m) male fin whale were removed from a fresh animal at the Bioproducts Inc. facility near Astoria, Oregon. Most samples were preserved by freezing, but stomach contents, liver, eye-ball and intestine were fixed in formalin. Samples were weighed, freeze-dried, and ashed at about 500° C. Oily tissues were burned in an open flame before ashing. Residual ash was analysed in the well of a 5 in. × 5 in. (12·7 cm) sodium iodide (Tl) crystal using a 256-channel pulse height analyser, with 100–200 min counting times. The eye was an exception. It was counted whole, lens downward, on top of the crystal. The external location of the eye-ball and its shape complicated the counting geometry and its value is subject to this additional error.

Zinc-65 was the most prominent peak in spectra of all whale tissues analysed (Fig. 1), and the large variations among tissues are probably related to differences in stable zinc and in individual turnover rates[3]. Potassium-40, the naturally radioactive isotope of potassium, was next in prominence, followed by manganeso-54, cæsium-137, zirconium-95, niobium-95, and cerium-141–144, in some tissues. Unlabelled peaks at 0·5 MeV arise from both ruthenium 103–106 and zinc-65.

The spectrum of muscle had a small peak due to ^{137}Cs, in addition to ^{65}Zn and ^{40}K, and evidence of $^{141-144}$Ce and ^{95}Zr–^{95}Nb (Fig. 1*a*). Cæsium is chemically similar to potassium and is probably taken up in the same way. The abundance of potassium in the sea reduces uptake of ^{137}Cs by marine animals, compared with terrestrial and freshwater animals.

The tongue contained much less ^{65}Zn than did other tissues in Fig. 1. Fission products (^{95}Zr–^{95}Nb and $^{141-144}$Ce) were present, with some indication of ^{137}Cs,

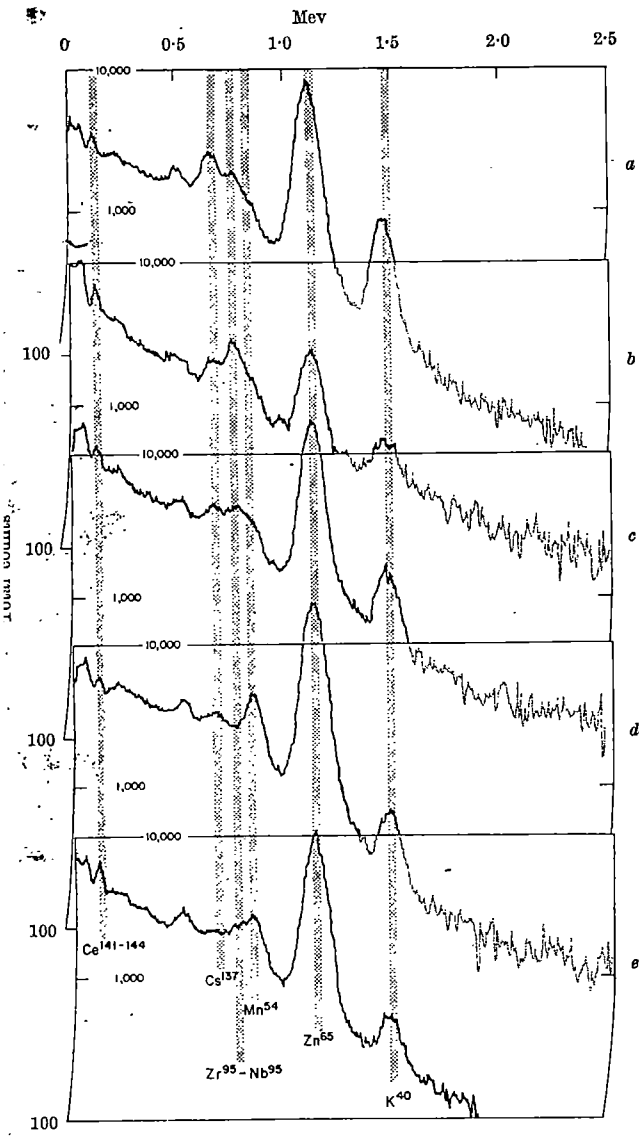

Fig. 1. γ-ray spectra of whale tissues (*a*, *b*, *c*, *d*) and stomach contents (*e*) all adjusted to the same wet weight (949 g): (*a*) muscle, (*b*) tongue, (*c*) lungs, (*d*) liver, and (*e*) euphausiids from the whale's stomach. Grey bands show location of γ emitters permitting direct comparison of relative amounts of radionuclides in each tissue. Dotted tracings of spectra indicate overlap. Counting times were 100 min with no background subtracted

even though the amount of ^{40}K was quite low (Fig. 1*b*). While the ^{95}Zr–^{95}Nb peak may result from surface adsorption, neither the spectrum of the skin (both dermis and epidermis) nor lungs (Fig. 1*c*) shows comparable evidence of this air-borne fall-out radionuclide. The spectrum of the lungs is most nearly typical of the spectra of tissues which are not individually illustrated, for example, testes, intestine, skin and blubber.

The liver contained ^{65}Zn, ^{40}K, traces of ^{137}Cs and $^{141-144}$Ce and a distinct peak of ^{54}Mn (Fig. 1*d*). Folsom *et al.*[4] reported ^{54}Mn both in sea-water and in marine organisms from off southern California. Osterberg *et al.*[5] found much larger ^{54}Mn peaks in the liver of albacore, *Thunnus alalunga*, from off Oregon, and freshwater clams, *Anodonta wahlamatenses*, from the Columbia River. Although ^{54}Mn is present in fall-out[4], it may be even more abundant in the vicinity of the Columbia River; but no direct comparisons have been made.

The stomach of the whale contained tremendous quantities of zooplankton ('krill'). Only 4 l. (primarily *Euphausia pacifica*) were removed, and a portion analysed. The resulting spectrum (Fig. 1*e*) contained mostly ^{65}Zn and

Table 1. ZINC-65 IN TISSUES OF A WHALE
The fish, used as a comparison, were various lantern fish from near the same area in which the whale was captured

Sample	^{65}Zn (pc./g wet wt.)
Liver	7·4
Lung	5·2
Stomach contents	4·0
Testes	3·6
Intestine	3·1
Muscle	2·7
Skin	2·3
Tongue	0·7
Eye (whole)	0·4
Blubber	0·2
Mesopelagic fishes	1·7–7·3

^{40}K, but $^{141-144}$Ce and ^{54}Mn and possibly a trace of ^{95}Zr–^{95}Nb were present.

In general, spectra of tissues from the fin whale resembled those of small mesopelagic fishes from the same trophic level[2]. Since fall-out is normally concentrated by herbivorous zooplankton and is discriminated against at higher trophic levels[2], the presence of ^{95}Zr–^{95}Nb in the whale tongue seems anomalous. Little, if any, appeared in zooplankton taken from the whale's stomach. Radioanalyses of euphausiids collected off Newport in October 1963 verified the virtual absence of fall-out radionuclides in euphausiids at this time. Levels of fall-out in plankton from surface waters off Oregon are much reduced compared with those observed during the past two years[5]. Therefore, the tongue may have been contaminated from terrestrial sources after capture of the whale, or by fall-out retained from a previous exposure. Since fin whales are highly mobile and our knowledge of the fall-out pattern at sea is limited, neither alternative can be readily discounted.

The activity of ^{65}Zn/g wet wt. of the various tissues is given in Table 1. Liver, lungs, testes and intestine contained the greatest amounts of this radionuclide, while the eye-ball and blubber contained the least. Maximum and minimum values for various small mesopelagic fishes, typical of levels of ^{65}Zn usually found in marine plankton and nekton in this area, are comparable with those in the whale. Since the Columbia River is the principal source of this radionuclide in the north-east Pacific Ocean[6], whales apparently accumulate ^{65}Zn rapidly during their sojourn in Oregon waters. Levels are extremely low and no health hazard exists. However, if whales retain this radioactive souvenir of the Columbia River for a sufficiently long period, the ^{65}Zn should provide a useful tracer for migration investigations of these ocean wanderers.

These preliminary results warrant further investigation, particularly since the great size of the whale provides samples of almost all tissues in quantities suitable for radioanalysis. Unfortunately, the small 90-ft. (27·4 m) whaling boat was damaged when it prematurely tied to an 80-ft. (24·4 m) whale[7]. This required a delay for repairs, and the subsequent onset of winter storms ended the whaling season.

We thank R. Carruthers and L. Anderson, of Bioproducts, Inc., and L. Hubbard for their assistance, and J. McCauley for identification of our samples.

Autoradiographic Evidence of Synthesis of an Arginine-rich Histone during Spermiogenesis in *Drosophila melanogaster*

The DNA-associated protein of the animal spermatozoon customarily undergoes two major changes in the course of differentiation of this cell during spermatogenesis. These changes, as have been established in a variety of organisms, are cytochemically delineable by the alkaline-fast-green, picric acid-bromophenol blue, and ammoniacal-silver staining methods[1–4], when used in conjunction with the procedures of deamination and acetylation[5–7]. The first of these changes relates to the replacement of a lysine-rich histone by one rich in arginine in the spermatid stage of development of the spermatozoon, and the second change reflects the acquisition of protamine in place of the arginine-rich histone by the maturing spermatozoon. In *Drosophila melanogaster*, however, there is observed only the first of these protein transformations[8,9], and this occurs, according to our observations, at the terminal stages of spermiogenesis, shortly before eclosion of the fly (within 24 h or so at 29° C); that is, the time of the arginine-histone shift during sperm development in *D. melanogaster* coincides with the second stage of these chemical alterations in some other organisms, and there is no subsequent change to protamine in the mature spermatozoon.

The implications of the sequential transition of chromosomal proteins during development of the spermatozoon must necessarily be considered at both the biological and biochemical levels. We have previously ventured to speculate in some measure on the biological significance of such chemical transformations as are operative during animal spermatogenesis[8,9]. We now wish to report the preliminary results of autoradiographic studies which were undertaken to elucidate the nature of the chemical processes that underlie protein transition in *D. melanogaster*.

Testes of the Swedish-*b* stock were removed from pupæ shortly before the time of emergence of the adults, by dissecting in a modified Ephrussi–Beadle medium (EBM) made by adding 0·7 g NaCl, 0·035 g KCl, and 10 mg glutathione to 100 ml. of 0·0125 M sodium phosphate buffer at *p*H 6·8. Groups of 12–15 pairs of testes were excised in the above solution and transferred for treatment to one of the following two solutions (designated as *a* and *b*), where they remained at either room temperature (about 22° C), at 25° C, or at 37° C for 3–5 h: (*a*) tritiated-arginine (0·1 ml. tritiated-arginine of specific activity, 105 mc./m.mole to 0·4 ml. EBM); and (*b*) puromycin (0·3 ml. of 0·01–0·1 mg/ml. puromycin to 0·1 ml. tritiated-arginine and 0·1 ml. EBM adjusted to *p*H 7·2–7·4).

These intact treated testes and other groups that served as untreated controls were then transferred to 10 per cent neutral buffered formalin and allowed to remain in the fixative for 6–12 h at room temperature. After washing and dehydrating, the testes were embedded in paraplast. Sections were then cut at 3–5μ. Following deceration and hydration, the sections were rinsed in cold perchloric acid to remove acid-soluble, low-molecular-weight precursors. Some of the sections from experiment *a* were stained specifically for arginine-rich histone. All sections were then covered with '*AR*-10' autoradiographic stripping film (obtained from Kodak, Ltd., England). The film was exposed for 4–6 weeks, after which the autoradiographs were developed and processed by the usual method.

Our previous cytochemical investigations of spermatogenesis in *D. melanogaster* revealed that a shift from a lysine-rich to an arginine-rich histone occurs during the final stages of maturation of the spermatozoon[8,9]. This transition was presumed, by analogy with the experimental studies of Bloch and Hew[2,3] on *Helix aspera*, to reflect a synthesis of new protein molecules. Confirmation has now been obtained by investigating the pattern of incorporation of tritiated-arginine.

Fig. 1. Longitudinal section of pupal testis of *Drosophila melanogaster*. Arrows indicate bundles of mature spermatozoa the heads of which show heavy incorporation of tritiated-arginine

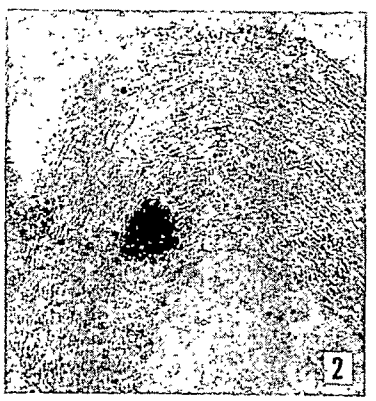

Fig. 2. A single bundle of spermatozoa at high magnification showing that tritiated-arginine has been incorporated in sperm heads

Microscopic examination of sections of testes offers clear evidence that tritiated-arginine is built into the nuclei (or heads) of maturing spermatozoa. The over-all distribution of the incorporated radioactive arginine parallels that of the arginine-rich histone, as determined by the specific colour reaction for nuclear basic proteins, namely, alkaline-fast-green stainability after deamination. For example, in some of the sections from experiment *a*, it could unmistakably be observed that the heaviest concentration of silver grains lies over nuclei of spermatozoa that exhibit by their staining reactions the presence of an arginine-rich histone (Figs. 1 and 2). However, in some bundles of mature spermatozoa showing alkaline-fast-green stainability after deamination, no evidence of incorporation of tritiated-arginine was detected, and in other bundles only a small fraction of the spermatozoa appeared to be labelled. We assume that these patterns reflect differences in the original distribution of the isotope within the testis, or differences in its uptake by spermatozoa with dissimilar physiological properties.

The incorporation of amino-acid may not in itself be considered as offering sufficient proof of protein synthesis, unless evidence can be presented of a net production of new protein molecules[10]. We have found that uptake of amino-acid becomes more pronounced (increasing beyond the threshold values) as the time and temperature of treatment increase. Moreover, uptake is inhibited in the

presence of puromycin. These findings suggest that the incorporation of tritiated-arginine into the spermatozoon of *Drosophila* reflects a true synthesis, which is expressed in the production of new molecules of arginine-containing proteins.

Synthesis and incorporation during the terminal stages of spermiogenesis involve a unique system, since the nucleus of the mature spermatozoon consists primarily of DNA-protein, and lacks any nucleolus-synthesized RNA of recent origin (the nucleoli having broken down during spermiogenesis[11]) as well as a large share of the cytoplasmic RNA that was present during earlier stages of transformation. The exact mechanism controlling the incorporation of amino-acids into DNA-associated protein within the head of the spermatozoon of *D. melanogaster* remains to be determined, and experiments designed to provide an answer are now in progress. In the grasshopper, *Chortophaga viridifasciata*, according to a recent report by Bloch and Brack[12], the arginine-containing histone is synthesized in association with RNA granules in the cytoplasm of the spermatid and then migrates into the nucleus where it combines with the DNA.

BIOLOGY

Schistosoma mansoni: Humoral Transfer of Protective Factors produced by Irradiated Cercariæ

Previous investigations[1,2] have produced information concerning the manner in which prior exposure of mice to irradiated cercariæ of *Schistosoma mansoni* affects the course of the challenge infection. The results indicated that the principal effect of the aborted infection with irradiated cercariæ was to slow the migration and development of worms from the challenge infection. The delay in accumulation of recoverable worms and eggs suggested the probability of inhibitory factors being produced by the aborted infection with irradiated cercariæ, although their relation to specific acquired resistance could not be defined.

The experiments described here produced additional information concerning the nature of the changes induced by irradiated cercariæ.

Mice were exposed on three occasions on alternate days to 500 mixed cercariæ irradiated with 2,000 r., thus making the total 1,500 cercariæ. The mice infected with

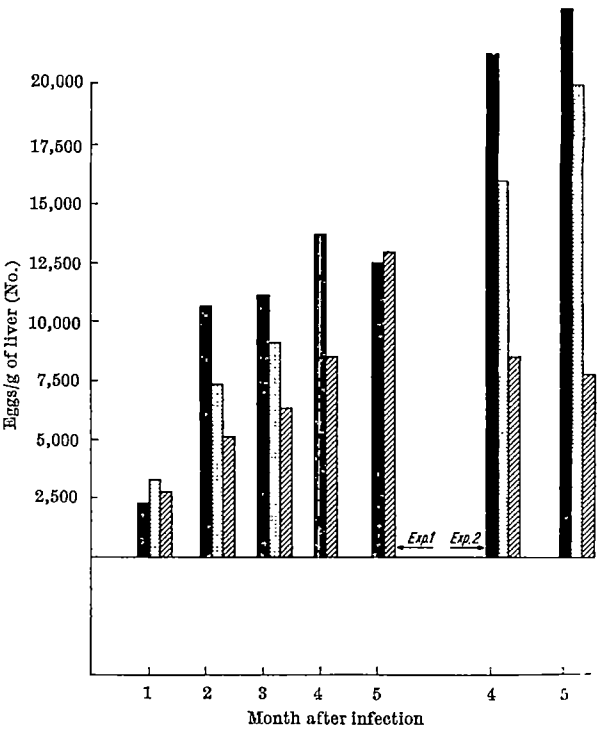

Fig. 1. Effect of humoral transfer of factors produced by irradiated cercariæ on liver–egg accumulation following infection with *S. mansoni*. Each bar represents the mean of counts based on 5–10 mice. Egg counts were compared by Wilcoxon two-sample test: immune serum versus control: Exp. 1; 3 months, P, 0·016, 5 months, P, 0·05. Exp. 2; 5 months, $P < 0·01$, 6 months, $P < 0·01$. Normal serum versus control: Exp. 1; 3 months, P, 0·016. Exp. 2; 5 months, P, 0·048. Immune versus normal: Exp. 2; 5 months, P, 0·054, 6 months, $P < 0·01$. The remaining comparisons did not show differences significant at the 10 per cent level. Black, control; stippled, receiving normal serum prior to infection; hatched, receiving 'immune' serum prior to infection

the irradiated cercariæ were bled 60 and 90 days after the last exposure and the sera used in immunization tests. The time chosen for bleedings were based on previous investigations[1,2]. The pooled sera from the 60- and 90-day bleedings were used in Exps. 1 and 2 respectively. In both experiments female white Swiss mice weighing 20–24 g were given 0·8 ml. of pooled serum intraperitoneally and then exposed to 70 sex-determined (35 female + 35 male) normal cercariæ. Evidence of humoral immunity transferred to fresh animals was sought in worm counts, in liver–egg counts and mortalities as compared with results from control mice. All procedures used for exposure of cercariæ to radiation, for infection of animals, and for evaluation of the infections have been described[1,2].

Data from both experiments are presented in Fig. 1. When mice were examined five months after infection, the egg counts from mice that received 'immune' serum prior to infection were significantly lower than egg counts from control mice (solid bars). While the counts rose in Exp. 1 and by month 6 after infection were not different from those of control mice, they continued much lower than counts from control mice in Exp. 2. As these two experiments differed only in that the 'immune' serum used in Exp. 1 was obtained from mice 30 days earlier than that used in Exp. 2, it appears that the protective factors produced by the irradiated cercariæ were more potent or at a higher titre 3 months after exposure than after 2 months.

The numbers of worm pairs in the portal system of mice that received immune serum prior to infection was also lower than those from control mice, and these counts did not rise as the infection became older. Thus, 30 days after infection the worm pair return in the portal system of control mice was 13 per cent and only 8–9 per cent in test mice. Ninety days after infection the worm pair return reached a maximum of 18–20 per cent in control

Table 1. The Effect of Humoral Transfer of Factors produced by Irradiated Cercariæ on Deaths of Mice Five Months following exposure to *S. mansoni*

Mice receiving	Exp. 1 * No. of mice used	Exp. 1 * Percent cumulative deaths	*P*	Exp. 2 † No. of mice used	Exp. 2 † Percent cumulative deaths	*P*
'Immune' serum	20	30	= 0·014	20	20	= 0·024
No serum	27	70		26	50	
Normal serum	15	73	> 0·10	20	35	> 0·10

* 'Immune' serum versus normal serum; *P*, 0·026.
† 'Immune' serum versus normal serum; *P* > 0·10.

mice receiving either normal serum or no serum at all, and remained unchanged in the immunized mice (8·6 per cent).

The cumulative deaths among test and control animals were compared with the use of a χ^2 test (and in one case, Fisher exact test), and results obtained are shown in Table 1. It is clear from these results that mice receiving 'immune' serum prior to infection tended to live longer than control mice receiving no serum or 'non-immune' serum. The answer to the question whether death of mice was prevented or only delayed is beyond the scope of those short-lasting experiments.

It is noteworthy that the numbers of eggs recovered from the livers of the control mice receiving the normal serum prior to infection were also lower than the egg counts from the control mice receiving no serum. However, they rose more steadily with the passage of time than those from mice receiving 'immune' serum prior to infection. The decreased mortality among mice receiving normal serum prior to infection, as seen in Exp. 2, suggests that specific humoral antibodies may not be essential for the observed protection against *S. mansoni* infection.

The results obtained concerning egg recovery seemed to parallel those previously reported[1,2], showing once again that the effect of humoral factors produced by irradiated cercariæ was to slow the liver egg accumulation after exposure to normal cercariæ. However, the effect on worm return differed. The worm return in mice pre-infected with irradiated cercariæ increased as the challenge infection became older, whereas in mice receiving 'immune serum' no such increase occurred. Furthermore, pre-infection with irradiated cercariæ neither delayed nor prevented death caused by a challenge infection. In mice receiving 'immune serum' mortality was significantly reduced during the period of observation.

Further experiments will be necessary to assess the potential importance of humoral protective antibodies in immunizing procedures against schistosomes.

I thank Dr. David W. Alling for making the statistical tests, and Mr. L. T. Cannon for his assistance.

Influence of Serum of Children and Adolescents on the Growth of Plants

Macht and Livingston introduced in 1922 a root-growth test for the investigation of the interaction between the physiology of the animal and vegetable kingdoms. Macht demonstrated in a large number of papers that, under standard experimental conditions, sera from healthy persons inhibit the growth of *Lupinus albus* roots. The sera from patients suffering from various diseases, especially cancer, were also investigated by Rønnike[1]. So far as we know, no experiments of this type have previously been made in children. From this point of view, we investigated 113 sera from children and healthy adolescents as well as 273 sera from patients affected by various diseases. In 113 sera from healthy individuals aged 9 months to 23 years we found that, with sera from individuals of increasing age and height, the growth of roots of *Lupinus albus* was increasingly inhibited. We found also that there is no substantial difference between the average inhibition caused by sera from boys or girls. Fig. 1 summarizes our experiments.

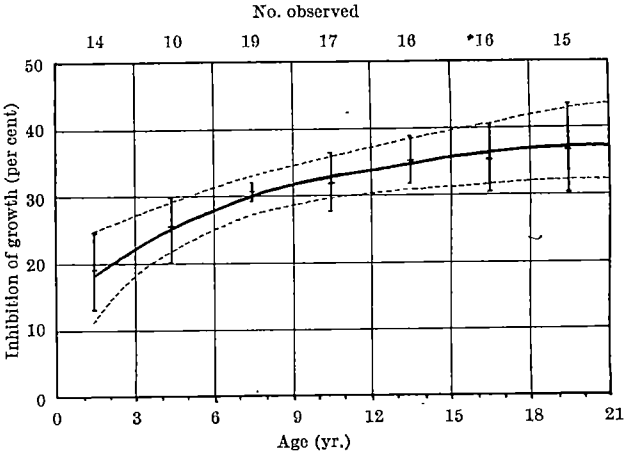

Fig. 1. Inhibition of growth of roots of *Lupinus albus* by serum from children and adolescents. Vertical lines, 95 per cent confidence limits of observed means; solid line, theoretical curve of mean values; broken lines, 95 per cent confidence limits of theoretical means

We have analysed the inhibitory effect of sera of healthy children as well as children treated for prolonged periods with corticosteroids, and children suffering from malignant growths. These results will be published in a later communication.

Hardening Treatment of Seeds as a means of increasing Yields under Conditions of Inadequate Moisture

Genkel *et al.*, as well as a number of other investigators, have claimed that 'hardening' treatment of seeds increases the drought, heat and frost resistance of plants developing from the treated seeds[1,2]. This 'hardening' treatment or 'P. A. Genkel's method' is nothing else but the repeated soaking and drying of seeds before sowing, a method already reported by Will[3] in 1883 as being effective in increasing drought and frost resistance. It is claimed that plants made drought resistant in this way yield higher yields under drought conditions. As an example, we cite Mart'yanova[4], who reports for barley grown in 1957 a yield of 28 centner/hectare of treated and of 18 centner/hectare for untreated plants.

Zubenko[5], working with corn, concludes that this method "could be recommended for wide use in crop production . . . when growing it in conditions of inadequate moisture without sprinkling and also with irrigation". In a recent extensive survey of the Russian work, May, Milthorpe and Milthorpe[6] have stressed the need of exploring the practical value of this technique because the 'hardening treatment', if successful, would be one of the

most important improvements of arid zone agriculture. It seemed, therefore, advisable to repeat the 'hardening' experiments. It was not intended to test drought resistance or tolerance which, according to recent tests of Waisel[7] and Jacoby and Oppenheimer[8], with wheat and sorghum, is not increased by the hardening treatment. Our experimental aim was a purely practical one as we only wanted to find out if 'hardened' plants when grown under water stress caused by insufficient soil moisture develop better and yield more than untreated controls.

In summer 1962, grains of *Sorghum* var. 'Early Haggary' were soaked at room temperature in distilled water until they had taken up an amount of water equivalent to 50 per cent of their imbibition water, after the maximum of water taken up by the grains during imbibition had been determined in a previous experiment. The moist grain was then spread out in a thin layer and air dried until it had reached its initial weight. The procedure was repeated three times. This method of pre-treatment was chosen after preliminary experiments had shown that germination and seedling development of pre-treated grains were normal.

Table 1. Average Height (cm) of all the Plants contained in the Ten Tins of Each Treatment, Total Number of Flowering and Fruiting Stalks per Each Treatment

Treatment	Average height (cm) per plant	No. of flowering stalks of all plants	No. of fruiting stalks of all plants
$N+$	45·7	10	20
$N-$	52·3	13	16
$N/2+$	26·9	1	0
$N/2-$	24·8	2	0

After the last drying, the grains were sown on May 29, 1962, into tins (22 cm × 22 cm × 22 cm), 10 grains to one tin. The tins were filled with 10 kg of loess soil each, collected from our desert farm in Avdath[9]. Before the sowing, the loess was watered to full saturation and was kept at field capacity for the following three weeks until the grains had germinated and the seedlings had started to grow. At that time the seedlings were thinned out and only five seedlings per tin were left. The tins were then divided into two lots. Lot N, consisting of 20 tins, received twice a week 1 l. of water per tin, which was sufficient to keep the soil wet, whereas lot $N/2$ (20 tins) received at the same times only 0·5 l. of water per tin. This last treatment put the plants under considerable water stress as can be seen from the results (Table 2). Ten tins of each N and $N/2$ contained pre-treated ($N+$, $N/2+$) and 10 tins untreated grain ($N-$, $N/2-$) serving as controls. All the tins were placed in a randomized block design on a plot in the experimental field of the department. As the experiment was carried out during the dry season, the tins received no rain.

Table 2. Average Height, Fresh and Dry Weight of Vegetative Parts, and Average Dry Weight of Grains of all the Plants of Each Treatment and Number of Fruiting Stalks per Treatment

Treatment	Average height (cm) per plant	Average fresh weight (g) per plant	Average dry weight (g) per plant	No. of fruiting stalks of all plants	Average dry weight of grains (g) per plant
$N+$	46·6 ± 7·15	7·9 ± 1·7	2·9 ± 0·41	42	1·70 ± 0·81
$N-$	56·0 ± 7·84	9·2 ± 1·73	3·4 ± 1·79	42	2·30 ± 0·57
$N/2+$	20·6 ± 3·69	2·1 ± 0·72	1·1 ± 0·26	6	0·23 ± 0·14
$N/2-$	19·4 ± 4·84	2·1 ± 0·84	1·3 ± 0·62	5	0·64 ± 0·05

The first flowers were formed by the N plants in the first week of August, whereas at that time the $N/2$ plants were still in the vegetative state. On August 21, 1962, the average height of the plants and the number of flowering and fruiting stalks were determined (Table 1).

On September 10, 1962, the plants were harvested, that is, cut at the soil surface, their height measured, fresh and dry weight of vegetative parts and grains determined (Table 2).

A statistical analysis has shown that all the differences between $N+$ and $N/2+$ and those between $N-$ and $N/2-$ are highly significant at the 5 per cent level. The differences in average height, average fresh weight of vegetative parts and average dry weight of grains between $N+$ and $N-$ are significant on the same level. There is no significant difference of average height and average fresh weight between $N/2+$ and $N/2-$, whereas the difference in dry weight of grains is highly significant at the 5 per cent level.

It is, therefore, obvious that under the conditions of our experiment with *Sorghum* the 'hardening' treatment of the seeds does not increase grain yields in either the normally watered plants or those which suffered from lack of water. The contrary is true, that is, in both cases the grain yield was negatively affected by the treatment.

In the case of the normally watered plants, height, fresh and dry weight of vegetative parts was also significantly lower in the 'hardened' than in the untreated plants.

Dependency of Pollination on Patterns in *Monarda* (Labiatae)

The members of the genus *Monarda* are usually pollinated by bees and wasps. The latter will also nip holes into the backs of the expanded corolla tubes to take the nectar directly and thus circumvent the process of pollination. Some corollas, like those of *M. clinopodia* and *M. lindheimeri*, are very rich in nectar. Nectaries are located in the throat of the corolla tube from the opening downward toward the base, and consist of short hair-like glands. They are protected by a dense ring of non-glandular pubescence at the inner throat opening. In the small and abruptly expanded corolla tubes of the sub-genus *Cheilyctis* the nectaries extend over a more restricted area than in the larger and more evenly expanded corolla tubes of most species in the sub-genus *Monarda*.

Many species have so-called 'nectar guides', which are composed of rows of spots on the lower corolla lip. Most taxa in the sub-genus *Cheilyctis* possess them, and *M. russeliana* and *M. bradburiana* in the sub-genus *Monarda*. These nectar guides lead to the throat opening. In one section of the sub-genus *Cheilyctis* there are, in the back of the throat, 3–5 additional distinct round spots of pigment above the nectaries. In the other section there are, instead of the dots, 3–5 thin vertical lines. The upper corolla lips in many species are also marked. These markings, I assume, increase the pattern of irregularity[1], and thus attract the insects. With the exception of *M. russeliana* and *M. bradburiana*, which are woodland species, all taxa with markings exude a strong fragrance. This undoubtedly is due often to their high oil content of thymol and carvacrol and its vaporization in nature. It is facilitated in those species which are exposed to direct sunlight. I believe that this fragrance attracts the pollinating insects from a distance. Once attracted near the plant by odour, the insect may be induced by colour and pattern to visit it. The insect then follows the nectar guides, especially in the sub-genus *Cheilyctis* with the very arcuate corolla.

Experimentation with colchicine, a mutagenic reagent, to induce teratologies in order to learn about evolutionary homologies produced flowers of *M. punctata* var. *arkansana* with entirely unspotted corollas. These, when grown in a nursery row, showed during periods of several weeks that bees and wasps would alight on the lower lip, but apparently being at a loss would always leave again without feeding. When these unspotted plants, however, were grown among ordinary spotted ones in nursery rows, the insects would ignore them altogether, but would visit the flowers of the spotted ones and enter the throat.

I believe that part of the *Blumenstetigkeit* in bees is not only due to distance, fragrance and colour of the flowers as such, but also to a definite colour pattern. The bees, therefore, would ignore the unspotted plants growing together with the spotted ones, if conditioned to or expecting spotted flowers. Their visits to the non-spotted flowers growing by themselves might have been due to random or accidental visits. It is also interesting to note that certain species of *Monarda* have developed a colour in their bracts subtending the glomerules which approaches that of the corolla. Some have even originated additional spotting on these bracts similar to that of the corollas, thus increasing the total effect of flower pattern.

VIROLOGY

Inhibition of Multiplication of Foot-and-Mouth Disease Virus by Guanidine Hydrochloride

It has recently been shown that the multiplication of many picornaviruses can be specifically inhibited by non-cytotoxic concentrations of guanidine hydrochloride and 2-(α-hydroxybenzyl)-benzimidazole (HBB)[1]. These inhibitors appear to act by interfering with the production of virus-induced RNA-polymerase[2].

Tamm and Eggers[1] have produced a classification of some small RNA viruses on the basis of their response to these two inhibitors. It was of interest, therefore, to determine the effect of these inhibitors on foot-and-mouth disease virus (FMDV) and to establish the position of FMDV in this classification.

Virus strains of all seven immunological types of FMDV were examined: strains 119–1 (type *A*), *C*997–1 (type *C*), *M*11–30 (type *O*), *Tur* 43/62–1 (*SAT* 1), *Rho* 1–285/1 and *Kenya* 3–476 (different sub-types of type *SAT* 2), *RV* 7–323 (type *SAT* 3) and *Pak* 1–1 (type *Asia* 1). These strains are all laboratory strains maintained by passage in pig-kidney monolayers, except *Tur* 43/62–1 which was passaged in *BHK* tissue.

Pig-kidney and *BHK*-21 cells (ref. 3) were used for virus assay, either as monolayers, suspended cell plates or in the metabolic inhibition test (pig-kidney only)[4]. The standard tissue culture procedure for FMDV was followed[5]. The results obtained were substantially similar whichever host cell system was employed and only the pig-kidney data will be quoted.

Guanidine hydrochloride and HBB (supplied by courtesy of Dr. K. Folkers of Merck, Sharp and Dohme, New Jersey) were incorporated into either solid overlay or fluid medium. HBB was not completely soluble and was treated as recommended by Tamm and Eggers[1].

It was found that HBB had no effect on the multiplication of the eight strains of FMDV tested by the methods of assay used (plaque inhibition, suppression of cytopathic effect and virus yield) at concentrations as high as 500 μg/ml. No HBB-susceptible virus was available to test the potency of the HBB sample used, but there was no reason for supposing that it was in any way defective. Moreover, unsubstituted benzimidazole had no effect on FMDV multiplication at concentrations (0·25–1 mg/ml.) which have been reported to reduce significantly yields of poliovirus[6].

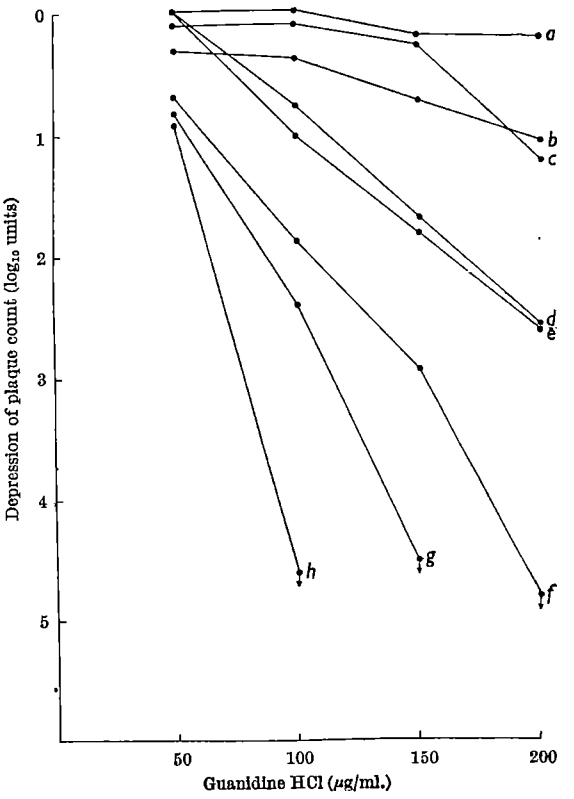

Fig. 1. Effect of increasing guanidine concentration on plaque count. Determined by titration on pig-kidney monolayers with guanidine hydrochloride incorporated in the overlay. *a*, C997–1 (type *C*); *b*, *M*11–30 (type *O*); *c*, 119–1 (type *A*); *d*, Kenya 3–476 (type *SAT* 2); *e*, *Pak* 1–1 (type *Asia* 1); *f*, *Rho* 1–285/1 (type *SAT* 2); *g*, *Tur* 43/62–1 (type *SAT* 1); *h*, *RV* 7–323 (type *SAT* 3)

On the other hand, it was found that these eight strains of FMDV were susceptible to guanidine inhibition. Three of the strains—119–1, *M*11–30 and *C*997–1—only exhibited appreciable inhibition at relatively high guanidine concentrations (200–600 μg/ml.). The remainder were susceptible at lower concentrations, and Fig. 1 indicates the relative susceptibilities of the eight strains in the concentration range 50–200 μg/ml. Guanidine hydrochloride was not observed to have any inactivating effect on the virus at these concentrations. Inhibition was reversible, and prolonged (24 h) pre-exposure of tissue to guanidine hydrochloride (200 μg/ml.) did not subsequently affect adsorption and virus yield even in the case of the most susceptible strains.

Although only a few strains have been examined it is of interest that the most susceptible strains were those of immunological types *SAT* 1, *SAT* 2, *SAT* 3 and *Asia* 1, whereas those of types *A*, *C* and *O* were much less susceptible. The fact that the former types are at present restricted to the African and Asian continents, whereas the latter are widespread, may be indicative of a taxonomic relationship.

Otherwise the different levels of guanidine susceptibility observed showed no obvious correlation with other virus properties. No difference in guanidine susceptibility was detected between an early virulent passage level of the *Tur* 43/62 strain and a late attenuated passage level (kindly made available by G. N. Mowat of this Institute).

It has been possible to isolate stable variants of increased resistance from the more susceptible strains. For example,

[illegible]ts resistant to 400 μg/ml. guanidine hydrochloride [illegible]been isolated from strains *Rho* 1–285/1 and *Kenya* [illegible]. Mutation of this marker was not associated with [illegible]on of any other of the marker characteristics [illegible] in these strains (heat resistance, capacity to [illegible]y at elevated temperature, adult mouse patho-[illegible]y). Estimates of the mutation rate of this charac-[illegible] by fluctuation test have been made and will be [illegible]ed elsewhere[7]. It has not as yet been possible to [illegible]e guanidine-dependent variants.

[illegible]n the basis of its response to these inhibitors FMDV [illegible]mbles the coxsackie *A* viruses[1]. Similarity between [illegible]e coxsackie viruses and FMDV in respect of their [illegible]athological effect in infant mice has previously been [illegible]noted[8].

Comparative Immunological, Biological and Biophysical Behaviour of Meningopneumonitis Viral Antigenic Preparations

THE Psittacosis-LGV-Trachoma (*PLT*) group of viruses is mainly characterized by their complement-fixing (*CF*) activity[1–5]. We have recently reported multi-functional, that is, *CF*, precipitating and leuco-agglutinating meningo-pneumonitis viral *MPV* sub-units[6]. These immunological sub-units differ from those observed by electron microscopy after negative staining. They could easily be obtained by genetron extraction of the virus (*FEM*)[6]. We now wish to report immunological, biological and biophysical behaviour of *FEM* sub-units in comparison with several other antigenic preparations reported in the past.

Fig. 1 shows the infra-red spectrum of *FEM* extracted with ether. The dip at 2·8μ is probably due to peptide N–H bond stretching and the band at 3·4–3·5μ is due to C–H bond stretching. Strong absorption at 5·8μ is strongly indicative of lipid. Protein is indicated by peptide absorption at 6·05 and 6·5μ. Bands between 9 and 10μ are due to nucleic acid. The curve in Fig. 1 is very similar to that of phenol-insoluble *MPV* antigen and of methanol–chloroform extract of *MPV* as published by Benedict[7]. This observation further substantiated the results obtained by enzymatic degradation of the precipitinogens, indicating a lipid, protein and nucleic acid composition[6]. The curve (Fig. 1) obtained from the ether extract of normal egg factor (prepared in the same way as *FEM*) exhibits few absorption dips, but it does indicate the N–H bond stretching at 2·8μ and a small amount of absorption at 5·9μ due to lipid.

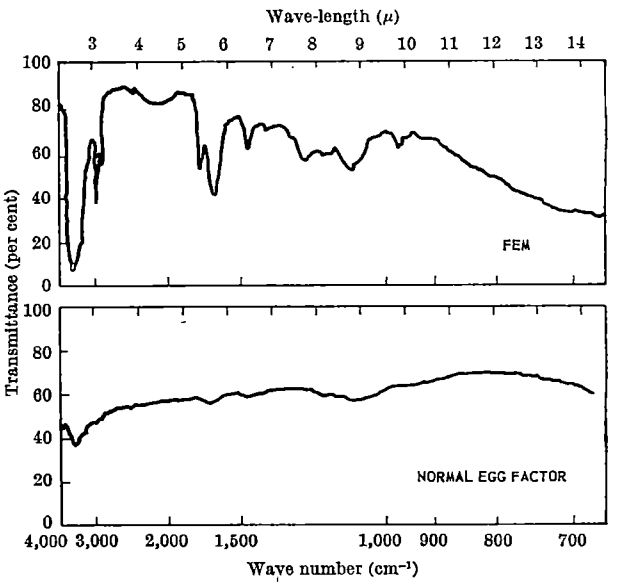

Fig. 1. Infra-red spectra of fluorocarbon-extracted meningopneumonitis virus (*FEM*) and normal egg factor antigens

CF abilities of *FEM* and its ether extract were compared with those of several antigenic preparations. *FEM* showed *CF* activity at a dilution of 1 : 512 with group-specific psittacosis antiserum. On ether extraction a 40-fold increase (1 : 20,480) in *CF* activity with type-specific antiserum and a 20-fold increase with group-specific antiserum were obtained (Table 1). It has previously been reported that species-specific activity has been unmasked by destruction of group-specific antigens with periodate or lecithinase[8–10]. Ross and Gogolak reported a titre of 16,000 in ether extracts of feline pneumonitis and psittacosis virus disrupted by ultra-sonication[9,10]. Ether-insoluble groups and type-specific *CF* antigens were isolated by making use of their alkali solubility. Cell walls of *MPV* isolated by sodium deoxycholate also had a type and group-specific *CF* activity of 1 : 1,280 titre. The deoxycholate-soluble fraction also contained both antigens. Ross and Jenkins[11] have reported only type-specific *CF* antigen in cell wall; our *MPV* cell wall preparations, however, contained two precipitinogens, one in position 1 and the other in position 7; the other five components were extracted in the sodium deoxycholate (Fig. 2).

All antigenic preparations, except the alkali-soluble one, showed multi-functional viral sub-units having precipitating or leuco-agglutinating and *CF* activities.

The thermal inactivation curves presented in Fig. 3 show that the five virus preparations listed could be divided into three groups based on the susceptibility of their *CF* ability to heat inactivation above 60° C. Group 1: Antigenic preparations characterized by thermolabile component(s) only, which showed linear inactivation with no constant residual *CF* activity above 80° or 90° C. Only the alkali-soluble, ether-insoluble extract of *MPV* exhibited thermolability of this nature. Group 2: Pre-

Table 1. COMPARISON OF COMPLEMENT-FIXING, PRECIPITATING AND AGGLUTINATING ACTIVITIES OF VARIOUS ANTIGENIC PREPARATIONS OF MENINGOPNEUMONITIS VIRUS

Antigenic preparations	Complement-fixing titre* of antigens		Ouchterlony's reaction (precipitating lines)	Agglutination of rabbit pseudo-eosinophils
	MPV specific-antiserum	Psittacosis group antiserum		
Genetron extract of *MPV* (*FEM*)	512	256	All (1–7)	+
Ether extract of *FEM*	20,480	5,120	All	+
Alkali-soluble, ether-insoluble *MPV*	1,280	640	None	−
MPV cell wall preparation	1,280	1,280	1 and 7	+
Deoxycholate extract (without cell wall) of *MPV*	640	640	2, 3, 4, 5 and 6	−

* Titre indicating reciprocal of highest dilution of antigenic preparations.

parations which exhibited a constant residual activity above 80° or 90° C, dependent on the concentration of the thermolabile components. The genetron extract (*FEM*), its ether extract and the preparations of *MPV* minus cell wall fell into this category. Group 3: Preparations relatively thermostable up to 90° C. The *MPV* cell walls alone showed this type of heat resistance.

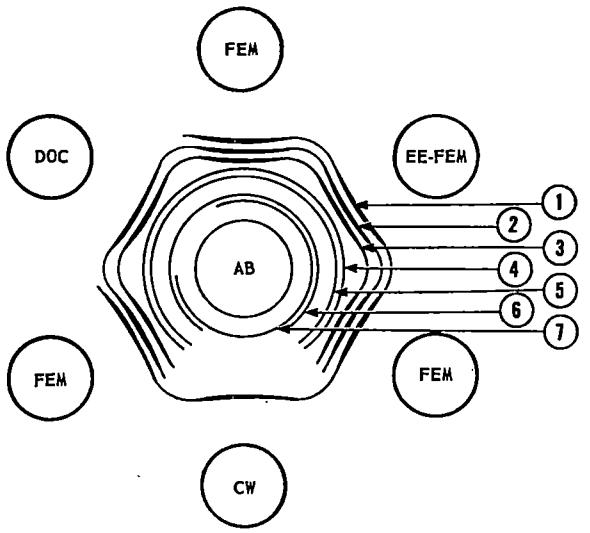

Fig. 2. Diagrammatic representation of precipitinogens of *MPV* by the Ouchterlony technique. *FEM*, undiluted fluorocarbon extract of the concentrated infected yolk sac; *EE-FEM*, ether extract of *FEM*; *CW*, cell wall of *MPV*; *DOC*, deoxycholate extract (without cell wall); *AB*, pooled undiluted rabbit antibody to *FEM*. Numbers 1–7 indicate precipitating lines from the antigenic cup to the antibody cup

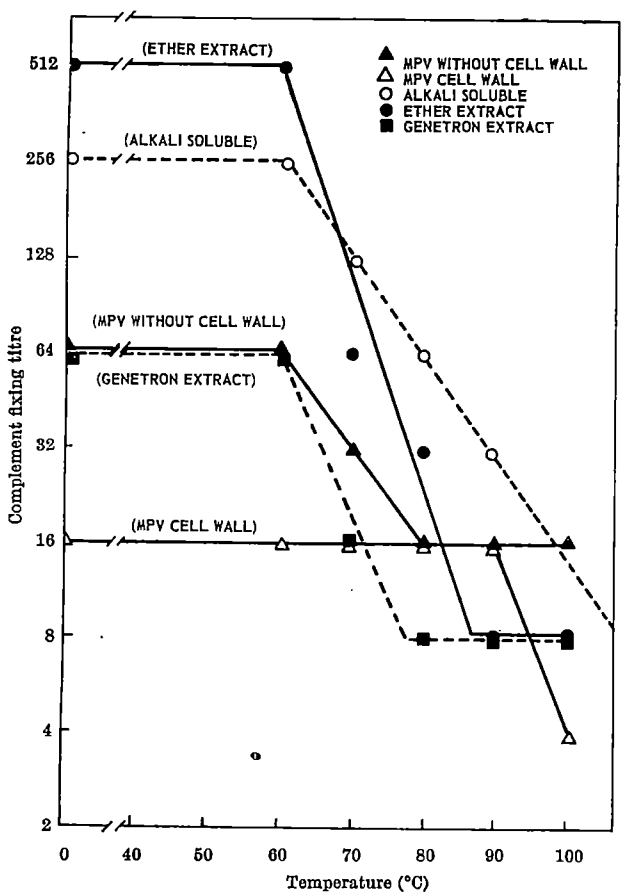

Fig. 3. Thermal curve of complement-fixing activities of various antigenic preparations of *MPV*

Thus, by careful inspection of the thermal inacti curves it is possible to suggest the location of the *CF* antigens in the virus particles. There appea at least two species of thermostable antigens in elementary bodies, one of which is located in or virus cell wall, and another which lies within the pa The thermostable antigen of the cell wall also seem responsible for leuco-agglutination and some deg precipitating ability (Table 1). The finding that th cell wall yielded a relatively thermostable antigen agreement with the report by Ross and Gogolak[9,10] similar antigen in *MPV*. *FEM* exhibits both ther stable and thermolabile antigens in addition to leu agglutinating ability. On ether extraction of *FEM* tw significant events take place. First, the thermostable antigen is completely taken up by the ether, and secondly, the thermolabile antigen undergoes some sort of unfolding or fission to yield two (or more) antigens, one of which is ether soluble and yields an eight-fold higher titre than the original *FEM*; this extract also shows leuco-agglutinating ability. Thus, it can be seen that the thermostable and thermolabile complement-fixing activity and precipitinogen formation at positions 1 and 7 (Fig. 2; Table 1) are associated with the cell wall and/or surface of the virus particle. In summary, then, the multifunctional *MPV* antigen responsible for leucoagglutination appears to be either a protein-lipid-carbohydrate-DNA complex which exhibits group specificity and is responsible for precipitinogen line 1 or a protein-lipid-RNA complex which is responsible for line 7, but which is not group specific (see ref. 6 for biochemical composition).

Similar thermal inactivation investigations have been carried out with psittacosis *CF* antigens. Early work by Bedson[2] showed that *CF* antigens derived from psittacosis infectious material could be separated into a group-specific antigen which was stable at 100° C, and a type-specific antigen which was heat-labile. More recently Volkert and Christensen[12] and Benedict and O'Brien[3] have separated psittacosis *CF* antigens into ether-soluble and ether-insoluble fractions, both of which contained *CF* activity. Ross and Gogolak[9,10] showed that although the alkali-soluble fraction and the ether-soluble fraction were serologically related, differences were observed both in their hæmagglutination properties and their gross heat stability. Kinetic studies of the thermal destruction of influenza *A* virus hæmagglutination have been reported by Lauffler and Carnelly[13]. Thermal differentiation of the adenovirus *CF* antigens showed that the *H* values derived from thermal constants of the virus and its *CF* antigens are not similar[14].

This work was partly supported by training grant *E*–3175–*C*2 from the Institute for Allergy and Infectious Diseases, and contract *Nonr*–3127(00), Office of Naval Research.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, December 7

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 10 a.m. and 2.30 p.m.—Colloquium on "Programmed Test Equipment and Techniques".

BRITISH SOCIETY FOR THE PHILOSOPHY OF SCIENCE (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Mr. G. C. Archibald: "Refutation or Comparison?"

INSTITUTION OF ELECTRICAL ENGINEERS, SCIENCE AND GENERAL DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Prof. J. C. West: "Non-Linear Circuit Theory".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"The Bridge" (Geographical Films).

UNIVERSITY OF LONDON (at Birkbeck College, Malet Street, London, W.C.1), at 6 p.m.—Prof. J. Th. Runnenburg (University of Amsterdam): "Some Practical Problems Solved with Simple Tricks from Probability Theory and Analysis".*

SOCIETY FOR ANALYTICAL CHEMISTRY, MICROCHEMICAL METHODS GROUP (at "The Feathers", Tudor Street, London, E.C.4), at 6.30 p.m.—Discussion Meeting on "The Characterization of Organic Compounds" opened by Dr. D. W. Mathieson and Mr. L. C. Cross.

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (joint meeting with the Paper and Textile Chemicals Group, at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. I. F. Hendry and Mr. J. A. S. Newman: "New Developments in Papermaking".

Tuesday, December 8

BRITISH INSTITUTE OF RADIOLOGY (in the Edward Lumley Hall of the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2), at 10 a.m. —Symposium on "The Scientific Bases of Permissible Levels".

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Royal Society of Tropical Medicine, 26 Portland Place, London, W.1), at 5.30 p.m. —Miss B. E. Sabey: "Hysteresis in Rubber". 7 p.m.—Mr. A. Dibbo: "Oscillating Disc Rheometer"; Mr. R. H. Norman: "Process Control and Cross-Linking Studies using the Wallace-Shawbury Curometer".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.— Mr. P. N. T. Wells: "Ultrasonics in Clinical Diagnosis". (Thirteenth of fourteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.— Prof. J. J. Pritchard: "The Skeleton and Homeostasis".*

UNIVERSITY OF LONDON (at the Institute of Archaeology, 31–34 Gordon Square, London, W.C.1), at 5.45 p.m.—Dr. M. V. Seton-Williams: "Tell Rifa'at".*

INSTITUTION OF MECHANICAL ENGINEERS, AUTOMOBILE DIVISION (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. T. Priede, Mr. A. E. W. Austen and Mr. E. C. Grover: "Effect of Engine Structure on Noise of Diesel Engines".

UNIVERSITY OF LONDON (in the Engineering Theatre, University College, Gower Street, London, W.C.1), at 6 p.m.—Prof. Stephen H. Crandall (Massachusetts Institute of Technology): "Random Vibration". (Further lectures on December 9, 10 and 11.)*

Wednesday, December 9

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 2 p.m.—Dr. I. Holden: "Toxicology".*

GEOLOGICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. K. Coe: "Intrusive Tuffs of West Cork, Ireland"; Dr. G. P. L. Walker and Dr. D. H. Blake: "The Formation of a Palagonite Breccia Mass Beneath a Valley Glacier".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. R. E. Young: "Telemetry—The Present Position and Future Trends".

INSTITUTION OF ELECTRICAL ENGINEERS, SCIENCE AND GENERAL DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "The Electrometer Amplifier—Its Design and Applications" opened by Mr. G. I. Hitchcox and Mr. G. R. Taylor.

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Annual General Meeting. 7 p.m.—Colonel G. W. Raby, C.B.E.: Presidential Address.

INSTITUTION OF MECHANICAL ENGINEERS, INDUSTRIAL ADMINISTRATION AND ENGINEERING PRODUCTION GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Trends in Machine-Tool Design and Development".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (at Shell-Mex House, Strand, London, W.C.2), at 6 p.m.—Annual General Meeting.

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Sir Rex Cohen, K.B.E.: "Leisure in an Affluent Society".

UNIVERSITY OF LONDON (at Birkbeck College, Malet Street, London, W.C.1), at 6 p.m.—Prof. J. Th. Runnenburg (University of Amsterdam): "The Influence of Markov-Dependence of the Arrival Intervals on a Simple Queue".*

INSTITUTE OF INFORMATION SCIENTISTS (at the Swedenborg Society Hall, 20 Bloomsbury Way, London, W.C.1), at 6.15 p.m.—Dr. B. C. Christian: "Report Writing and Editing in an Industrial Research Laboratory".

OIL AND COLOUR CHEMISTS ASSOCIATION (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 7 p.m.—Mr. V. Jenkins: "The Use of Furoic Acid in Alkyds".

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN (at 17 Bloomsbury Square, London, W.C.1), at 7.30 p.m.—Mr. D. Stephenson: "Experiences and Experiments in Tabletting" (Harrison Memorial Lecture).

ROYAL AERONAUTICAL SOCIETY, GRADUATES' AND STUDENTS' SECTION (at 4 Hamilton Place, London, W.1), at 7.30 p.m.—Mr. D. C. Armstrong: "Ultra-Light Aircraft".

Thursday, December 10

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Prof. B. Katz, F.R.S., and Mr. R. Miledi: "Propagation in Impulses and the Release of Transmitter in Motor Nerve Endings".

INSTITUTION OF CIVIL ENGINEERS, HYDROLOGICAL GROUP (at Great George Street, London, S.W.1), at 5.30 p.m.—Informal Discussion on "The Prediction of River Flows" introduced by Mr. T. O'Donnell.

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. D. Jones: "Resistive Earthing of Electrical Distribution Systems".

ROYAL INSTITUTION, LIBRARY CIRCLE (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Mr. Edward Ironmonger: "Tyndall in America".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.— Prof. R. B. Fisher: "Chemical Transfer Across Membranes". (Last of fourteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

UNIVERSITY OF LONDON (at the School of Pharmacy, 29/39 Brunswick Square, London, W.C.1), at 5.30 p.m.—Prof. Rita Levi-Montalcini (Washington University): "Growth Control of Sympathetic Nerve Cells by a Protein and Its Antiserum".*

UNIVERSITY OF LONDON (in the Physiology Lecture Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. R. J. Rossiter (University of Western Ontario): "Biosynthesis of Phospholipids" (Further lecture on December 15).*

INSTITUTION OF MECHANICAL ENGINEERS, NUCLEAR ENERGY GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Fast Start-Up of Gas-Cooled Reactors".

ROYAL AERONAUTICAL SOCIETY (at 4 Hamilton Place, London, W.1), at 6 p.m.—Mr. E. H. Heinemann: "Aviation in Perspective" (Fifty-third Wilbur Wright Memorial Lecture).

SOCIETY FOR ANALYTICAL CHEMISTRY, BIOLOGICAL METHODS GROUP (at the 'Feathers' Restaurant, Tudor Street, London, E.C.4), at 6.30 p.m.— Twentieth Annual General Meeting, followed by Informal Discussion on "Present Position with Regard to Microbiological Assay" opened by Dr. E. C. Barton-Wright.

RADAR AND ELECTRONICS ASSOCIATION (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 7 p.m.—Mr. K. A. Russell: "Pay Television Systems".

TELEVISION SOCIETY (in the Conference Suite, I.T.A., 70 Brompton Road, London, S.W.3), at 7 p.m.—Discussion Meeting on "Television Servicing—Is it Satisfactory?"

Friday, December 11

ASSOCIATION OF APPLIED BIOLOGISTS (in the Lecture Hall of the British Museum (Natural History), Cromwell Road, London, S.W.7), at 10.50 a.m.— Meeting on "Bacterial Plant Pathology".

BIOCHEMICAL SOCIETY (in the Department of Chemistry and Biochemistry, St. Thomas's Hospital Medical School, London, S.E.1), at 11 a.m.—Scientific Papers.

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 4 p.m.—Dr. I. MacIntyre: "Magnesium Deficiency".*

OCCAM SOCIETY (at the Northampton College of Advanced Technology, St. John Street, London, E.C.1), at 6.15 p.m.—Prof. R. O. Kapp: "Some Problems of Chairmanship".

Saturday, December 12

LONDON COUNTY COUNCIL (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. A. Robinson: "Bird Life of South-East London".*

Monday, December 14

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 4 p.m.—Lord Cohen of Birkenhead: "The Lipidoses".*

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Mr. J. G. Attfield and Mr. D. A. Wheeler: "Vapona Insecticide".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Prof. E. H. Thompson, O.B.E.: "An Itinerant Scientist in China".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURER IN GEOLOGY—The Registrar, The University, Manchester, 13 (December 10).

EXPERIMENTAL OFFICER (with at least a B.Sc. degree in biology and physics) for the Tropical Stored Products Centre based at the Pest Infestation Laboratory, Slough, for research investigations on the importance of moisture in stored products and the design and suitability of new types of storage containers—The Research Department, Ministry of Overseas Development, Eland House, Stag Place, London, S.W.1, quoting Ref. RE 255/230/01 (December 11).

LECTURER (with an interest in either experimental or theoretical physics) IN PHYSICS—The Registrar, Queen Mary College (University of London), London, E.1 (December 11).

MYCOLOGIST (with a degree in agricultural botany or botany or equivalent qualifications) IN THE POTATO BRANCH, to assist in the assessment of disease resistance in potatoes—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge (December 11).

ASSISTANT LECTURERS (2) IN PATHOLOGY—The Secretary, St. Thomas's Hospital Medical School, London, S.E.1 (December 12).

SENIOR LECTURER OR ASSISTANT LECTURER IN PHYSICS IN THE SCHOOL OF MATHEMATICS AND PHYSICS—The Registrar, University of East Anglia, Earlham Hall, Norwich, NOR 05G (December 18).

SENIOR LECTURERS, LECTURERS OR ASSISTANT LECTURERS IN MATHEMATICS IN THE SCHOOL OF MATHEMATICS AND PHYSICS—The Registrar, University of East Anglia, Earlham Hall, Norwich, NOR 05G (December 18).

LECTURER (Grade II) IN THE DEPARTMENT OF MECHANICAL ENGINEERING—The Registrar and Secretary, The University, Bristol (December 21).

ASSOCIATE PROFESSORS OR PROFESSORS IN THE DEPARTMENTS OF MATHEMATICS AND PSYCHOLOGY; and LECTURERS OR ASSOCIATE PROFESSORS IN CHEMISTRY, PHYSICS, SOCIOLOGY, GEOLOGY AND GEOGRAPHY—Dean of the Faculty of Arts and Science, Laurentian University, Sudbury, Ontario, Canada (December 31).

CHAIR OF PHYSICS at the University of New England, Armidale, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (December 31).

LECTURER/SENIOR LECTURER IN THE DEPARTMENT OF CLINICAL PSYCHOLOGY, School of Applied Psychology, The University of New South Wales—The Agent General for New South Wales, 56–57 Strand, London, W.C.2; and The Appointments Section, The University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia (December 31).

PROFESSOR OF ENGINEERING PRODUCTION—The Registrar, Ref. 60Y/E, Bradford Institute of Technology, Bradford, 7 (December 31).

PROFESSOR OF STATISTICS AND OPERATIONAL RESEARCH—The Registrar, Ref. 61Y/E, Bradford Institute of Technology, Bradford, 7 (December 31).

LECTURER (with some teaching experience and qualifications in the theory of education) IN EDUCATION—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (January 1).

LECTURER OR RESEARCH ASSISTANT IN GEOGRAPHY—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (January 2).

CHAIRS (2) OF PURE MATHEMATICS—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (January 4).

CHAIR OF SOCIOLOGY OR SOCIAL ANTHROPOLOGY—The Registrar, Room (T), The University, Hull (January 8).

RESEARCH FELLOW in the Ion Research Unit of the Research School of Physical Sciences, Institute of Advanced Studies, Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 8).

LECTURER/SENIOR LECTURER (with a Ph.D. in chemical engineering and several years industrial experience) IN CHEMICAL ENGINEERING at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 15).

CHAIR OF PHARMACOLOGY at the University of Ibadan, Nigeria—The Secretary, Senate Committee on Higher Education Overseas, University of London, Senate House, London, W.C.1 (January 18).

ASSISTANT IN MATHEMATICS—The Secretary of the University Court, The University, Glasgow (January 30).

LECTURER (preferably interested in numerical analysis or a related field) IN PURE MATHEMATICS in the Faculty of Science—The Registrar, The University, Manchester, 13 (January 30).

RESEARCH FELLOW IN MATHEMATICS—The Secretary of the University Court, The University, Glasgow (January 30).

CHAIR OF BIOLOGICAL SCIENCES (Botany) at Massey University of Manawatu, Palmerston North, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, January 31).

LECTURER IN THE DEPARTMENT OF PSYCHOLOGY, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 31).

SENIOR LECTURER OR LECTURER IN THE DEPARTMENT OF MATHEMATICS, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 31).

UNIVERSITY LECTURER IN GEOCHEMISTRY IN THE DEPARTMENT OF GEOLOGY AND MINERALOGY—The Professor of Geology, Department of Geology and Mineralogy, University Museum, Oxford (January 31).

BIOLOGIST (well qualified) to teach up to University Scholarship standard and to be Head of the Department—The Warden, St. Edward's School, Oxford.

EXPERIMENTAL RESEARCH ASSISTANT (with a Ph.D. degree or approximately equivalent research experience) IN THE PHYSICS DEPARTMENT, to join a group working on liquid metal physics under Dr. N. E. Cusack—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1.

OIL PALM AGRONOMIST (with a degree in agriculture and postgraduate training, preferably with previous experience as an agronomist) in Sarawak, to open up and establi h a new experimental Station, mainly to be concerned with oil palm and other crops new to Sarawak, for example, cocoa and hemp—The Appointment Officer, Room 301, Ministry of Overseas Development, Elanc House, Stag Place, London, S.W.1, quoting Ref. RC 213/155/08.

POST-DOCTORAL RESEARCH FELLOW IN PHYSICAL CHEMISTRY, for work concerned with the application of radiotracers and other methods to the study of the defect solid state, under the direction of Dr. J. N. Sherwood—Prof. M. Gordon, University of Strathclyde, George Street, Glasgow, C.1.

INVENTION AND DISCOVERY

PROF. I. D. RATTEE'S inaugural lecture in the chair of Colour Chemistry and Dyeing at the University of Leeds (now published*) deserves wide attention, not only for its percipient and highly stimulating discussion of the relations between discovery and invention, but also for its reasoned refutation of the false idea which is widely held that technology as an intellectual activity is inferior to pure science. Apart from this, he is particularly concerned as to the danger that applied science may become increasingly the activity of those in whom there is not fusion of the scientific, social and technological disciplines which are so necessary, and who tend to regard that fusion as neither necessary nor desirable. It is, as Prof. Rattee observes, very important that scientists should enter the applied sciences because of the valuable contribution they can make, but it is vital that applied science should never be dominated by the pure-science attitude as it largely exists to-day. This attitude of superiority may well persist, if the evidence of a recent survey of intending university entrants made by the Department of Education of the University of Oxford is any guide.

Prof. Rattee does not think that there is any rapid solution to these problems, although much could and should be done to discourage the prevailing attitude among prospective university students towards applied science and technology. Much could also be done to avoid the present imbalance in disciplines and to break down the divisions between pure and applied science within the universities themselves. He believes that in the long run it will be demonstration rather than hypothesis which will prevail: the greater inventiveness of university-trained applied scientists and the penetration of problems by university-based research will play the greatest part in making the change.

The plea for effective combination of scientific and technological disciplines is not based solely on its value in attempts to develop new and improved products for industrial use. The combination is also of particular value in fields which would generally be regarded as falling within the province of academic research—the type of problem, it might be added, which is sometimes the subject of 'fundamental' investigations by a research association or an industrial research department. It is this, Prof. Rattee suggests, that gives a particular excitement to work in the field of applied science, an excitement which is associated, on one hand, with the application of knowledge in a way which may benefit society, and on the other, with an intellectual challenge and inspiration directed towards discovery as in pure science. The inventor needs curiosity about things no less than the discoverer, as well as curiosity about his fellow men, about the sociological and technological background to his problem, and knowledge about the historical reasons for existing practices.

Prof. Rattee's exposition of the way in which the right teaching of technology develops a broad and not a narrow outlook could not easily be bettered, and it is to be hoped that it will not be overlooked by the Minister of State for Education and Science, Lord Bowden, some of whose recent utterances regarding higher education have been disturbingly neglectful of this question of quality. Moreover, the statement gains added force from the skilful way in which it is built up from a discussion of the relations between discovery and invention, and from a lucid account of the way in which a scientific approach to the behaviour of dyes has been developed in Britain under the influence of the Department of Colour Chemistry at the University of Leeds and comparable centres in other institutions, and not in Europe where organic chemistry dominates the fields of dyes and dyeing. This tribute should be noted by those who are ever ready to disparage Britain's readiness to develop new knowledge. The gap between application and discovery is seldom closed without bringing together the efforts of people whose interest bridges the gap between science and industrial practice. In its absence, subsidiary or even wrong objectives may be pursued and the difference between invention and discovery confused.

Prof. Rattee does not seek in this lecture to defend the triviality of some university research, and the whole tenor of his lecture is in keeping with that of an inaugural lecture by Prof. T. H. Cotterill in Edinburgh and numerous papers read at the recent conference on "Materials Science" organized by the Materials Science Club (*Nature*, 204, 831; 1964). He recognizes that there has always been a difference of approach to research in industry and in the universities—not necessarily in quality so much as in attitude and objective. He is concerned that what could be regarded as a reasonable and desirable differentiation is becoming a rift, and that great difficulty is often being encountered in establishing common ground between workers in the two fields. This is a highly dangerous situation, in which the academic teacher may fail to recognize his broad social responsibilities while, on the side of industry, the rate of technical progress may be impaired by shortcomings not in the numbers but in the kind of scientist or technologist trained.

Prof. Rattee does not accept the extreme industrialist view that academic research lacks a clear objective: on the contrary it is clear and praiseworthy, if difficult to describe in specific terms. It is discovery. Confusion arises not from the lack of motivation but from a failure to appreciate the difference between discovery and invention, and to some extent the failure of both sides to grasp the fact that these are objectives of equal stature and challenge, sustained by the use of the same sort of methods, but from two distinct lines of approach. Discovery, he suggests, may be regarded as the revelation of what exists in our environment and the study of the laws which condition it, while invention is the utilization of the results of discovery, new or old, in order to change our environment.

Thus, to take an inventive step, a discovery must be made, or old discoveries juxtaposed in a new relation. A discovery may be examined no more than is necessary to achieve the practical objective, though significant inventions usually stimulate fundamental work which enlarges the understanding of their basis, and may lead to a further invention. Nevertheless, it is unreasonable to argue that because it goes deeper, fundamental research possesses a higher intellectual standard than inventive research. The differences arise purely from the kind of issue and the way of thinking involved—from the

* *Discovery or Invention?* (Inaugural Lecture delivered in the University of Leeds on January 20, 1964.) By Prof. I. D. Rattee. Pp. 23. (Leeds: The University Press, 1964.) 2*s*. 6*d*.

differences between those seeking to understand the world and those seeking to change it.

Clearly the two modes of thought are interdependent but not identical, and in almost any scientist both instincts may operate. Prof. Rattee again illustrates his argument by reference to the dyestuffs and pigments industry and its tendency to overlook the difference between discovery and invention. His critical examination of the development of new products leads him to conclude that research directed at specific targets has proved restrictive in the sense that deeper examinations, which might well have given rise to a greater number of discoveries, could not be pursued: however, research is not primarily directed towards invention. This is a serious situation because it can generate attitudes leading to the restriction, and even the virtual cessation, of research on grounds of efficiency, economy and financial deployment. A similar situation is to be found in the synthetic fibre industry.

Prof. Rattee does not pursue this aspect beyond pointing out that it falls within the scope of managerial methods in industrial research. Before commenting on his analysis, however, it may be as well to consider his discussion of the other factors involved in the organization of invention. It is important that the research worker should possess an understanding of and a feeling for the technical and economic environment in which the results of his work will be used, so that he may see in correct terms the significance of his observations or the validity of the technical targets with which he is presented. Quite correctly Prof. Rattee maintains that this condition was not met in the dyestuffs industry—at any rate in general or at one time. He argues that in the chemical field interest in the product of the experiment is the beginning of the inventive step—a step that leads from discovery to invention. The view is plausible though a little superficial compared with C. Nicolle's study *Biologie de l'Invention*, but, by and large, his comments as to the rarity with which a student who prepares a dye evinces curiosity regarding its dyeing behaviour and the extent to which research objectives are based in present practice are well founded. He emphasizes the latter point by describing how the solution to a continuous dyeing problem in the shape of dyes which react with the fibre was found outside the normal processes of industrial research.

Historically, Prof. Rattee appears to rely on a secondary source of information, the soundness of which is open to challenge on various grounds. Further, the figures quoted for the appearance of new commercial dyes at least within the period from 1915 until perhaps 1930 take little account of the circumstances in which the British industry made its research effort at that time. If it had not concentrated on supplying its customers with the dyes with which they were familiar, there would have been no renaissance of the British industry at all. The Dyestuffs Development Committee has paid adequate tribute to the achievements of the British industry in entering new fields and, so far as the new synthetic fibres are concerned, those achievements necessitated a fresh look at methods of dyeing. This was true to some extent of viscose rayon as well as of acetate rayon. In the research which led to the development of new level dyeing products there was close co-operation between the dyestuffs research laboratory and the rayon manufacturer. In the main the search was for dyestuffs to be applied by conventional methods, but it may be mentioned that at about that time a suggestion was made that the difficulty could be overcome by pigmenting the rayon before it was spun—a suggestion which was discouraged on grounds of policy.

Prof. Rattee's argument is thus generally substantiated, and since his lecture was published in October there has been welcome evidence that his words may have fallen on receptive ears. It has been announced that an experimental course is to be established at the University of Liverpool to bridge the gap between academic life and industry. This is to start next year, and will be for post-graduate students in science and engineering. The course, which will run for two years, is being organized jointly by the University and Imperial Chemical Industries, Ltd., who are seconding Mr. R. D. S. Glascodine, research works manager and research engineer in the Mond Division, as director of industrial studies: a board of industrial studies has been created. If successful, the course will be renewed annually and the support of other industrial organizations included. Specifically it will aim at easing the transition from the research-orientated attitudes of a university to those required in modern industry, and will deal with general industrial problems, including motivations for university research and industrial research and development, and collaboration between industry and the universities in matters affecting research and design. Clearly it is designed to heal that rift between industrial and academic research with which Prof. Rattee is most concerned, and the benefits should be mutual.

It has long been held by experienced directors of industrial research that in its closer contact with production the research department of an individual firm has a great advantage over the normal industrial research association. Prof. Rattee obviously thinks that that contact may sometimes have a restrictive effect on research. Whether that is so or not, his argument points to one direction in which the research association could have an important advantage if there is really effective contact and co-operation between its members. The wider range and variety of experience which a research association represents should stimulate a much wider outlook and help to correct the weaknesses of target-directed research when excessively influenced by existing practices.

This is an aspect of co-operative industrial research which deserves closer examination. It is related, moreover, to the educational functions of the research associations. Whatever decisions may be taken as to the future of these associations, their functions and future do not concern either the Department of Technology or the Ministry of Education and Science alone. Both should be concerned with the independent appraisal and the creative thinking which Prof. Rattee's lecture is so well designed to stimulate.

RECENT ADVANCES IN THE RARE EARTH ELEMENTS

Progress in the Science and Technology of the Rare Earths

Vol. 1. Edited by LeRoy Eyring. Pp. 532. (Oxford, London, New York and Paris: Pergamon Press, 1964.) 120*s*.

THE rare earth elements are to some extent a misnomer. As pointed out in the final chapter of this new book, problems of dumping of the rare earths as by-products of thorium production occurred first in the

Welsbach mantle industry, and later (1940's and 1950's) in connexion with atomic energy activity. However, only with the development since 1947 of modern methods of separation, ion-exchange columns and solvent extraction methods have the individual rare earth elements become easily available to research workers.

The elements themselves, while possessing very similar chemical properties, because of the filling up of the partly filled 4*f* shell, show a variation in physical properties of the greatest scientific interest. Following on their availability, these elements have found numerous applications in industry. Because of the importance of these activities for science and technology, the present volume, the first of an annual series, is very much to be welcomed.

Prof. LeRoy Eyring, as editor, has wisely decided to provide a firm basis by starting with a review of the six years 1955–61. It cannot be too much emphasized that a review is little use unless it is comprehensive in scope (this does not mean that it should not select the wheat from the chaff) and covers a definite period, as here. A list of authors and chapters would occupy too much space, but it may be said that the coverage of subjects in sixteen chapters is comprehensive and authoritative. Starting with geochemistry, passing through separation methods, solution and solid-state chemistry, analytical chemistry and physical properties, it ends with an excellently documented chapter on "Uses and Applications". I was able to test out my own special interest, catalytic properties, on this last chapter. While this comprises only thirteen lines out of thirty-seven pages, there is a list of eighty references which I found of the greatest value in this work.

The book is well edited and printed, and a really useful production. It will no doubt justifiably join the ever-growing family of 'Advances' and 'Progress' volumes on the library shelves. At its price it is not expensive. In modern times the provision of lucid review volumes is more a public service than the proliferation of new journals, and workers in this particular field will be grateful for the present effort. D. D. ELEY

POPULAR ASTRONOMY

Pictorial Astronomy

By Dr. Dinsmore Alter, Dr. Clarence H. Cleminshaw and Dr. John G. Phillips. Pp. 312. (London: Museum Press, Ltd., 1964.) 42*s*. net.

Astronomy with Binoculars

By James Muirden. Pp. 146. (London: Faber and Faber, 1963.) 25*s*.

BOOKS dealing with popular astronomy are now very common. Most of them follow a set pattern, and it is therefore refreshing to find accounts which have something new to say.

This applies to *Pictorial Astronomy*, written jointly by three American astronomers, of whom Alter and Cleminshaw are associated with the Griffith Planetarium in Los Angeles. The influence of planetarium presentation is very evident, since although the book covers a wide range there are several unusual chapters—such as "The Visit of Arcturus to the Sun", in which the appearance of Arcturus as seen from our Earth is traced from the remote past to the equally remote future. The general impression is that of a series of articles instead of a wholly connected text. This is said as a comment, not as a criticism, since it leads to a very interesting book even though some aspects of astronomy are necessarily treated rather briefly. The line drawings are excellent, and the numerous photographs are reasonably well produced, even though black sky too often appears as a grey. The amateur with a little previous knowledge of astronomy will find the book very rewarding, particularly in view of the fact that it is extremely well written. There are some sections which are already somewhat out of date, but this is inevitable, and neither authors nor publisher can be blamed. Recent developments will presumably be included in any future edition.

Muirden's *Astronomy with Binoculars* is of a different type. Its range is aptly summed up by its title; the author caters for the interested beginner who possesses no equipment other than a pair of binoculars, but who is anxious to use a very modest optical aid to the best advantage. He considers that some useful work may be accomplished in such a way, and, as he points out, telescopes are of little use for observing auroræ, while binoculars are ideal for observing bright comets (though not, of course, for measuring comet positions). After dealing with fundamentals, he turns to the bodies of the Solar System, describing what can and what cannot be seen with binoculars, after which he turns to the changing skies; there are chapters on the stars of spring, summer, autumn and winter, illustrated by clear star-maps which should enable the beginner to identify the various constellations without much difficulty. Stellar objects within binocular range are shown and described. Here, too, the writing style is good, and is well calculated to hold the reader's attention.

It is true to say that the range of amateur astronomers to-day is considerably more limited than was the case even ten years ago; the opportunities for serious and useful research have lessened, though in some fields they still exist and are likely to continue indefinitely. Yet not all enthusiasts aspire to carry out such research; there are many who are content to do no more than look at the skies and learn what they can without making any attempt to delve into technicalities. To these people, Muirden's book will be of great interest, and for this reason alone it has been well worth writing. Moreover, it may well persuade some of those who read it to take a more positive interest in astronomy, to their inevitable benefit. Generally speaking, the advice given is perfectly sound, but it is most unwise to recommend that direct observation of the Sun may be carried out using darkened filters placed over the object-glasses of binoculars. Admittedly, the procedure is safe enough provided that sufficient care is taken; but the book is aimed at the complete beginner in astronomy, who may not be able to judge what is harmless and what is not.

PATRICK MOORE

ATLAS OF LIVER STRUCTURE

Submicroscopic Ortho- and Patho-Morphology of the Liver

(Submikroskopische Ortho- und Patho-Morphologie der Leber). By Dr. Heinz David. Text volume: Pp. 412. Atlas: 361 illustrations. (London and New York: Pergamon Press, 1964.) 500*s*. net per set.

THE study of the ultrastructure of the liver cell is still proceeding apace in many countries in the world. Electron microscopy is playing a leading part in this field. However, the interpretation of many of the findings is difficult and in recent investigations such interpretations have often been aided by an experimental approach or by the use of biochemical or histochemical techniques. Gradually some aspects of normal cellular functions can be related to structure, and abnormal structure found in spontaneous or experimental lesions interpreted in the light of normal structure and function. The subject is developing so rapidly that any attempt at a comprehensive account must inevitably be out of date before it appears. Dr. H. David mentions this difficulty in his introduction to *Submicroscopic Ortho- and Patho-Morphology of the Liver*, but this does not obviate it and it remains a serious defect particularly since the introduc-

tion is dated February 1962 and the text appears to be of about the same date but the date of publication is 1964. A supplementary list of references up to August 1963 is given, but the papers in this list are not discussed in the text. Partly as a result of the delay between writing and publication, the book presents a rather unsatisfactory account of this developing field.

The account of lysosomes, cytosomes and microbodies is confused. The author includes the work of Daems in his additional list of references, but he does not consider it in the text in relation to his own. Fig. 77 and 78 of vacuoles containing Periston are identical to the structures found by Daems after injection of dextran. Daems showed that these structures are lysosomes containing the injected material and not dilated endoplasmic reticulum as David suggests. Many other aspects of the subject have changed significantly since the book was written. The use of histochemical techniques is dismissed in two paragraphs. The work of Novikoff and of Sabatini and his colleagues is included in the additional list of references and again not considered in the text.

The material in the volume is of interest and the technical standard of the electromicrographs is good. The presentation, however, is most extraordinary; the work is in two volumes, the text in one and the electronmicrographs in the other. The text is in German followed by an English and then a Russian translation; however, the English translation is stilted and betrays a lack of familiarity with the subject-matter. The legends to the illustrations are in the text volume, but the figures are not referred to in the body of the text when a point illustrated is alluded to, but are given as a list at the end of each chapter. In reading the book one has an exasperating time referring rapidly from one volume to the other. The structures in electronmicrographs are profusely labelled with abbreviations of their German names. It was only after looking through the book many times that I discovered the key to the abbreviations hidden under the dust cover inside the back cover. Probably the most extraordinary thing of all about the two volumes is their price, £25.

D. B. Brewer

MECHANISMS OF ENDOTOXIN ACTION

Bacterial Endotoxins

Edited by Maurice Landy and Werner Braun. (Proceedings of a Symposium held at the Institute of Microbiology of Rutgers University.) Pp. xvi+691. (New Brunswick, N.J.: Institute of Microbiology, Rutgers, The State University, 1964.) 12 dollars.

In September 1963 a three-day symposium devoted to the problems of bacterial endotoxins was held at Rutgers University. Following the example set by the Society for General Microbiology the texts of the principal papers were circulated to the 212 participants and this greatly increased the time available for discussion. The symposium has been published with commendable speed and consists of the original papers grouped into eight sections, each one being followed by an edited version of the discussion. The habit of publishing the discussion has its critics but in this volume it reads well and does supplement the preceding section.

There are a total of 58 papers which vary in length and quality. Some are well-documented reviews of a particular problem while others are short reports of a few experiments. There is a variation in the treatment of the references in that in some papers the bibliography gives the titles of the works cited while others do not. Many readers prefer to see the titles quoted, and it seems a pity that all the papers did not follow this pattern.

There is an extremely interesting introduction by Dr. I. L. Bennett which clearly describes the type of problem which is to be discussed. As he points out, endotoxins have a complex chemical structure which attracts considerable interest in its own right. On the biological side their range of activities is not only vast, it is confusing, since to take two examples they may raise or lower body temperature and increase or decrease resistance to bacterial or viral disease. While they are antigenically specific, in many biological tests they are surprisingly non-specific. Endotoxins, while not so potent as some exotoxins, are very toxic and have been used clinically to produce artificial fever. Repeated injection may, however, lead either to tolerance or hypersensitivity. These few pages set the scene for the papers that follow.

The first section is devoted to the chemical research that is taking place and covers such problems as the structure of bacterial cell walls and the relationship between structure and biological activity. The pharmacological effects are discussed in two sub-sections and the attempt is made to relate the action of endotoxins to the fundamental processes in the cells involved.

Parts 4 and 5, devoted to immunological phenomena and the effects on host resistance to infection, overlap to some extent and may be taken together. The problems of natural antibodies and recovery from infection figure largely in these sections. In Part 6 there are eleven papers devoted to the conflicting problems of tolerance and hyperreactivity. The symposium closes with two sections devoted to the mode of action of endotoxins and in many ways this is the most interesting.

In terms of research interest for many years endotoxins have been the poor relations of the exotoxins. *Bacterial Endotoxins* will, I think, do a great deal to redress the balance and may be warmly recommended to a wide range of readers.

R. H. Gorrill

THE POGONOPHORES

Pogonophora

By A. V. Ivanov. Translated from the Russian and edited by D. B. Carlisle. With additional material by Eve C. Southward. Pp. xvi+479. (London: Academic Press, Inc. (London), Ltd., 1963.) 90*s*.

Pogonophora, although rather common marine animals, have until recently been almost unknown. In 1962 only three species were recorded against the eighty species described by 1964. Such a sudden acquisition of knowledge of a widespread group of animals is unprecedented in the history of zoology, and it is all the more surprising in a phylum related to the Protochordata. During the 1920's the R.R.S. *Discovery* dredged enormous masses of apparent fibres from the abyssal depths of Antarctic and sub-Antarctic waters, and many tons of unrecognized Pogonophora in their tubes were shovelled overboard. These amazing animals, lacking a gut and feeding exclusively by means of tentacles, form the dominant element in the fauna of quite large stretches of the sea bed, but elsewhere they appear to be entirely absent.

The examination of Pogonophora is now an active pursuit in the marine laboratories of many countries. These animals have been exhibited alive in the rooms of the Royal Society in London. But it is the intensive collection by Soviet oceanographical expeditions and the subsequent investigation of this material by Prof. Ivanov in Leningrad which has provided the wealth of information concerning structure, manner of life, life-cycle and systematics of these creatures.

Prof. Ivanov's beautifully illustrated monograph on the Pogonophora, issued in Russian in 1960, has now been translated by Dr. D. B. Carlisle, and this English edition of the *Pogonophora* has been brought up to date by the inclusion of diagnoses of new species described between 1960 and 1963 and of further data concerning geographical distribution and general biology, so pro-

ducing a book half as long again as the original. Much of the new material has been provided by Prof. Ivanov himself, and also by Dr. Eve C. Southward, Dr. Olga Hartman and Dr. Carlisle.

Abundant black-and-white drawings of excellent quality depict the structure of the species described. Coloured stereograms and diagrams illustrate the basic organization of different types of pogonophore, and some photographs in colour of living pogonophores, by Dr. A. J. Southward, have been included. This English edition provides also very many additional line drawings.

The systematic account, well illustrated and provided with keys and tables, occupies more than half the book. Part 1 (147 pp.) presents a general account of the Pogonophora, illustrated by 86 figures, 3 plates and a map showing global distribution. These chapters meet the needs of the general zoologist besides those of the specialist.

The vermiform cœlomate body is divided, usually by grooves, into three regions. A tentacle-bearing cephalic lobe or protosoma contains an undivided cœlom opening to the exterior by paired excretory cœlomoducts, the exits corresponding with the proboscis pores of the Hemichordata, etc. A short mesosoma always bears cuticular keels, the 'bridle', which probably permits the animal to cling to the inner surface of the tube. Internally lie a large pair of cœlomic cavities. The metasoma, or trunk, forms the greater part of the body, and may be very long indeed. A pair of cœlomic spaces traverses the whole. A few girdles of toothed platelets divide the anterior from the posterior metasoma, and serve no doubt to fix the middle part of the body in the tube. Adhesive papillæ, which are frequently secondarily metameric in arrangement, lie in front of the girdles. Behind them the papillæ are irregularly distributed. The sexes are separate; a single pair of gonads lies in the metacœls, the cœlomoducts of which are transformed into gonoducts opening on the metasoma. There appears to be no asexual budding. A heart is formed by elaborations of the ventral blood vessel, and lies between the proto- and meso-cœls. Red blood containing hæmoglobin is pumped forwards, through the tentacular apparatus, which is digestive, absorptive and respiratory, there being no gut. Well-developed longitudinal muscles (unstriated) are associated with giant nerve fibres situated in the dorsal nerve trunk —features doubtless associated with an ability for 'panic withdrawal' of the anterior part of the body into the protection of the tube, the toothed bristles of the girdles fixing the middle part of the body to the tube wall. The nervous system is entirely ectodermal in position, as in the Hemichordata and Phoronidea, resembling also the ecto-neural system of the echinoderms.

Heavily yolked eggs are laid into the distal part of the tubes. The embryonic development resembles that of the echinoderms and chordates in the radial, indeterminate cleavage, the association of the blastopore with the anus and the trisegmental body plan.

The long unbranched tubes secreted by pogonophores are several times the length of their owners. Transverse lamellæ are usually apparent, although the superficial appearance of the tubes is very varied. Chitin, and protein hardened by tanning, are present in the tube wall. The organic remains of graptolites have similarly yielded glucosamine.

Accounts of the habits of life, ecology and geographical distribution provide most interesting reading, together with a discussion on secondary metamerism in Pogonophora and of other phyla, the affinities and systematic position of the Pogonophora and evolution within the group. The evidence fully supports the conclusion that the "pogonophores are an independent phylum within the Deuterostomia".

The monograph as a whole is a masterly production brought out in record time, and Dr. Carlisle's translation and amplification supplies an English edition of great worth. Passing references to matters outside the echinoderm–protochordate–chordate animals, however, are less fortunate. I know of no copepod or other crustacean which lacks a blood system, as stated. Small Crustacea exhibit a variety of ways of effecting blood circulation without a heart, using sometimes a pulsating pericardial floor, but the hæmocœl and associated structures are not absent[1]. Few invertebrate embryologists would agree with the claim that the fate of the blastopore of, say, the Arthropoda, a group exceeding in numbers of species the whole of the rest of the multi-cellular animal kingdom, can be explained away as "merely the result of secondary changes". No evidence supports such a sweeping generalization. The objections to the use of the term 'Prosterostomia' and its implied community in blastoporal fate throughout most of the Invertebrata still stand[2,3]. The determinate spirally cleaving invertebrates are probably related to one another, but not because of the various fates of the blastopore. These matters are by the way, and the book as a whole is an excellent and much wanted contribution to our libraries.

A LIZARD FOR TEACHING AND RESEARCH

The Life of the Rainbow Lizard

By Dr. Vernon A. Harris. (Hutchinson Tropical Monographs.) Pp. 174. (London: Hutchinson and Co. (Publishers), Ltd., 1964.) 21*s*.

I AM pleased to see this work on three grounds. First, the author recognizes an important need in any developing country—educational materials which bear some relation to the experience of the pupils concerned. I well remember a country secondary school in the West Indies in which the sixth-form pupils knew all about the English frog in the text-book but did not even realize that the frogs in the school yard were different. Secondly, the choice of material is admirable: diurnal lizards enter into our daily life in the tropics in a manner which is matched by no wild vertebrate in the temperate regions. Thirdly, the book is easy to read.

The anthropomorphic but unsentimental style gives "life to the narrative" without being irritating. These lizards share our gardens and our houses; Dr. Harris shows how we can get to know them as individuals. As the book is largely concerned with behaviour, I think that it would have been useful if the author had given details of how to discriminate between *Agama agama* and other related species. The book shows how much can be learned by careful observation of individually marked lizards. I was particularly intrigued by the way in which the author was able to take advantage of the regularity with which each lizard defæcates at a particular time and place, to collect the scats and analyse the feeding habits of different age groups under undisturbed conditions. He demonstrates a number of relationships between the activities of the lizards and variations of the environment; for example, he interprets their geographical distribution in Nigeria in terms of their thermal requirements in relation to features of climate and vegetation. Dr. Harris also shows what can be done by simple experiments, many of which could be repeated in a school yard. Simple models were, for example, used to elucidate the importance of colour pattern and behaviour in defence of territory, courtship and mating.

References are given throughout the book to work on other lizards so that we have some idea of how far the behaviour of *Agama* is representative of lizards in general. The chapter that I found the weakest was that on colour change. In the general discussion the three major

factors influencing colour change were not brought out clearly: background response mediated by the intermediate lobe of the pituitary, response to stress mediated by the autonomic nervous system and adrenal gland and direct response of the chromatophores to temperature. I remain uncertain as to whether *Agama agama* shows a background response.

I like to think that those interested in animal behaviour will feel that lizards offer a splendid and almost untapped field of study. We can observe almost every phase in the life of a diurnal lizard; some of them seem to thrive as commensals of man. The fact that they, like us, are eye-minded animals makes it easier for us to appreciate much that is important in the life of such lizards. This book should be used by every school in Africa; indeed, it furnishes an argument for the teaching of biology in every school in Africa. I would like further to commend the book to every biology teacher in those warm countries in which lizards abound. Your common lizards will certainly differ from *Agama agama*, but Dr. Harris's book will give you a wealth of suggestions as to the kind of studies that can be made.

GARTH UNDERWOOD

AMPHIBIAN PHYSIOLOGY

Physiology of the Amphibia

Edited by John A. Moore. Pp. xii+654. (New York and London: Academic Press, 1964.) 128*s*. 6*d*.

OWING to their wide range of habitat and their poikilothermy, the Amphibia are a group of cardinal importance in the comparative physiology of the vertebrates. A second, and too often quite distinct, claim to fame is that some members of the group, the frog in particular, have provided generations of physiologists with convenient, readily available, preparations. It is to be hoped that *Physiology of the Amphibia*, with its clear indications of the many gaps in our present knowledge, will help to shift the emphasis from the latter role and accelerate progress toward an integrated physiology of these animals in relation to their varied environments.

The book is intended to be useful to both the amphibian and the general physiologist, and there can be no doubt that it performs a signal service for the former, for chapters on the digestive system (W. G. Reeder), blood and respiration (G. E. H. Foxon), water balance and kidney (I. J. Deyrup), and amphibian metabolism (G. W. Brown) may be instanced as providing lucid and effective syntheses of work which, with the possible exception of endocrine aspects of water balance, was sorely in need of collection and evaluation. For good measure, the book concludes with two chapters of a rather more specialized nature on developmental physiology (C. J. Barth) and regeneration (S. M. Rose). The general physiologist, on the other hand, will be primarily interested in this book because it makes work on the Amphibia more readily accessible, although there are two chapters ("Amphibian Muscle", B. C. Abbot and A. J. Brady; "The Amphibian Heart", A. J. Brady) which deal with fields where the frog has usually provided the experimental material without itself being the animal under investigation. Both contributions, which are heavily biased on the electrophysiological side, deal with work which is regularly reviewed at greater length than has been possible here, and it is therefore a pity that, apart from the slow fibre system in muscle, the opportunity has not been taken to include peculiarly amphibian aspects, such as seasonal phenomena.

The general editorial plan has not completely overcome the problems inherent in any attempt to produce a physiological treatise on a single group of animals. Several contributors feel that it is necessary to cover the whole range of their subject, at least in outline, even when nothing is derived from the Amphibia directly. This leads to the inclusion of several pages which can surely contain nothing but gratuitous information for most readers. Is this the type of book to which even a student would turn for an account of the tricarboxylic cycle or the β-oxidation of fatty acids? There is also a certain amount of overlap between some contributions, this being particularly evident in the endocrine field. The control of blood-glucose level is considered in a wide-ranging article on amphibian metabolism (G. W. Brown) and the hypothalamic control of pituitary secretion in a thoughtful section on amphibian metamorphosis (W. Etkin). Both these subjects are at least partially covered by A. Gorbman in the chapter on amphibian endocrinology, yet the important field of reproductive endocrinology is only given passing mention as one which has attracted the attention of many investigators.

The text is adequately illustrated, reasonably free from typographical errors and, despite the above strictures, the book is a valuable addition to the literature which should supplement Noble's earlier classic and be welcomed by all who wish to learn of the amphibian way of life.

C. L. SMITH

CROCIDURA

A Systematic Revision of the Shrew Genus *Crocidura* in Southern Africa

By Jurgens Meester. (Memoir No. 13.) Pp. vii+127. (Pretoria: Transvaal Museum, 1963.) n.p.

THE shrews of the genus *Crocidura*, and of related genera, constitute one of the most difficult taxonomic groups among the Mammalia. The difficulty lies mainly in the fact that the observable interspecific differences are so slight as to be obscured, if not equalled, by regional intraspecific variation. ('Observable' is the critical word—the shrews presumably recognize each other by scent, and if we could learn to do likewise many taxonomic problems would be resolved.) The taxonomist aiming to delimit the species is faced in reality with two tasks: first, the detection of the essential characters, leading to the recognition of the species as biological entities; and secondly, the description of those specific characters that are of practical value for identification of the species.

The revision of a genus can only be regarded as definitive when it is considered simultaneously throughout its entire range. Such a task is premature at present for *Crocidura*, ranging as it does from the Cape of Good Hope to Japan, but this volume, dealing with the southern part of Africa (south of the Zambesi), is a very valuable contribution towards that end. Nine species are recognized, and there are serious doubts about the validity of only one of them. The diagnoses, based almost entirely on size, colour of the pelage and dentition, inspire confidence in the validity of the results, but do not give a great deal of help to the non-taxonomist trying to identify species. A more detailed study of such external features as ears, nose, feet and scent-glands might have contributed some additional characters of practical as well as theoretical value. A valuable feature is the inclusion of distribution maps of each species, but the interpretation of the distribution is made unnecessarily devious by the attempt to correlate distribution primarily with rainfall and only secondarily with vegetation zones. The fact that the homoiothermic vertebrates are much more directly dependent on the biotic than the climatic component of their environment has been curiously overlooked by generations of biogeographers.

The introductory chapters contain a general account of the genus *Crocidura* and very detailed illustrated description of the skull and dentition of one species, *C. flavescens*. This should prove invaluable to the less experienced, or less specialized, taxonomist tackling other parts of this fascinating but frustrating group.

G. B. CORBET

Virological Technique

By D. W. G. Busby, W. House and J. R. Macdonald. Pp. x+218. (London: J. and A. Churchill, Ltd., 1964.) 30*s*. net.

THERE is, undoubtedly, need for an up-to-date handbook describing the techniques used in applied virology, and the aim of this one has been to provide a "reliable guide to laboratory practices in everyday use". The laboratories in mind are clearly those engaged in the routine isolation and identification of human pathogens and the measurement of immune responses to them.

There is a concise and lucid section on the cleaning and sterilization of apparatus, while filtration is described shortly. In discussing disinfectants it is difficult to see why ether and glycerol are mentioned and why more emphasis is not given to the proven virucidal range of agents recommended. Apparatus such as egg incubators, gassed incubators, homogenizers and the high-speed centrifuge are described in some detail.

The section on light microscopy is sometimes unhelpful; for example, the only use mentioned for inverted microscopes is to "examine cell monolayers growing in Petri dishes . . .". Electron microscopy is given brief introductory treatment. The account of inclusion bodies is outdated and contains some inaccuracies; for example, basophilic elementary bodies are described in the cytoplasm of cells infected with herpes febrilis and type *B*, intranuclear inclusions are attributed to herpes febrilis and zoster, both NITA viruses.

The chapter on animal isolation and inoculation techniques is clear and simple, though it is difficult to see why arterial cannulation is preferred to cardiac puncture for obtaining chicken plasma. Embryonated egg techniques, cell-culture methods and media receive good attention, but there are disturbing generalizations; for example, "Results obtained from cell cultures are invariably quicker . . . than those from laboratory animals". There is a brief general description of serological tests.

A very useful practice throughout the book is to append footnotes giving the addresses of suppliers for recommended items.

Systematic virology is dealt with in the final third of the book. In view of the apparent aim to cater particularly for workers in Britain, it is occasionally difficult to understand the relative allocation of space. For example, there are more than two pages devoted to a list of arboviruses, but no mention of rubella. The final chapter is a short account of freeze-drying techniques—not intended to be a practical guide to those required to carry them out but directing attention to more comprehensive reference works.

This well-produced volume will be very useful in its intended sphere and goes a considerable way towards filling the previous hiatus.

The Nature of Parasitism

The Relationship of Some Metazoan Parasites and Their Hosts. By W. P. Rogers. (Theoretical and Experimental Biology: an International Series of Monographs, Vol. 2.) Pp. ix+287. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1962.) n.p.

THE first edition of this compact, original and attractively-written book earned for itself a unique place in the considerable and growing literature about parasitology. It is not a text-book, nor is it a book for those who wish merely to know about the structure of parasites and how to identify them, or about the diseases they cause and the treatment and control of these diseases. The aim of the book is expressed rather in its sub-title. It is written for those who wish to understand the biochemical and other conditions which govern the way of life called parasitism as revealed especially by the nematodes and flatworms parasitic in Metazoan hosts.

As the author rightly observes, the mere entry of a parasite into a host does not constitute parasitism. Once a parasite has successfully overcome the many difficulties that may prevent it from reaching the right host and succeeded in entering it, it is confronted by many powerful factors challenging its very presence and continued existence inside the host. Against these adversities it must feed, grow and reproduce its kind and, if it can, overcome the biochemical, physiological or immunological resistance reactions of the host.

The Nature of Parasitism contains an excellent account of our knowledge of the biochemistry of these factors which govern the relationship of parasite and host. These are illustrated by reference to the more common and better known parasites of man and domesticated animals. To understand the text the reader will require a considerable knowledge of biochemistry and its technical terms and at least an elementary knowledge of the structure and life-histories of the parasites used to illustrate Dr. Rogers's views. He discusses in detail the remarkable effects of parasitism on the parasite and gives much space to a discussion of the basis, especially the biochemical basis, of the key problems of the host-specificity of parasites, the biology of their infective stages, and the modifications of the reproductive processes of the parasite, including the structure, formation and biochemistry of the parasite's egg-shell, its production of eggs and sex ratio and other factors which enable it to ensure reasonable chances of infection of the right hosts. The later chapters of the book discuss the ecological factors which influence the origin of parasitism and Dr. Rogers's own interesting views on the evolution of this mode of life.

The book deserves, and will no doubt achieve, many more editions, to which all parasitologists who wish to understand the way of life they are concerned with will eagerly look forward.

G. LAPAGE

Cats of the World

(World Wildlife Series No. 1.) By Armand Denis. Pp. 119+36 illustrations. (London: Constable and Co., Ltd., 1964.) 30*s*.

Rhinos Belong to Everybody

By Dr. Bernhard Grzimek. Translated by Oliver Coburn. Pp. 207 (138 photographs). (London: William Collins, Sons and Co., Ltd., 1964.) 63*s*. net.

THESE are two animal picture books by television personalities; both emphasize the impending extermination of much of the world's fauna and plead for effective conservation before it is too late. It remains to be seen whether such conservation is possible while the human population pressure increases at its present rate. Unless war, pestilence or famine reduces the number of men in the comparatively near future there will literally be no room for wild animals before many years have passed. Although politicians refuse to face the one problem of overwhelming importance to mankind, and fritter their efforts away on parochial controversies and international paper-pushing, they will before the end of this century be forced in all civilized countries to abandon subsidizing human breeding, to institute family planning permission and the imposition of heavy taxes on families of more than two children. The most optimistic estimates of the size of the world population in A.D. 2000 show that through the whole of the twenty-first century there will be food-rationing all over the world for at least a hundred years; the ration-book and the food queue will be as much a normal part of life to our great-grandchildren as the motor-car and the television are to us. Conservation of the fauna, ardently as it is desired by zoologists, is no more than a pipe-dream if the population explosion is not very soon extinguished.

Mr. Denis acknowledges the help of his editor, Dr. Bruce Campbell, in writing his book, and indeed it seems

that Dr. Campbell's hand can be recognized on most pages. It would therefore have been more gracious had the book not been written throughout in the first person singular. There is a useful check-list of all the species of the Felidae in an appendix, and there are illustrations of all species. The format and production are not distinguished. In contrast, Dr. Grzimek's book is beautifully produced and contains a collection of colour and monochrome photographs printed in Germany and second to none, all of them interesting and many of great beauty. The text, which is mainly a personal narrative of travels in Africa, has been skilfully translated by Oliver Coburn. L. Harrison Matthews

Theory of Excitons

By Robert S. Knox. (Supplement 5 of Solid State Physics: Advances in Research and Applications.) Pp. vii+207. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1963.) 68*s*.

THE absorption-edge spectrum of a semiconductor or insulator often shows a complicated structure which can, in many cases, be explained by exciton theory. An exciton is the simplest kind of electronic excited state of a crystal, in which a single electron has been excited across the forbidden energy gap to form an electron-hole pair.

The book by Robert S. Knox is a review of exciton theory covering the period from its first formulation by Frenkel in 1931 up to the present. Although the exciton has been investigated for more than thirty years, the papers referred to in the book—almost 400 in number—have mostly been published in the past decade. The increased interest in recent years has been stimulated by the large number of optical measurements on semiconductors, as it is for these crystals that exciton theory has had most success in explaining the features of experimental absorption spectra. According to Dr. Knox, a plateau has now been reached, with the electronic structure of the exciton well understood, but with much work still to be done on its transport and statistical behaviour.

The theoretical discussions of the book are based on a thorough account of the one-electron theory of the ground state and simple excited states of an insulating crystal. Dr. Knox then shows how this theory leads in different limits to the tight-binding Frenkel exciton and to the weak-binding Wannier exciton, the connexions between the two cases being emphasized. The theory of the effects of electric and magnetic fields and of mechanical strain on the exciton energy-levels is well presented, and the supporting experimental results are compared with theoretical predictions. The importance of excitons is almost entirely due to their influence on the absorption spectra of crystals, and a large and excellent section of the book is devoted to the theory of the optical properties of excitons. The final main section of the book deals with the theory of exciton transport.

Dr. Knox's book is well written, with the theory clearly presented and with the large volume of published work on excitons exhaustively covered. It can be wholeheartedly recommended both as a detailed account of the present state of exciton theory and as a stimulating source of ideas for experimental and theoretical research worth pursuing in the future. R. Loudon

Recommendations of the International Commission on Radiological Protection

(As Amended 1959 and Revised 1962). (ICRP Publication No. 6.) Pp. v+70. (London and New York: Pergamon Press, 1963. Published for the International Commission on Radiological Protection.) 25*s*. net.

PUBLICATION No. 6 of the International Commission on Radiological Protection contains the amendments made in 1962 by the Commission to its recommendations first adopted in 1958 and amended in 1959.

The greater understanding of the interactions and effects of radiations, resulting from the large volume of research in this field, makes it possible for more precise recommendations on radiation protection to be drawn up. The need for continuous revision arises from the considerable expense involved in maintaining the necessary standard of protection; any relaxation of the requirements compatible with safety is, therefore, of great practical value.

Apart from introducing the concept of Dose Equivalent (*DE*), to be measured in rems, which takes into account the difference in the biological effects of radiation by using the Quality Factor (*QF*), the main changes to the previous recommendations concern exposure of women of reproductive age. For those occupationally exposed, the maximum permissible exposure during any 13-week period has been reduced from 3 rems to 1·3 rems, although the annual maximum permissible exposure of 5 rems remains unchanged. This reduction was necessitated by evidence that the embryo is more sensitive to radiation, particularly in the early stages of pregnancy. For the same reason, all women of reproductive age should avoid X-ray exposure of the lower abdomen, except during the ten-day interval from the start of menstruation, when it is virtually certain that there is no pregnancy. Other modifications concern the lens of the eye, short-term exposures and emergency work, dose-rate effects, and the addition of external and internal exposures.

The maximum permissible concentrations of strontium-90 in air and water have been relaxed by a factor of 4, without reducing the maximum permissible body burden; this again follows a better understanding of the metabolism of strontium. New data are also given for many transuranium elements, up to fermium. These and other modifications to maximum permissible concentrations are tabulated in the book as a supplement to the previously published tables. Considerable confusion may arise from the existence of two sets of data and it would have been advisable to reproduce the tables in full, even though this may have resulted in the book costing slightly more.

J. Rotblat

Economic Development

By Prof. John Kenneth Galbraith. Pp. xiii+109. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1964.) 12*s*. 6*d*. net.

THREE chapters of *Economic Development*, on education and economic development, on developing and developed, and on development and the industrial corporation, are substantially unchanged from Mr. Galbraith's earlier book, *Economic Development in Perspective*, but the titles of the second two are changed. Substantial parts of a fourth chapter, "Development as a Process", are also taken unchanged from the first and title chapter of the earlier book. For the rest, though the main theme is the same, this is virtually a new book, rewritten and expanded with all the wit and realism that characterized the first. It carries, too, the same warning of the danger of any rigid classification of the nations into developed or underdeveloped nations: almost all, to some extent, fall into both categories, as well as into a third category of developing nations, to which most also belong. There are now eight instead of five chapters, the others discussing the process of economic development, the causes of poverty, and the choice. There is also a postscript on population and a brilliant introduction which explains the origin of the book and its evolution. Although concerned mainly with the underdeveloped or developing nations, and the ways in which technical or economic assistance can most effectively be given, the refreshing challenge of the book to doctrinaire thinking of any order makes it a stimulating and pertinent contribution to constructive thought about economic development in Britain or anywhere else. R. Brightman

SOCIAL ORGANIZATION OF INFORMATION*

By The Right Hon. Lord SHACKLETON, O.B.E.

President of the Association of Special Libraries and Information Bureaux

IN using the above title I mean organization by and on behalf of society or the community. This is a somewhat ambiguous title, but unfortunately we are operating in a field where many of the words are for us going to have a special significance, while popularly retaining a more general meaning; even the word 'information' has come to have a specialized meaning to us. I rather think the time has come when we need a single word to describe all these matters in which we are dealing. Otherwise we shall need a sentence, indeed a definition covering such words as 'information', 'documentation', 'storage', 'retrieval', 'dissemination', 'communication'. It is arguable we should perhaps have the definition before we have the word, but this need not deter one from the game of word invention.

I do not know how Norbert Wiener, if he was really the author, came to invent the name 'cybernetics' but it is a convenient and appropriate term with an impeccable derivation from the Greek work 'guberneo' (Greek letters γυβερνέω)—a most evocative derivation for the purpose. Inspired by this thought, I hastened to the Exeter University Library where, aided by their system of instant retrieval and by a Liddell and Scott Greek Lexicon, I devised the word 'exagellectics' from the Greek 'exagello' (Greek letters ἐξαγγελλω), meaning 'to inform'. I am not sure that the word is an entirely happy one, indeed it is certainly open to misinterpretation, but so is the title Aslib itself (being an abbreviation for Association of Special Libraries and Information Bureaux), and at least it is no uglier than 'ergonomics'. I think we might say that exagellectics is a branch of epistemology but must stop playing a game that any linguistic philosopher would scorn. However, I still urge the need for a single word to describe our study and our craft.

There is, alas, no professorial chair at a university with a sustained study of this subject and, although much of the thinking and some research is being carried on, I cannot discuss the whole of what will have to be the subject of major research in the future. However, in the absence of a professor it is perhaps not a bad idea for a politician or even a businessman to attack the subject.

The broad purpose of this article is to argue the case for action by the new Government in accepting responsibility for establishing machinery on a national footing for the provision and organization of scientific and all other research information and documentation. I will state right at the beginning that the purpose of a body operating in this way will be to define and identify, to advise, promote and co-ordinate, and to investigate and administer in the information field.

There are some grounds for supposing that the progress which can be made by any civilization is limited by the speed and effectiveness with which knowledge can be communicated. In Egypt hieroglyphic writing on papyrus made it possible for knowledge to be communicated to others and stored; but the process was so slow that the limit was soon reached. The remarkable flowering of Greek culture must have had some association with the Greek form of writing which made the transfer of knowledge more rapid and precise. though fortunately for contemporary classical research many accounts were kept on tablets. There was little progress from Roman times until the invention of printing, and we to-day must make sure that the progress we are capable of achieving by the new methods of communicating, storing and retrieving knowledge is not halted through failure to develop system or organization.

Scientific knowledge is doubling itself every 10–15 years and so are the documents within which it is contained. We need to be a great deal more concerned about the scientific explosion and its recording if we are to hope to find the means of making use of it.

While probably few would dissent from the proposition that much of a nation's wealth lies in its accumulation of specialized knowledge, I suspect that, for many people, it would be a very long step from that position to acceptance of the fact that, for those sections of a nation's wealth to be converted into real terms, an integral part of national economic planning must consist of the development of systematic arrangements for the control and exploitation of the specialized knowledge generated by mankind. (The word 'control' is a loaded one when used in its popular sense, but I am here using it in a technical and precise sense.) They would look at you with slightly pained surprise if you suggested that the range of operations involved in this process should have both an expertise and a philosophy of its own, capable of development and refinement by the processes of research and testing and discussion, and that this process of refining and testing is a discipline that could be of real value in itself. We in Aslib have come to accept this, but now we have a very much harder task of pressing our beliefs on those who have the power to convert them into the mainstreams of national vigour.

While we have been accustomed to think and plan information activities—in so far as we do either—in terms of harnessing scientific and technical knowledge. we must be ready to acknowledge the needs of other disciplines in the near future. The country has not yet faced up to the importance of the social sciences and equally we have not yet fully come to grips with their information needs. No doubt when the Heyworth Committee reports we shall see the formation of a Social Science Council and of course this will give impetus to research in these subjects. The need for a proper national organization of information services concerned with the social sciences will then become much more apparent. and I hope that Aslib is giving urgent attention to ways of adapting to this field at least some of the lessons learned in relation to the natural sciences.

Nor can I see why we should overlook the humanities. I can see no reason why, for example, historical or linguistic studies should not be modernized and streamlined by the adoption of the most modern information techniques. Nor might I think that some university librarians are shocked by the suggestion that the computer might on

* Substance of the Presidential Address delivered at the thirty-eighth conference of Aslib held in the University of Exeter on September 28. The full address will be published in *Aslib Proceedings*, 16, No. 12, December, 1964.

occasion replace the quill. After all, Canon Morton did much of his researches into the Epistles of St. Paul with the aid of a computer, though this was not strictly speaking an information technique. Librarians must of course see that the benefits of their techniques and work show themselves much more evidently and cogently in a steadily widening range of subjects. But there is more to it than this. Not only must they develop and adapt techniques of operation that should transform their own image into a combination of what is best in classical scholarship and modern technology; they must also, and so must we all, recognize that their activity is fundamental to political and economic planning. As a legislator I know from experience how very patchy is much of our real, organized knowledge in the field of economics, education and psychology—indeed, in all aspects of industrial and civil life, not to mention the law. We know, too, that new techniques are being developed that may revolutionize government—for example, by Prof. J. R. N. Stone of the Department of Applied Economics at Cambridge who is seeking, with the aid of a computer, to feed the multitudinous economic variables into a cybernetic model. The structure of government is still rather old-fashioned, but as life gets more complex it is bound, I hope, to adjust its machinery so as to improve both departmental and legislative decision making. Two scientific clerks to the House of Commons Library have recently been appointed, on the initiative of Mr. Austen Albu, one of the few MPs who understands this problem. This is at least a sign of the times.

There is, of course, already much first-class information provision—for example, in the Board of Trade, Ministry of Pensions, Ministry of Public Building and Works, and, not least, the Commissioners of Inland Revenue. Much of this has produced valuable raw material for all forms of research, including sociological research. As more and more is produced, a way has to be found of ensuring that this information is not only made available but is also known to be available and, furthermore, retrievable, and this needs both machinery and properly trained people to organize it. A special problem arises from the growth of new sciences and especially of inter-disciplinary studies where even the words used carry different meanings to different specialists. The meaning of words has already created difficulties in medical engineering. Furthermore, as the specialist reaches out into other fields, he finds the information resources of his own subject inadequate and possibly wholly lacking in important respects for his new purpose and he is unable to find a new starting point. An example of this is the investigation of gerontology where the searcher may be concerned not only with radiobiology, psychology, and biochemistry, but even zoology and botany, and he may well be unable to find (as was indeed the case in a particular instance in a well-known medical library) suitable reference information in the latter two fields. There was only one course open to my frustrated research friend and that was to join Aslib. This worked well enough but serves to illustrate the problem, which increasingly will call for radical solutions.

It must be apparent that a much more far-reaching revolution in the work of documentation and information research is called for than the modest steps which Aslib has been quietly and painstakingly leading during the last thirty or forty years. All this implies a radical re-thinking of our approach to information and documentation services. What has often been regarded as just a series of technical operations incidental to particular research and development must be recognized as a study in its own right. Increasing effort must go into developing a theory and philosophy. Cybernetic concepts are already available and are of some value. Much of the theory is at an early stage, but other disciplines even as far afield as ecology may provide useful analogies.

The President's Science Advisory Committee of the United States in its report on *Science, Government and Information* has said: "The flow of undigested information will surely engulf our science and shatter it into isolated fragments unless we change the traditional methods that we use to handle the flood". To do this we are enjoined to examine the information transfer chain and seek desirable qualities such as compatibility between one system and another. Only thus can information, like the living species in an ecological system, survive and fulfil its role. We must recognize the complexity of systems, and accept that we are not confronted with just a narrow professional problem. We are dealing with a hybrid discipline. Documentation and control of information are something that can straddle all cultures and help to set Sir Charles (now Lord) Snow's mind at rest.

In the past Aslib has spearheaded this attack with considerable assistance from the Department of Scientific and Industrial Research within the limitations of grant aiding, but I am doubtful as to whether the research association scheme, admirable though it is in many ways with its linking of grant-aid with subscription income, has been particularly suitable for the financing of work which is essentially of interest not just to those few people who are aware of it, but also to the nation at large.

During the past years Aslib, despite shoe-string resources, has achieved a great deal and we owe much to its officers, its Director, Leslie Wilson, and his dedicatep staff. Aslib has united in a common purpose and with, I understand, a really remarkable degree of loyalty, organizations from industry, education and government; and I think we have probably been much freer from the frictions that other associations have suffered. Intellectually, leadership by Aslib is acknowledged in the international field despite the fact that there are more massive resources available in other countries, especially the United States and U.S.S.R. I think, in fact I am sure, that no other national information organization has won—whether they campaign for it or not—the membership support of six hundred organizations in countries other than its own, in addition to its home membership, as well as many more regular subscribers to its publications. This is the point at which we always pride ourselves that this is the typically British creation, and we follow our time-honoured practice of appointing a chosen instrument and then forgetting to give it the resources that the task demands.

We have, however, now reached a stage when the new Government must accept full responsibility for establishing on a national footing machinery for the proper organization of information and documentation. The Government must do so not only for its own purposes but also because it, alone, can harness the diverse activities and support them on an adequate scale. Support must be found for more research, particularly if we are to achieve economy and cogency in the recording of information by using various forms of mechanization. I am glad that Aslib is putting mechanization firmly at the head of its research programme. There may be a need to concentrate much more of our information resources into a relatively small number of information centres under expert staffs. But the primary need is for a national authority of some kind which must accept responsibility for identifying national information needs, for ensuring that they are filled and for helping to develop the information system according to whatever tasks the national interest demands. "Hitherto the Government's attitude in Britain has been negative rather than constructive", according to an editorial in *Nature* of May 23, 1964. The editorial goes on to say that "some central authority competent to take an overall national view and identify weaknesses as well as having the resources and influence to rectify such weaknesses is obviously imperative". This is

precisely what Aslib said to the Minister for Science concerning the Trend Committee Report which, in this respect, was a rather disappointing document. Certainly Trend reckoned that the Minister for Science should assume general responsibility in regard to methods of disseminating research information, but that is only one aspect of the matter. While the Committee proposes that the Industrial Research and Development Association should have a division responsible for co-ordinating information activities within its own sphere, there is no reference to the need to encourage information studies within either the Science Research Council or the Natural Resources Research Council. Nor must we overlook the enormous interest of both private and public industry in obtaining this information.

Now that responsibility for science and education is concentrated in one Ministry and under one Minister, and this includes universities and public libraries, it is logical for this Ministry to accept responsibility for establishing an authoritative body with undivided responsibility for development in the information field. So far, with our limited resources, we have not done too badly, but we are beginning to lag behind. The United States has established the Office of Science Information Service of the National Science Foundation in Washington, and in Moscow there is the All-Union Institute of Scientific and Technical Information. In Britain I hope we shall develop a system that is both more subtle and more far-reaching and that it will cover all the 'cultures'.

Aslib has always preached the oneness of information and has rightly seen it as an incipient discipline with philosophies, techniques and aspirations of its own. While I believe that a centralized approach is essential to the solution of these problems, any national body that is set up must recognize that there is immense diversity in this field. There will need to be links with libraries of all kinds, public and private. In particular, the needs of users both corporate and individual must be known and this means more research. The professional in this field will need not only training but also education on a broad inter-disciplinary basis—a requirement indeed for any good librarian. While he may often be required to be a technologist too, he must be ready to draw on the older wisdoms. To achieve all this, the authoritative body to be set up must have adequate resources and must be able to initiate or itself carry out research.

Granted that the principle is accepted—and there are signs that these needs are becoming recognized—it is important to establish the right organization. We must approach this great issue of communication and information in a questioning mind. We do not want just a short bout of crystal gazing by a few wise men, which has so often been the basis of government decision. But of one thing I am certain, that if—and this is the central theme of my article—this service is to be the unifying force that I hope it will be in regard to knowledge and research of all kinds, it cannot be tied to science and technology alone. It must be made crystal clear that this body would not seek to exercise control over the subject of study though it will, I hope, influence the individuals concerned, especially some of the professors, to accept a greater degree of responsibility for 'exagellectics' or information used in their investigations, for no one is better equipped as a rule than the professor to do this and to guide and assist the professional librarian.

My own view is that something is needed of the nature of an independent Research Council. The Government cannot directly run everything, nor would we want it to. The example of the Nature Conservancy which with limited resources has achieved an authoritative position is before us. It has spread much of its thinking and influence far beyond its main conservation role, especially in establishing ecological concepts. A Research Council would fit in well with the post-Trend situation. It could have flexibility of staffing and occupation and some measure of freedom and independence in its day-to-day activities, while at the same time retaining essential links with the Government. There may be other ways of tackling the problem but I hope that we shall no longer dodge the issue. I will not attempt to describe how the organization will work. Certainly much consideration will have to be given to abstracting services and to documentation on an international basis. Some measure of co-ordination is necessary in relation to existing national scientific libraries such as the National Lending Library for Science and Technology at Boston Spa and the new National Reference Library of Science and Invention. The present relationship is a reflexion of the piecemeal 'ad hoccery' of Government decision. The membership, I would beg, should not be wholly scientific and technological. Let us by all means have people who cross the cultural frontiers whether it be the mathematician, the social scientist, the philosopher or even simply the historian. Among the scientists, I would have particular reasons for advocating the membership of zoologists. The Research Council will of course need a pluralistic approach, and will certainly need to maintain links with the users, for the body will exist for them.

Where would Aslib fit in? This is difficult to say, but it is certainly too early to consider assimilating Aslib completely into the organization. Aslib will need the final strength to carry on and to continue to approach the gap in its traditional semi-voluntary way. Aslib has successfully brought together information interests in all fields—government, private and public industry, university colleges, learned societies, publishers and the rest. Nor must we be afraid of some overlap, though this need not mean that there is excessive duplication of effort—merely variety in approach and particularly in new ideas. It would be quite wrong in my view to contemplate, certainly at this stage, a monolithic structure.

We are dealing here with one of those elusive subjects, the full extent of whose import is apt to be missed. In any project or activity, communication, liaison, information—all these are things which people tend to deal with as an afterthought. This can no longer continue. The time has come when we must ensure that Aslib's accumulated knowledge and experience together with that gained through other bodies with an interest, even a peripheral one, is used for the benefit of all. Sooner or later we shall need something of the standing of an independent research council and it may be that what is needed in the long run is what is needed in the short run. Its functions should be to define and identify needs and problems, to advise, promote and to co-ordinate, to carry out research and to administer directly where this is appropriate national institutions such as the National Lending Library for Science and Technology and perhaps even the National Reference Library of Science and Invention.

Perhaps some will think that what I am proposing is premature and that other solutions can be found. Perhaps in the next thousand years, perhaps in the next million, we shall all become cybernetic men with instant recall and telepathic aids to communication. Yet now with our limited, inadequately used brains we must seek to organize the full utilization of the product of those brains. This is a field in which, in every way, it would be fatal to be guilty of under-investment, yet we squander nothing so prodigally as knowledge. Money, metals, farm produce—waste these and the balance sheet, the scrap yard, and the muck heap stand as monuments to folly. But treat knowledge as a luxury, a frill to gracious living, the product of an intellectual exercise to be tossed back and forth between experts and finally allowed to drop into the tranquil pool of things that do not count because they cannot be measured—and we can live for years with never an eyebrow raised. Or can we? Well, perhaps we could. But we shall not do so again.

COMPARISON OF RADIO AND OPTICAL POSITIONS OF SOME IDENTIFIED RADIO SOURCES

By R. L. ADGIE
Royal Radar Establishment, Great Malvern

THE identification of radio sources is one of the most vital problems in radio astronomy and demands the utmost precision in the determination of positions. Recent observations of lunar occultation of radio sources have made it possible to determine certain angular positions to an accuracy of about 1 sec of arc. This is potentially the most precise method of measuring position, but is unfortunately limited by the path of the Moon to a band of declination close to the ecliptic, and it takes several years to cover this band completely. For the majority of radio sources, the positions have to be measured with an aerial system of high resolving power, such as a two-aerial interferometer.

It is very difficult to make an absolute measurement of position with these aerial systems, because of the uncertainty about the precise location of the radio phase-centres of the aerials and the exact phase changes through the electronic equipment and cables. But provided these parameters are stable, the systems are capable of measuring the relative positions between sources very accurately, and can be calibrated by observing sources the positions of which are already known. Obviously the sources observed by lunar occultation provide ideal calibrators over a limited range of declination close to the ecliptic, but others are needed throughout the whole declination range under observation, and these must be taken from the optically identified radio sources. The optical positions of these sources are known very precisely, and they can be used as calibrators provided the radio and optical positions are the same. In general this is likely to be a valid assumption, especially as agreement in position is the initial basis of an identification, but there could be exceptions. This problem arose recently during the calibration of the interferometer at the Royal Radar Establishment (R.R.E.); fortunately there are many more optically identified sources available than are strictly necessary for the calibration, so a comparison can be made between the different calibrators to check the agreement between the radio and optical positions.

Observation of radio sources. The R.R.E. interferometer[1] consists of two steerable paraboloids, 25 metres in diameter, mounted on movable carriages, which can be separated up to 750 metres in any direction. The present operating frequency is 610 Mc/s, giving a lobe-width of 140 sec of arc at maximum spacing. Two separate sets of observations had to be made to determine positions in two co-ordinates. A baseline of about 750 m was oriented approximately east–west to measure the right ascension and near north–south to measure the declination.

Variations of the phase changes through the amplifiers and cables have been minimized by careful design and temperature control, and the shift in the interferometer pattern corresponds to only 1 per cent of a lobe-width over a few days. The errors due to random noise on the records have been reduced to a negligible value by averaging over several periods of the interferometer pattern. However, the accuracy of the determination of the positions of weak sources is influenced by the confusion of the numerous other sources within the aerial beam. The root mean square value of the confusion is 0·5 flux units* with this equipment, which corresponds to a directional error of 1·6 per cent of a lobe-width when observing a source of 5 flux units. All the identified sources observed have flux densities greater than 5 flux units, so the accuracy of the relative positions should vary from ± 4 sec of arc root mean square, to better than ± 2 sec of arc for the most intense sources.

Only sources having a small angular diameter can be measured with this large aerial spacing. The selection has been limited to those the apparent amplitude of which does not fall below half the amplitude at close spacing, which imposes a limit of 60 sec of arc diameter for a single source and 40 sec of arc separation for a double source. In any event, there is less significance in determining the effective centres of large diameter sources to an accuracy of a few sec of arc; measurements of the positions of such sources can be made with sufficient accuracy with a smaller aerial spacing.

The measurements have been corrected where necessary for ionospheric refraction, using values of total electron content from the critical frequency data. These corrections are less than 3 sec of arc, and can be estimated so as not to contribute a significant error.

Calibration procedure. The calibration of the system was determined by the examination of 18 sources fulfilling the required conditions of small diameter, flux density greater than 5 units, and with information available on the positions of optical objects that may be identified with the radio sources. For three of the sources, radio positions are known from lunar occultations[2,3]. The remainder are included in Griffin's list[4], giving positions of optical objects in the vicinity of radio sources with an accuracy of better than 0·5 sec of arc.

An approximation of the true callibration was first obtained by direct geometrical measurement of the co-ordinates of the baseline. The measurements were then put into the appropriate equations to give a first approximation to the radio positions, which can then be compared with the optical or occultation positions. In general the positions will differ, because of errors in the approximate calibration, and the differences will be a function of declination.

These differences, for both right ascension and declination, are plotted in Fig. 1. For convenience, the differences in right ascension have been converted to true angular displacements in secs of arc by multiplying seconds of time by 15 cos δ, where δ is the declination. The true calibrations are represented by curves through these points satisfying the correct form of the equations of calibration. These equations contain three unknown constants, so the curves can be made to fit points at each end and at the centre of the declination range. The curves drawn in Fig. 1 are considered to be the best fit to the observational data, and their departure from straight lines parallel to the declination axis indicates the extent to which the approximate calibrations were in error. One of the unknown constants in the declination equation is the wave-length, and since this cannot be measured sufficiently accurately it has been adjusted to give the best fit in the calibration.

* One flux unit is taken as 10^{-26} Wm^{-2} $(c/s)^{-1}$.

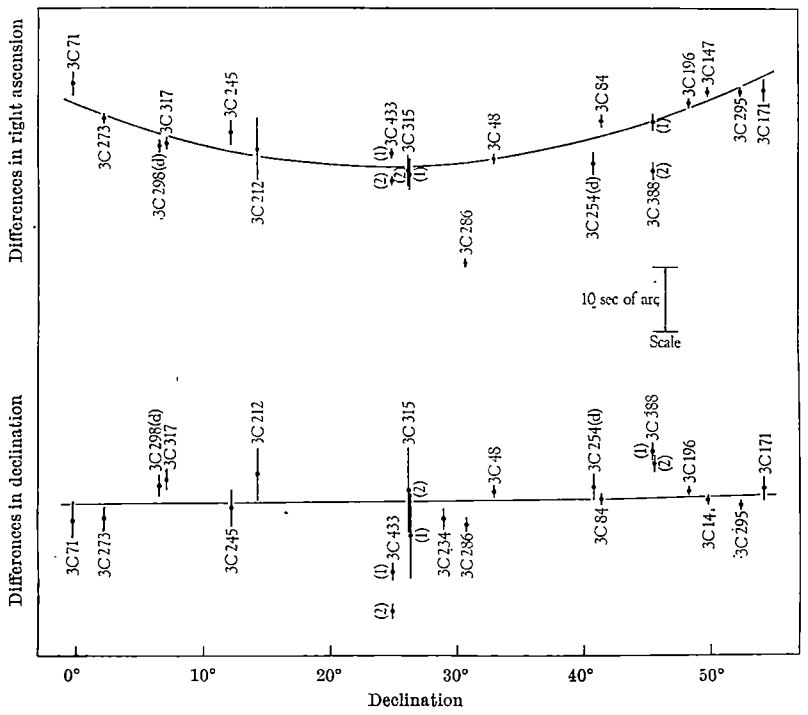

Fig. 1

It is clear that the calibration curves cannot be drawn through all the points and that certain discrepancies exist between the radio and optical positions. The two groups of sources at each end of the declination range appear to be self-consistent, and it is gratifying to find that the three radio occultation positions (3*C* 273, 3*C* 212 and 3*C* 245) fit the calibration curves. But at the centre of the declination range, where the agreement is rather less close, the determination of the calibration curves relies rather heavily on the true position of 3*C* 48. Despite this, it is unlikely that the calibration curves are in error by more than 1 sec of arc throughout the range.

Once the calibration curves have been determined then the true radio positions can be calculated. Table 1 gives a list of the differences between these radio positions and the corresponding optical or occultation positions, both in the right ascension direction, Δ(R.A.), and declination, Δ(Dec.). To appreciate the significance of these differences they should be compared with the tabulated estimates of the root mean square errors derived from the equipment stability, confusion and the fitting of the calibration curves. Errors for the occultation sources also include the uncertainties in the radio occultation positions. Significant differences, greater than 4 times the root mean square error, exist for four sources (3*C* 234, 3*C* 286, 3*C* 388 and 3*C* 433), but for the remaining sources the differences are within the experimental limits of error. As discussed later, the source 3*C* 298 would show a large discrepancy on the basis of a previous identification, but good agreement is now obtained on substituting a revised identification.

To obtain a good agreement for the majority of the sources indicates that the prime object of calibrating the interferometer has been achieved. It also means that in general the radio and optical positions agree to within about 2 sec of arc. The radio positions represent the 'radio centre of gravity' of the sources, many of which have angular diameters greater than 2 sec of arc. The angular diameters of the radio sources are given in Table 1, information being obtained from references 5–7 and from the present observations.

Table 1. Position Differences: Radio Minus Optical

3*C* No.	Right ascension Δ(R.A.)[a]	R.m.s. error	Diam.	Declination Δ(Dec.)	R.m.s. error	Diam	Optical object

388	−5·7	±1·6	30	+6·3	±1·5	25	Double galaxy[f]
433	−0·1	±1·1	15	−13·8	±1·5	30	Double galaxy[f]

Notes: (*a*) to convert to seconds of time, divide by 15 cos δ. (*b*) These differences are relative to the radio occultation positions and not to the optical. (*c*) The occultation measurements give a detailed picture of the structure of these sources. (*d*) Optical object '*d*' (3*C* 254) in Griffin's list[4]. (*e*) Optical object '*d*' (3*C* 298) in Griffin's list[4]. (*f*) The optical position has been taken as the mean of the two galaxies.

The results will now be discussed in greater detail, grouping the sources according to type.

3*C* 71 *and* 3*C* 84. These have been identified with the two Seyfert galaxies *NGC* 1068 and *NGC* 1275. Seyfert galaxies have very small bright nuclei, and in these two cases the agreement between radio and optical positions suggests that the nuclei are responsible for the radio emission. Although the radio diameters are larger than the optical nuclei they are less than the overall size of the optical galaxies. (3*C* 84 has also a radio halo of 26 min of arc diameter.)

3*C* 212, 3*C* 245 *and* 3*C* 273. The radio occultation and optical positions[2,3] are in good agreement, and these three sources have been identified as 'quasi-stellar' radio sources (Q.S.R.S.s). For the interferometer calibration the radio occultation positions have been used, after making allowance for the change with frequency in the relative amplitude of the two components in the case of 3*C* 273. The interferometer and occultation positions agree within the experimental limits.

3*C* 48, 3*C* 147, 3*C* 196 *and* 3*C* 286. These are the remaining sources in the list which have also been identified as Q.S.R.S.s, and the present observations show a good agreement between radio and optical positions, except for 3*C* 286. The discrepancy in right ascension in this case is 15·6 sec of arc (or 1·21 sec of time), which is well beyond the experimental limits. Earlier observations at 400 m spacing had shown a similar discrepancy[8].

The measurement of radio diameter of 3*C* 286 at 159 Mc/s (ref. 5) indicates a single source of less than 1·5 sec of arc diameter in the right ascension co-ordinate. So the puzzling picture is of a small diameter radio source, displaced from a quasi-stellar optical object. Before the previously claimed identification is dismissed as false it is interesting to examine 3*C* 273 again. This has two radio components separated by 20 sec of arc which are coincident with a very bright small object and the end of a faint jet. At 610 Mc/s the radio component associated with the jet is the strongest, and in fact the effective centre of gravity at this frequency is 12 sec of arc from the bright optical object. If the jet were appreciably fainter it would not be seen and the situation would then be similar to the case of 3*C* 286. Some clue to the problem of 3*C* 286 might be given by

accurate position measurements at other frequencies to find if the effective centre is frequency dependent as it is for 3*C* 273.

In general the Q.S.R.S.s have seemed likely to be the ideal optical position calibrators for radio astronomy; they have small radio angular diameters and the identifications can be established from their unusual optical spectra. But the evidence of a substantial discrepancy, for 2 sources out of 7, between the radio position and the position of the brightest optical component shows they must be treated with caution.

3C 254 and 3C 298. 3*C* 298 had previously been identified as a galaxy, but the optical position differs by 43 sec of arc in declination from the radio position given by these observations, and it seems very unlikely that this is the correct identification. No positive identification has been stated for 3*C* 254. Both these radio sources agree in position with stars listed by Griffin, the chance of finding an optical object of comparable brightness within the experimental limits being less than 1 in a 1,000. In addition, they have small radio diameters, which tend to support their possible identification as Q.S.R.S.s.

3C 171, 3C 234, 3C 295 and 3C 317. These are all single optical galaxies. 3*C* 171 and 3*C* 295 agree closely in optical and radio positions. 3*C* 295 is a double radio source with the components separated by only 4 sec of arc[9], probably symmetrically placed about the optical galaxy. Although 3*C* 234 agrees in declination it disagrees too widely in right ascension for inclusion in Fig. 1; but this is probably because the radio source is double, thus introducing a phase change and consequently a misleading position at this wide interferometer spacing. The agreement in declination for 3*C* 317 is not good but the difference is only about 25 per cent of the radio angular radius so is well within the limits of the radio source.

3C 315, 3C 388 and 3C 433. This group consists of double optical galaxies which are too close together to be resolved by the radio measurements. The separate optical positions have been plotted in Fig. 1, and it is clear that the identifications cannot be attributed to only one of the optical components. In view of this uncertainty the mean optical positions have been adopted in compiling Table 1. The agreement is not good, but the differences are still within the limits of the radio diameters. The diameter of 3*C* 315 in the declination direction is really too great to justify its inclusion in Table 1, although in this event the agreement is satisfactory. The large reduction in apparent amplitude at this wide spacing accounts for the abnormal error.

We conclude that the interferometer system at the Royal Radar Establishment has achieved a directional accuracy of about 2 sec of arc at 610 Mc/s in the measurements of the positions of radio sources in both angular co-ordinates. Calibration of the system by optically identified sources has proved a satisfactory procedure. For the majority of the chosen calibrator sources, the differences between optical and radio positions are within the estimated experimental errors. For three radio sources, 3*C* 234, 3*C* 388 and 3*C* 433, larger differences are explicable in terms of the angular size and complexity of the sources. The previous identification of the source 3*C* 286 with a quasi-stellar radio source may need modification, as a significant difference in positions has been revealed. It is also shown that the previous identification of 3*C* 298 with a galaxy has been erroneous. New identifications are suggested for this source and for 3*C* 254, and both of these appear to be quasi-stellar radio sources.

The calibration measurements described above now enable accurate positions of other sources to be determined. The analysis of observations of about 100 small diameter sources is nearly complete and will be published later.

POLYMER RESEARCH FOR INDUSTRY

By WENDY HEAP

Rubber and Plastics Research Association of Great Britain, Shawbury, Shrewsbury

ON September 29, Mr. P. C. Allen, president of the British Plastics Federation, opened the new laboratories and library of the Rubber and Plastics Research Association (RAPRA) at Shawbury, Shropshire. This important event resulted from the formation in 1960 of a joint Research Association for the Rubber and Plastics Industries developed from that of the British Rubber Manufacturers (RABRM), which had been formed as far back as 1919 and which moved to its present premises at Shawbury in 1954.

Research Association for the Plastics Industry

During the 1950's the rapidly developing plastics industry began to feel the need for a research association and the British Plastics Federation investigated the possibility. With the increasing use of flexible thermoplastics by the rubber industry, such as polyethylene and PVC, together with the fact that rubbers and plastics are both polymeric materials and so the approach to their basic physical and chemical properties is similar, it became apparent that the needs of the plastics industry could be most economically served by a joint research association with the rubber industry.

The existing establishment (RABRM) had much of the equipment and knowledge necessary for dealing with polymers and its interest in plastics had already been shown, for example, by the investigation in the mid-1950's of the frictional properties of PVC. To cope with the challenge brought by the plastics industry new buildings and more staff were acquired. The new laboratories house the main physics and chemistry departments and the process laboratory, while a new library wing has been built to accommodate much of the information department.

The increased scope of the work of the Association is reflected in the activities of all the departments. New scientific and technological research projects on plastics are arising by the side of those on rubbers, new testing methods are being examined, new problems are being overcome, and the scientific basis of the plastics industry is being strengthened.

Information Centre

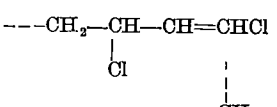
Although more than 50 per cent of the Association's annual income is spent on research, and the most exciting developments appear to occur in this field, the horizons

of the information department have also widened. The work of the Association in acting as an information centre for the industry which will help research workers and technologists to keep up to date with the literature in their fields is extremely valuable. To this end, RAPRA surveys the technical literature and publishes abstracts of all that is relevant. An efficient classification system makes all the information speedily available to deal with members' enquiries.

In a very far-seeing move information has been collected on flexible thermoplastics ever since it was published, thus there is already a considerable body of information on plastics in the library. As from 1965 the scope of the work of the information division will be extended to include rigid plastics.

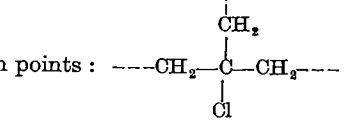
An arrangement with the British Plastics Federation has resulted in its information service discontinuing and in the transfer of its library facilities to RAPRA, where information will consequently be available to cover the whole field of rubbers and plastics. New developments resulting from this arrangement include the publication of two series of abstracts, one covering rubbers and the other plastics, and the adoption of a new classification system. This was necessary since the old system, while allowing the inclusion of thermoplastics, would not adequately cover the addition of thermosets. This unification of information on rubber and plastics makes an important contribution to the establishment of RAPRA as a central co-ordinating body for both industries.

Scientific Research



The fundamental scientific problems which are chosen to be investigated are those which can be expected to produce results which may eventually be of practical advantage to industry. This is necessitated by the very nature of the Association, and may be illustrated by some examples of present research projects.

Thermal degradation of PVC. Temperatures of up to 200° C are attained during the processing of PVC, which would result in degradation of the material if no stabilizer was added. Since little is known about the mechanism of degradation, the method of choosing stabilizers is mainly empirical. In an attempt to rationalize their use, and to develop cheaper and more efficient stabilizers, RAPRA is investigating why PVC does not possess the thermal properties expected from its ideal structure.



$$\text{------}(CH_2 \cdot CHCl)_n\text{------}$$

The effects of degradation, which are cross-linking and coloration of the material with evolution of hydrogen chloride, suggest that the reaction may be initiated by a chlorine atom. This, by attacking the chain, starts a 'zipper' reaction in which hydrogen chloride is eliminated. The resulting double bond system absorbs in the visible region of the spectrum producing the coloration.

The importance of the chlorine atom in this process makes its origin an obvious point of interest. In an attempt to find out where it originates consideration is being given to two possible points of weakness in the PVC chain—the chain ends :

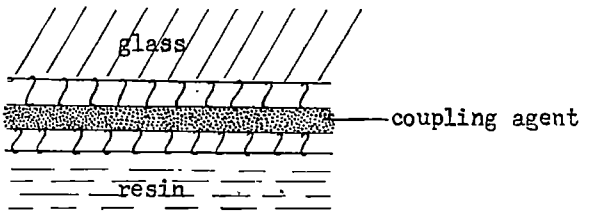
and the branch points :

The possibility that it is produced as a result of free radical impurities from the catalysts used in polymerization is not excluded.

The problem is being approached kinetically with measurements of viscosity, molecular weights, evolution of hydrogen chloride, and ultra-violet and visible absorption spectrophotometry. It is also hoped that model compounds of low molecular weight will be made which will contain a high proportion of possible weak points. From an examination of the degradation rates of these the required information about the chlorine atom should be obtained, although there will be difficulty in relating the results to the complex commercial materials available.

Glass-reinforced plastics. An increasing interest is being shown in glass-reinforced plastics for constructional work. Their major weakness, a loss of up to half their strength after prolonged contact with water, is unimportant in many cases since more material than is strictly necessary for the required strength must be used to obtain rigidity. If maximum strength for weight is required, as for example in the aircraft industry, this factor becomes a grave disadvantage.

Under contract to the Ministry of Aviation, RAPRA is investigating the nature and strength of the glass/resin interface, the failure of which contributes to the loss in strength (Fig. 1).



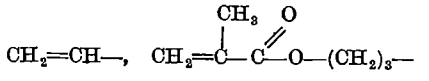


Fig. 1. Diagram of glass/resin interface

The glass fibre/polyester resin interface with and without coupling agents present has been studied by photomicrographs before and after boiling the specimen in water. The pattern of failure indicates that the presence of a coupling agent decelerates the water attack at the interface and that it is the coupling agent/resin bond, and not the coupling agent/glass bond, along which failure gradually occurs.

Since the presence of a coupling agent retards water attack its coverage of the glass is obviously important. This will be investigated by contact angle measurements on a glass filament in a drop of water. The presence of the coupling agent will be clearly indicated by this method since the difference between the contact angle for water and clear glass, water and covered filament is about 80°.

The silanes, R^1 Si $(OR)_3$, are usually used as coupling agents, the R^1 group to react with the resin, for example:

and the OR group, where R can be CH_3, C_2H_5, C_2H_4. OCH_3, to react with the glass. Various coupling agents must be investigated for good covering and bonding properties.

Electron microscopy. The acquisition of an electron microscope in the near future by the physics department will assist in their approach to the problems of the glass reinforced plastics. It is also an important asset to the rubber and plastics industries since it will give RAPRA increased facilities for research which few of the members possess for themselves.

Rheology of elasto-viscous fluids. Another instrument which RAPRA has recently obtained is the Weissenberg rheogoniometer which will be used to study the flow properties of polymer melts. The sample is sheared between a cone and a horizontal plate and two forces are measured, the resistance to rotation and the vertical force exerted on the plate, the latter effect being peculiar to elasto-viscous fluids.

By interpreting these results it is hoped to elucidate the present theories on the flow properties of elasto-viscous fluids. Two basic approaches are involved, that on the molecular level which although useful qualitatively is almost impossible to apply quantitatively, and that which treats the fluid as a continuous medium.

Three polymers which represent different systems are being studied: polystyrene, high-density polyethylene, and PVC. Since much of the processing of plastics, such as extruding and moulding, depends on their flow properties, this investigation should contribute directly to improving productivity.

Technological Research

The emphasis in the technology division is on practical assistance to the member firms, by helping them to increase the quality of their products and thus their productivity. Many industrial techniques are based only on practical experience and many of the problems arising are common to several firms. Frequently the technical services of the individual concerns have neither time nor resources to investigate the fundamental problems involved in processing, whereas the Association by tackling these can save duplication of effort by the individual firms and assist industry as a whole. Several projects which are being undertaken at the moment specifically for the plastics industry are: the moulding of polypropylene, an assessment of acrylonitrile/butadiene/styrene terpolymer, and an investigation into the effects of catalysts on the curing of polyester resins.

The Future

The Association's work on plastics is only just beginning, the research projects are in their early stages, and the information division is not yet besieged with enquiries on rigid plastics. Far from neglecting the needs of the rubber industry RAPRA has been stimulated by the new challenge to increase its endeavours in all aspects of its work. The scope of the Association's work has been extended, not to the detriment of the rubber industry but to the advantage of both the rubber and the plastics industries of the future.

SEX CHROMOSOMES AND SEX CHROMATIN*

By Dr. URSULA MITTWOCH
Galton Laboratory, University College, London

BEFORE defining the terms 'sex chromosomes' and 'sex chromatin', it is appropriate to quote the following remarks by the American embryologist, Frank Lillie[1]: "There is no such biological entity as sex. . . . What exists in Nature is a dimorphism within species into male and female individuals, which differ with respect to contrasting characters, for each of which in any given species we recognize a male and a female whether these characters be classed as of the biological, or psychological, or social order. Sex is not a force that produces these contrasts; it is merely a name for our total impression of the differences".

Although no attempt will be made to discontinue the use of the word 'sex', its meaning in the present context should be clearly stated: namely, the differences exhibited by male and female organisms within the same species.

There can be no doubt that the causes underlying the differences between the sexes is of fundamental importance in biology, for in many animals, as well as some plants, such differences are much more striking and far-reaching than are normally found in closely-related organisms.

Theoretically, the cause which brings about the divergence of the sexes might be either inherent in the organism or moulded on it by its environment, and until about sixty years ago there was no means of deciding which of the two alternatives was right. At the beginning of the present century the sex chromosomes were discovered, and by now their existence is common knowledge. It is known that the sex of an embryo is determined at the moment of fertilization, by the sex chromosomes which are contributed by the sperm of the father and the ovum of the mother. What is the evidence underlying this now commonplace statement?

During the last quarter of the nineteenth century it was found that when a cell is about to undergo division its nucleus resolves itself into a definite number of threads, which have a special affinity for certain dyes, and for this reason were given the name 'chromosomes', or 'coloured bodies'[2]. Our knowledge of sex chromosomes is based very largely on discoveries made on insects. In 1891, Henking[3] studied the chromosomes during the development of spermatozoa in a bug, *Pyrrhocoris apterus*, and found one of the chromosomes behaved differently from the rest. This chromosome was more darkly stained and moved at a different rate from the others. At the end of cell division, this chromosome passed undivided into one of the daughter nuclei, with the result that only half the spermatozoa finally contained this chromosome. Henking arrived at no very clear idea about the nature of this chromosome and in his drawings he merely labelled it with an *X*. The idea that this chromosome might be concerned with the determination of sex was first formulated by McClung in 1902 (ref. 4); McClung suggested that the two types of spermatozoa, which were produced in equal numbers, would give rise to two equal classes of individuals of different sex. The truth of this hypothesis was proved within the next few years, particularly by the cytologist, E. B. Wilson[5]. Wilson showed that, in a variety of insects, the males produced two types of spermatozoa, which differed in their chromosome constitution, that is to say, half the sperm contained an *X*-chromosome, while the other half lacked it; but all the eggs of the females were alike in this respect, since they all contained an *X*-chromosome. Wilson further showed that different insects could be divided into two classes, namely those in which the *X*-chromosome was present on its own, and a second group, in which the *X*-chromosome was partnered by another, but different-looking, chromosome, which was called the *Y*-chromosome. This second group of insects, therefore, produces two types of spermatozoa, those containing an *X*-chromosome and those containing a *Y*-chromosome; on fertilization these give rise to female and male offspring, respectively. Since the *X*- and the *Y*-chromosome differ in males and females they are called 'sex chromosomes'[6]; all the other chromosomes are the same in both sexes and are called 'autosomes'[7].

Evidence for the existence of an *X*- and a *Y*-chromosome in human males was put forward by Painter in 1921 (ref. 8), but final agreement on this matter could not be reached until thirty-five years later[9,10] when, as a result of improved techniques in tissue culture and cytology, the establishment of the chromosome constitution in man became a commonplace investigation.

The unequivocal demonstration of the sex chromosomes in man is a remarkable discovery made in recent years; but there have been others equally remarkable. The

* Substance of a lunch-hour lecture delivered in University College, London, on November 10.

chromosomes can be seen only in cells which are dividing; but in 1949 Barr and Bertram[11] announced that they had found a sex difference in the nuclei of the neurones of the cat, and soon afterwards it was shown that such a sex difference could be demonstrated in many types of cells and in many species, including man[12–14]. It consists of a small, very intensely staining body, which is most commonly situated at the periphery of the nucleus, just inside the nuclear membrane. Such a body is present only in females and is absent in cells from males and has been called the sex chromatin body. There is now conclusive evidence, which will be elaborated later, that the sex chromatin consists of one of the two *X*-chromosomes in a heavily condensed form[15]. Whereas the chromosomes can be seen only in dividing cells, the sex chromatin can be seen only in non-dividing or so-called 'interphase' nuclei. The simplest way of demonstrating sex chromatin is by scraping off some cells from the inside of the cheek, where the sex chromatin will be seen in cells from females but not from males.

Yet another sex difference was described by Davidson and Smith[16] in polymorphonuclear leucocytes of the blood. Some of these nuclei in cells from females bear a special appendage, which is known as a drumstick. A drumstick consists of a darkly staining head which is attached to the nucleus by a stalk. Drumsticks do not occur in blood cells from males, and it is now known that they also represent one of the two *X*-chromosomes of a female[17,18]. Drumsticks are, therefore, equivalent to sex chromatin, and their distinctive shape is merely a reflexion of the peculiar shape of the nuclei of the polymorphonuclear leucocytes.

Our knowledge of sex chromosomes is thus based on three separate events: (1) the discovery of the sex chromosomes at the beginning of the century; (2) the discovery of sex chromatin which began in the late 1940's; (3) the unequivocal demonstration of the sex chromosomes in man, which happened in the second half of the 1950's. It may be of interest to note that the discovery of the sex chromosomes in insects was directly related to the perfection of the microscope, that is to say with the invention of apochromatic and oil immersion lenses, during the 1880's (ref. 19). By contrast, the demonstration of the sex chromosomes in man had no connexion with any advances in scientific technology; rather, it was made possible by certain improvements in scientific cookery, as a result of which the chromosomes, instead of being glued together in an indigestible lump, appeared nicely separated, like the grains of rice which has been properly cooked. The discovery of sex chromatin did not even require any advance in cookery. In their first publication on this subject, Barr and Bertram[11] wrote: "It appears not to be generally known that the sex of a somatic cell as highly differentiated as a neurone may be detected with no more elaborate equipment than a compound microscope following staining of the tissue with the routine Nissl method". When the discovery of drumsticks was announced in 1954 (ref. 12), people could scarcely believe that such an obvious structure could have been overlooked for so long, in view of the large numbers of blood films which are examined daily both in medical practice and in research.

These discoveries have already had a very profound effect in clinical medicine as well as on our knowledge of the theoretical aspects of chromosomes. To begin with the more practical aspect, it is now well known that in a small proportion of cases the process of sex determination is faulty, so that persons with an abnormal sex chromosome constitution result. Thus a person with two *X*- and one *Y*-chromosome suffers from Klinefelter's syndrome[20]. Such patients are phenotypically male, but the testes remain small and spermatogenesis does not occur. By contrast, a patient having only a single *X*- and no *Y*-chromosome (Turner's syndrome)[21] is phenotypically female, having rudimentary ovaries in which oogenesis does not occur. Patients with three *X*-chromosomes[22] are also females; they may have various abnormalities but some are essentially normal and fertile.

The mere existence of patients with abnormal sex chromosomes has given us some very important information about the nature of the sex chromosomes. If we had nothing but normal males and females, it would be impossible to know whether male development is due to the presence of only a single *X*-chromosome or the presence of a *Y*-chromosome; and, similarly, whether female development is brought about by the presence of two *X*-chromosomes or the absence of a *Y*-chromosome. It is now clear that a single *X*-chromosome in the absence of a *Y*-chromosome gives rise to a female, while two *X*-chromosomes in conjunction with a *Y*-chromosome cause development to be male. This proves that in man the *Y*-chromosome is essential in ensuring male development. Nevertheless, if a normal male is to be formed, the *Y*-chromosome must be associated with a single *X*-chromosone; similarly to ensure normal female development two *X*-chromosomes are required.

Furthermore, these patients have clarified our ideas about the nature of sex chromatin. All patients with abnormal *X*-chromosomes have a characteristic sex chromatin pattern, and, indeed, the sex chromatin test is of considerable value in diagnosing such patients. Patients with Turner's syndrome have no sex chromatin, although they are female; patients with Klinefelter's syndrome have sex chromatin, although they are male. Persons with three *X*-chromosomes have two sex chromatin bodies. More rarely, patients are found with four *X*-chromosomes and even five *X*-chromosomes[23,24] and they have three and four sex chromatin bodies. It is clear that basically sex chromatin has no connexion with sex, or male or female development, but merely reflects the number of *X*-chromosomes present in the nucleus. If only one *X*-chromosome is present, no sex chromatin body is formed, but any *X*-chromosomes in addition to the first may form a sex chromatin body.

The relationship of sex chromatin to the *X*-chromosomes has been strikingly confirmed as a result of labelling chromosomes with radioactive markers. Although the chromosomes can be seen only during cell division, they synthesize their DNA in the interphase prior to cell division, when the chromosomes are dispersed and invisible. One of the necessary components of DNA synthesis is thymidine and, by offering the cells radioactive thymidine, the time at which this substance is taken up can be accurately determined. In this way it has been found that in normal females one of the *X*-chromosomes synthesizes its DNA later than the other chromosomes[25]. Such a late replicating *X*-chromosome is not found in normal males; it is, however, present in males with Klinefelter's syndrome who have two *X*-chromosomes. Moreover, in patients with multiple *X*-chromosomes, the number of late-replicating *X*-chromosomes is equal to the number of *X*-chromosomes minus one[26]—just like the number of sex chromatin bodies.

There is evidence, too, that the *Y*-chromosome replicates late[27], but the *Y*-chromosome is too small to be seen as a separate body in interphase nuclei. By contrast, the single *X*-chromosome of males and one of the *X*-chromosomes of females replicate at the same time as the autosomes—indeed, it might be justified to call them autosomes, for they behave like autosomes and they are the same in males and females.

Now that the origin of sex chromatin has been explained, its existence prompts the following rather naïve question: Why are sex chromosomes different from all other chromosomes? All other chromosomes replicate their DNA more or less in unison, but the sex chromosomes replicate late. All other chromosomes become dispersed and invisible during interphase; but the sex chromosomes remain compact and in a discrete body. Any answers to these questions must at present be speculative—even though the problem is by no means new.

Chromosomes and parts of chromosomes which thus behave differently from the majority are said to be composed of 'heterochromatin'[28], in contrast to all the rest of the chromosomes which are made up of 'euchromatin'[28]. The subject of heterochromatin has had a somewhat unhappy childhood, but there is every prospect that its future will be brighter. Before this subject is discussed further, brief mention should be made of sex-linked genes.

For practical purposes, sex-linked genes are those borne on the *X*-chromosome. In man, the two best-known sex-linked genes are those for colour blindness and hæmophilia; they are characterized by a peculiar mode of inheritance, which is governed by the mode of transmission of the *X*-chromosome. On the human *X*-chromosome there are many other genes, apart from colour blindness and hæmophilia, which are inherited in essentially the same way. In fact, more than 50 genes have been described the location of which on the *X*-chromosome is known or postulated with varying degrees of probability[29]. They include genes for an enzyme deficiency causing hæmolytic crises, for a type of muscular dystrophy, for eye diseases as well as a normal blood-group variant. None of the genes appears to affect sex determination although some sex-linked genes may interfere with normal sex development. The absence of a gene affecting sex determination is even more significant in *Drosophila*. Here, more than one hundred genes are known to be located on the *X*-chromosomes, and their actual place on the chromosome is known with great accuracy[30]. It is also known that the *X*-chromosome in *Drosophila* determines female development[31]. An intensive search has been made to try to identify such female-determining genes in *Drosophila*[32]. As Goldschmidt[33] wrote: "The first unequivocal result is that no single female sex gene could be located"; and the most obvious conclusion is that such sex genes do not exist.

The *X*-chromosome, therefore, fulfils two functions, namely, to ensure normal female development and, secondly, to carry a large number of genes affecting a variety of characters. For normal female development, the presence of two *X*-chromosomes is required; and in mammals this is determined in early embryonic life. Beyond this stage it is likely that one *X*-chromosome is sufficient to carry out the functions of the genes, since this function is adequately fulfilled by the single *X*-chromosomes of males. It has been postulated by Lyon[34–36] that it may be the function of the sex chromatin to put the second *X*-chromosomes of females out of action by curling it up into a tight bag. This hypothesis is in agreement with traditional views that heterochromatin is genetically relatively inactive. At present, much work is in progress trying to test the Lyon hypothesis and to see to what extent it is applicable to human cells.

Finally, how do the sex chromosomes carry out their task of determining whether an organism is to develop into a male or female? Nowadays it is a commonplace notion that the chromosomes act via the genes which they carry, and it is one of the triumphs of present-day biochemistry to have discovered the pathway from the DNA of the gene to the protein of the gene product. There can be little doubt that characters such as hæmophilia and colour blindness, and all the other characters which are determined by genes borne on the *X*-chromosome, will be found to be controlled in this manner. However, there seems to be strong evidence that the inheritance of sex may follow a different route, which is controlled not by individual genes but by whole chromosomes or at least large parts of chromosomes. This conclusion is based on three sets of facts: (1) the different behaviour of the sex chromosomes; (2) the absence of genes determining sex; (3) the apparent absence of a specific substance which differentiates the sexes; for the sex hormones, which are so powerful in promoting sexual differentiation, act not by their presence or absence but by the relative proportion with which they occur in either sex. It is a remarkable fact that the human testis produces, in addition to androgens, also small amounts of œstrogen, while the ovary is capable of secreting androgens[37]. There appears to be every indication that the basic difference between the sexes is of a quantitative, rather than a qualitative, nature.

Commoner[38] has recently put forward the view that DNA participates in two systems of genetic control. One of these systems accounts for the characters showing typical Mendelian inheritance, which may be assumed to be due to specific biochemical differences. This system is localized in the euchromatic regions of the chromosomes. In the second system, DNA gives rise to the genetic regulation of certain metabolic processes, thus determining quantitative differences such as cell size and the rate of oxidative metabolism. This second system is assumed to be localized in the heterochromatic portions of the chromosomes. It would appear that the sex chromosome mechanism of mammals provides the most striking example of this type of dual genetic control. The first *X*-chromosome is euchromatic and presumably exerts its control via the sex-linked genes which it carries. The second *X*-chromosome is heterochromatic (whether this is so in every cell is not certain) and ensures normal female development; but, if present in addition to a *Y*-chromosome, this type of *X*-chromosome precludes normal male development.

The age-old question of what determines the sex of an individual has been formally answered in terms of the sex chromosome mechanism. The subject now provides a challenge to discover the biological realities underlying this mechanism—and a promise that progress in the years ahead will be at least as rewarding as that which we have just witnessed.

OBITUARY

Prof. I. A. Preece

PROF. I. A. PREECE, who died suddenly at the age of fifty-seven on August 12 while on holiday in Switzerland, was a leading figure in the world of brewing science. Born in Birmingham in 1907, he graduated at the University of Birmingham in 1927 and was later awarded the degree of D.Sc. (Birmingham) in 1950. Meanwhile, following three years on the staff of the Department of Biochemistry in Birmingham, he was successively lecturer (1931–45), head of the Department of Brewing (1950) and professor in the Department of Brewing and Applied Biochemistry (1950–64) in the Heriot-Watt College, Edinburgh.

Prof. Preece found in brewing, and particularly in malting, a fertile field for his early and abiding interests in plant biochemistry. Structural problems in connexion with the carbohydrates of barley and of malt led him to undertake with exemplary precision work on numerous difficult topics such as the hemicelluloses and phytin, on the nature and function of the amylases, and on proteolytic and cytolytic enzymes. None of these subjects would attract anyone easily repulsed by difficulties, for all abounded in preparative and analytical problems. Nevertheless, many of Preece's papers, especially those dealing with the cytases, phosphatases and amylases of germinating barley, are clearly destined to become indispensable to future advances. His interests extended, however, far beyond his personal research. Prof. Preece was a gifted teacher, as evidenced by his postgraduate students, who came from many parts of the world, and by many audiences at home and abroad, who knew him as an expert lecturer whose lectures were, quite apart from their invariably substantial scientific content, always memorable for their lucidity and nice distinction of language.

Among many professional and educational activities, Prof. Preece played a prominent part in the Royal Institute of Chemistry and the Institute of Brewing. He had since 1949 been editor of the *Journal of the Institute of Brewing*, the high quality of which over recent years owes much to his meticulous standards. Prof. Preece was elected a Fellow of the Royal Society of Edinburgh in 1949 and early in 1964 was awarded the Horace Brown Medal as the highest honour which the Institute of Brewing could bestow. Perhaps, however, his most effective memorial is to be found in the large number of brewers whom he trained. Preece probably more than anyone else, at least in the English-speaking world, inspired them with the possibilities of scientific understanding and control in what is in some respects still a markedly traditional industry. A. H. COOK

NEWS and VIEWS

The Royal Society: Officers for 1964

AT the Anniversary Meeting held on November 30, Sir Howard Florey, Provost of The Queen's College, Oxford, and formerly professor of pathology in the University of Oxford, was re-elected president of the Royal Society. The other officers re-elected for the ensuing year were: *Treasurer*, Lord Fleck, formerly chairman of Imperial Chemical Industries, Ltd.; *Physical Secretary*, Sir William Hodge, Master of Pembroke College and Lowndean professor of astronomy and geometry in the University of Cambridge; *Biological Secretary*, Prof. A. A. Miles, director of the Lister Institute and professor of experimental pathology in the University of London; *Foreign Secretary*, Sir Patrick Linstead, Rector of the Imperial College of Science and Technology. The other members of Council elected (or re-elected, marked *) were: Sir Eric Ashby, Master of Clare College, Cambridge; Prof. D. H. R. Barton, professor of organic chemistry in the Imperial College of Science and Technology; *Prof. P. M. S. Blackett, professor of physics in the Imperial College of Science and Technology; Sir William Cook, deputy chief scientific adviser, Ministry of Defence; *Prof. A. H. Cottrell, Goldsmiths' professor of metallurgy in the University of Cambridge; *Prof. C. A. Coulson, Rouse Ball professor of mathematics in the University of Oxford; Prof. F. S. Dainton, professor of physical chemistry in the University of Leeds; Prof. K. C. Dunham, professor of geology in the University of Durham; Prof. G. W. Harris, Dr. Lee's professor of anatomy in the University of Oxford; Prof. W. O. James, professor of botany in the Imperial College of Science and Technology; *Prof. B. Katz, professor of biophysics in University College, London; Sir Hans Krebs, Whitley professor of biochemistry in the University of Oxford; Dr. N. Kurti, reader in physics in the University of Oxford, and Senior Research Fellow, Brasenose College; *Sir Bernard Lovell, professor of radio astronomy in the University of Manchester and director of the Nuffield Radio Astronomy Laboratories, Jodrell Bank; Prof. K. Mather, professor of genetics in the University of Birmingham and Vice-Chancellor elect of the University of Southampton; *Prof. J. W. S. Pringle, Linacre professor of zoology in the University of Oxford.

Crystallography in the University of Birmingham: Prof. A. J. C. Wilson, F.R.S.

PROF. A. J. C. WILSON, at present professor of physics in the University College of South Wales and Monmouthshire, Cardiff, has been appointed to the newly established chair of crystallography in the Department of Physics in the University of Birmingham. Born and educated in Canada, Prof. Wilson was engaged in research at the Massachusetts Institute of Technology before joining the Cavendish Laboratory, Cambridge; he holds Ph.D. degrees of both the Massachusetts Institute of Technology and the University of Cambridge. In 1945 he moved to University College, Cardiff, and became head of the physics department there in 1954. Prof. Wilson is well known for his distinguished contributions to X-ray analysis in the elucidation of the atomic structure of crystals. He was elected a Fellow of the Royal Society of London in 1963. His new appointment will take effect from October 1, 1965.

Aeronautics and Astronautics in the University of Southampton: Prof. G. M. Lilley

PROF. G. M. LILLEY, who has held the chair of experimental fluid mechanics in the Department of Aerodynamics at the College of Aeronautics, Cranfield, since January 1963, has been appointed to the chair of aeronautics and astronautics at the University of Southampton in succession to Prof. E. J. Richards, who has recently been appointed to the new chair of applied acoustics and to the directorship of the Institute of Sound and Vibration Research at Southampton. Prof. Lilley, a graduate of the University of London, has been a resident member of

the teaching staff at Cranfield since 1946. First appointed as a lecturer in the Department of Aerodynamics, he was promoted to senior lecturer in 1950 and to deputy head of the Department in 1955. He has played a major part in the development of the Aerodynamics Laboratory and its research activities. Prof. Lilley is a recognized authority on turbulent flow and its relationship to aerodynamic noise and is chairman of the Noise Research Committee of the Aeronautical Research Council. Other fields of research in which Prof. Lilley has made important contributions include hypersonic flow and its related problems, boundary layers, the design and operation of wind-tunnels and their associated instrumentation and problems of fluid motion. He is a Fellow of the Royal Aeronautical Society, and a member of the Society's Man-Powered Aircraft Group Committee.

Agricultural Research Council Food Research Institute, Norwich: Prof. S. R. Elsden

Prof. S. R. Elsden, professor of microbiology in the University of Sheffield and honorary director of the Agricultural Research Council's Unit of Microbiology, has been appointed the first director of the Agricultural Research Council's new Food Research Institute at Norwich; he will take up his appointment on July 1. Prof. Elsden graduated from Cambridge in 1936 with first-class honours in Part II of the Natural Sciences Tripos in biochemistry. In 1937 he was appointed assistant lecturer and, later, lecturer in physiology in the University of Edinburgh. In 1943 he returned to Cambridge as a member of the scientific staff of the Agricultural Research Council's Unit of Animal Physiology in the Department of Physiology. Prof. Elsden's early research dealt with bacterial fermentation, and he was much influenced by the work of the late Marjory Stephenson. He was the first worker to demonstrate that the formation of succinic acid in the fermentation of glucose by *Escherichia coli* is dependent on the presence of carbon dioxide. His research in the Unit of Animal Physiology was concerned mainly with rumen bacteria and he has retained an interest in these organisms, especially in their fatty acid metabolism. In 1946 he went to the United States for a year to work with Prof. C. B. van Niel and Prof. H. A. Barker of the University of California. This visit stimulated him to direct his attention to the metabolism of photosynthetic bacteria. In 1948, Prof. Elsden was appointed senior lecturer in microbiology in the Department of Bacteriology in the University of Sheffield, and in 1952 he was placed in charge of the new Department of Microbiology in the University and appointed honorary director of the Agricultural Research Council's Unit of Microbiology. He held an exchange professorship in the Department of Bacteriology of the University of Illinois for six months during 1956, and was appointed West Riding professor of microbiology in the University of Sheffield in 1959. At Sheffield Prof. Elsden has extended his researches into the physiology of microbial growth, and particularly into the relationship between growth and adenosine triphosphate production. He has built up a strong team of microbiologists some of whom will go with him to Norwich.

Science in Parliament: Cancer Research

In a written answer in the House of Commons on November 23, the Secretary of State for Education and Science, Mr. M. Stewart, said that the Medical Research Council expected to spend about £1,029,000 on cancer research, excluding capital expenditure. The Government supported cancer research by financial grants to universities and medical schools through the University Grants Committee and at hospitals within the National Health Service. Much basic research which could throw light on this disease was supported from public funds, while in 1963 the British Empire Cancer Campaign for Research approved expenditure of £1,314,787 on research and related activities, and the Imperial Cancer Research Fund in 1962–63 expended £1,232,000.

Under-water Research

In reply to a question in the House of Lords on November 26, Lord Shackleton stated that there was already very close co-operation between the Ministry of Defence, the Fisheries Departments and other agencies and other Government-supported bodies concerned with research under water. Pressed further for an assurance that an effective co-ordinating body would be set up, Lord Shackleton said that he assumed that Lord Wakefield was referring particularly to diving techniques, which could be used in many fields and especially for research purposes. He questioned whether this was a field in which the Government should attempt to co-ordinate all activities, but it would be interested to receive any representations from Lord Wakefield or from the British Sub-Aqua Club, to which the Department of Education and Science made a direct subvention of £1,500.

Overseas Research and Development

In a written answer in the House of Commons on November 25, the Minister of Overseas Development, Mrs. B. Castle, announced that the targets for sending volunteers overseas in 1965 would be increased from 1,000 to 1,200 for graduates and from 300 to 400 for school-leavers and apprentices. The Government would, as already arranged, pay 75 per cent of the British costs of this programme, which were estimated at £900,000.

Industrial Research and Development

In a written statement in the House of Commons on November 26, the Prime Minister stated that the Minister of Technology had the general responsibility of guiding and stimulating a major effort to bring advanced technology and new processes into British industry. The methods used would include an intensified use of the appropriate research stations and of the National Research Development Corporation, civil development contracts, and investigations to identify particular industries or parts of industries suitable for action. The Minister would consider what changes might be made in the arrangements for procurement financed by public funds to contribute to the promotion of technological advance. He would initiate investigations of the status of the engineering profession. All these tasks would be undertaken in close consultation with the other Departments concerned.

As already announced, the Minister would be responsible for the Atomic Energy Authority and the National Research Development Corporation and would take over elements of the Department of Scientific and Industrial Research headquarters which have been concerned with research and technical development in industry. The Ministry of Technology would in future be the sponsoring department for the machine tools, electronics, telecommunications and computer industries. Close relations would be established with the British Standards Institution and the Ministry would support its work in the engineering field. Mr. Wilson added that in the Science and Technology Bill now before Parliament it was proposed to extend the powers of the Atomic Energy Authority to permit the Authority to undertake research and development outside the nuclear field, and legislative action would also be taken to increase the powers and resources of the National Research Development Corporation.

Research Councils

The statement on November 26 was complemented by a written answer given on the same day by the Secretary of State for Education and Science outlining the arrangements that would be made following the enactment of the Science and Technology Bill. The Secretary of State

for Education and Science would be responsible for the Research Councils and for the support of research in the universities. The Research Councils would be financed by the Ministry, which would be advised on finance by the Council on Scientific Policy. The Natural Environment Research Council, which would be created, would support research in the earth sciences and ecology, taking over the Nature Conservancy, the Geological Survey and Museum, the Hydrology Research Unit, the National Institute of Oceanography, and the functions of the Development Commission in relation to marine and freshwater biology and fishery research. Recognizing that the Minister of Land and Natural Resources would be closely interested in some of the work of this Research Council, Mr. Stewart undertook to consult him and other Ministers interested on certain appointments in this organization.

A new Science Research Council would also be created, taking over the functions of the Department of Scientific and Industrial Research in respect of research grants and postgraduate training awards not within the fields of the other Councils. It would also take over the activities of the National Institute for Research in Nuclear Science and would also be responsible for the Radio Research Station, the Royal Observatories, and the scientific space research programme, and for advising on relations with the Centre for European Nuclear Research and with the European Space Research Organization. Except for the Road Research Laboratory, which would become a responsibility of the Minister of Transport, and the Tropical Products Institute, which would be the responsibility of the Minister of Overseas Development, the remaining stations of the Department of Scientific and Industrial Research would become a responsibility of the Minister of Technology. The other functions of the Department would be divided between the Ministry of Education and Science and the Ministry of Technology, which would take over information functions concerned with disseminating technical information in industry. The National Lending Library for Science and Technology, and the more general information work and the control of the Scientific Attachés, would come under the Ministry of Education and Science.

National Physical Laboratory and the National Chemical Laboratory

Mr. Stewart stated that the decision to place the National Physical Laboratory under the Ministry of Technology was reached after careful consideration and discussion with the President of the Royal Society. It is intended to combine the National Chemical Laboratory with the National Physical Laboratory under one director, and arrangements have been concluded with the Royal Society which will continue the long-standing close association between the Laboratory and the Royal Society.

Post-doctoral Research at the Smithsonian Institution, Washington

The U.S. National Academy of Sciences and the Smithsonian Institution have announced a joint programme to extend postdoctoral research opportunities to visiting investigators from other institutions in the United States and abroad. Under the programme, which begins in 1965, 12 visiting research appointments tenable at the Institution have been established in the following departments: *History of Science and Engineering*, including research in the history of science and technology within the new Museum of History and Technology; *Biological Sciences*, including research in anthropology, systematic biology, mineral sciences, and ecology within the Division of Radiation and Organisms, Museum of Natural History, National Zoological Park, and the Canal Zone Biological Area; *Physical Sciences*, including research in the Smithsonian Astrophysical Observatory at Cambridge, Mass. Applications for the programme at the Smithsonian Astrophysical Observatory, with tenure beginning in January 1965, are immediately available. Brochures describing the 12 separate associateships in detail and applications for the programme at the Smithsonian can be obtained from the Fellowship Office of the National Academy of Sciences–National Research Council, 2101 Constitution Avenue, N.W., Washington, D.C.

The Indian Brain Research Association

The Indian Brain Research Association, an organization of scientists actively associated with research and professions relating to the brain, has recently been formed. This Association, it is hoped, will meet the long-felt need for an organization aimed at unifying research and professional activities within their diverse fields. The Association is a non-profit, scientific and educational organization, and will serve as a platform for the interchange of ideas and results concerning brain research by means of discussions, symposia, meetings, publications, etc. All branches of neurosciences are open to membership of the Association. The headquarters is located at the Department of Applied Chemistry, University College of Science and Technology, Calcutta-9. At present a steering committee, headed by Dr. B. Mukerji, director, Chittaranjan National Cancer Research Centre, Calcutta, performs the executive functions. A bi-monthly bulletin of the Association, *Brain News*, will help to keep members abreast of recent discoveries and techniques in neurological fields, with emphasis on the latest developments in brain research, teaching and profession. Articles of special interest and papers presented in the Association's meetings and seminars will also be featured.

Wellcome Trust Grant for the Royal Society of Medicine Library

A grant of £50,000 has been made by the Wellcome Trust to the Royal Society of Medicine in order to enable the Society to provide new storage space for its Library—probably the most comprehensive medical collection in Europe. Space will be made available in the basement of Chandos House, an Adam mansion in Queen Anne Street, London, W.1, of which the Society has purchased a 99-year lease. The Society's Library is noted for its collection of medical journals, built up in the nineteenth century and now totalling more than 2,000 titles. The growth of the Library is such that about 150 yards of shelving are filled every year. About 50,000 volumes each year go out on loan from the Library, which is open 12 hours a day for reference by Fellows of the Society. During 1952–53 a grant of £125,000 from the Wellcome Trust enabled the Society to extend its present building and to provide an extra floor for library use.

Peaceful Uses of Outer Space

A review of national and co-operative international space activities has been issued by the Committee on the Peaceful Uses of Outer Space of the United Nations General Assembly (*Review of National and Co-operative International Space Activities*. Pp. 114. New York: United Nations, 1964). Such activities are listed for 37 countries, 17 of which are represented on the Committee itself, while 4 others have other international commitments in this field. Detailed information on outer-space research activities is not included, but fairly full information is given, particularly for the U.S.S.R., the United Kingdom and the United States.

Tropical Medicine

For many centuries the term 'tropical medicine' suggested something exotic: strange diseases caused by strange parasites producing strange clinical manifestations. During the past two decades this outlook has been entirely revolutionized, and it has now come to be realized

that tropical medicine is merely a facet of general medicine and that disease recognizes neither colour nor race. Geographical factors undoubtedly play a part, but, fundamentally, the sick African and the sick Asian respond to the vicissitudes of life in the same way as the sick Caucasian. Equally important in emphasizing the universality of disease, from the British practitioner's point of view, has been the increasing number of African, Asian and West Indian immigrants settling in Britain, and to-day practitioners are encountering diseases entirely new to them. It is mainly for these reasons that a symposium in *The Practitioner* has been devoted to "Tropical Medicine" (193, No. 1154; August 1964). The symposium presents an authoritative review of the more important aspects of the subject. As modern methods of transport speed up the comings and goings of the inhabitants of all five continents, it is incumbent on every practitioner to be aware of this world picture of medicine.

Training Courses in Concrete

THE programme of residential training courses offered by the Cement and Concrete Association in 1965 varies little from that of the previous year (*Training Courses in Concrete—Prospectus and Programme for 1965*. Pp. 15. London : Cement and Concrete Association, 1964). The *Prospectus and Programme for 1965* now available lists the various courses offered at different times spread throughout the year; it includes instruction on many aspects of concrete technology, among which may be mentioned: concrete roads and cement-stabilized bases for general foremen, clerks of works and highway superintendents; concrete for engineers; concrete mix design and quality control for engineers; ultimate load design; design of reinforced and pre-stressed concrete bridge decks (in two parts, including a combined course and overseas visit); concrete roads and cement-stabilized bases for engineers; concrete construction for local government engineers and surveyors; formwork for engineers; concrete for architects; concrete products; concrete technology for suppliers of ready-mixed concrete; and aggregates for concrete. The educational and technical value of these training courses, ever since their inception, has been widely appreciated, as is attested by the fact that the demand for places offered during 1964 was such that as many applications had to be refused as were accepted. This is one of the reasons why the programme for 1965 is following closely the 1964 pattern: to give those who could not be admitted in 1964 an opportunity to attend in 1965. With an eye to the future, the decision has been made to build a new Training Centre on a neighbouring estate recently acquired by the Association, capable of housing more than twice the number of applicants at present catered for. It is anticipated that the new premises, on which work has already begun, will be ready for use in 1966. As a result of this move, the residential facilities at the Centre will be greatly improved; two fully equipped lecture theatres and new laboratories will be built, with greatly increased facilities for carrying out the experimental work which is a vital part of most of the courses.

Crystallographic Course in Peking

A SCHOOL in "Experimental X-ray Crystallography" was held, under the auspices of the Scientific and Technical Association of the Peoples' Republic of China, in the recently built Conference House, Peking, during November 2–14. About 70 students attended the lectures and demonstrations and a further 60 attended the lectures only. The course was similar to that held in Cambridge during August 31–September 2 (*Nature*, 204, 731; 1964). The lectures, originally written in English by Dr. W. A. Wooster, had been translated and were delivered in Chinese by members of the staffs of various universities and academic institutes. The translated lectures were printed together with all diagrams, photographs and charts, and a complete set of this material was issued to each student before the course began. The lecturers amplified the original text, where they thought it would help the students, and the style of lecturing showed a good understanding of the students' needs. In the practical demonstrations, Dr. Nora Wooster and Mr. A. M. Wooster assisted, and, with the aid of interpreters, the language difficulty did not prove serious. The students came not only from Peking but also from distant parts of China. In addition to the 20 lectures and demonstrations there were seven sessions of questions put by the students—the day's work started at 8 a.m. and continued through to 6 p.m. The large Conference House, Peking, was completed in four months during this summer. It had a well-equipped lecture theatre, and numerous rooms were made available for the practical demonstrations. Apparatus for demonstration in the lectures was lent by many institutes, and the willing co-operation shown by so many professors and research workers was the basis of the successful organization of the course, under Prof. Wu Chien-chang (Institute of Physics, Peking).

The Jean Julliard Hæmostasis Prize

AN annual prize of 2,000 French francs is being offered by the Editor of the journal *Hémostase* in memory of one of its founders, the late Jean Julliard. The prize is intended to honour and to assist a young research worker who submits an original paper on an experimental or clinical subject relating to hæmostasis, coagulation, hæmorrhagic disease or thrombosis. In exceptional cases the award may be shared. Candidates, who may be of any nationality, must be less than 35 years old. Manuscripts may be written in French or English and the prizewinning entry will be published in the journal. Further information can be obtained from Editions S.P.E.I., Département Médical, 14, rue Drouot, Paris-9ème.

Announcements

DR. ROBERT GLEN, assistant deputy minister (research) of the Canada Department of Agriculture, has been awarded the 1964 Gold Medal of the Entomological Society of Canada, in recognition of his distinguished services to entomology, especially his outstanding research on elaterid larvæ.

THE Scientific Products Foundation Award for "Outstanding Contribution to the Advancement of Pathology" for 1964 has been conferred on Dr. Alan R. Moritz, vice-president of Western Reserve University, for his many contributions to the field of forensic pathology. Dr. Moritz was instrumental in founding the first academic department of forensic medicine in the United States, at Harvard University. The award is made by the College of American Pathology.

A SYMPOSIUM on "Modern Aspects of Stereochemistry", arranged by the Sheffield Local Section of the Chemical Society, will be held in Sheffield on December 18. Further information can be obtained from Dr. J. McKenna, Department of Chemistry, The University, Sheffield.

AN informal open meeting on "Electronic States of Biological Macromolecules" will be held by the Physical Biochemistry Group of the British Biophysical Society at King's College, London, on January 16. Further information can be obtained from Dr. A. Herzenberg, Department of Theoretical Physics, University of Manchester.

CORRIGENDUM. In the article "European Mid-Devonian Correlations", which appeared on p. 363 of the October 24 issue of *Nature*, the words "half-size" in the caption to Fig. 1 should read "twice natural size", and "*Desatrypta flabellata*" should read "*Desatrypa flabellata*". In the caption to Fig. 2, "half-size" should read "natural size".

UNITED STATES BUREAU OF STANDARDS

1963 Research Highlights is the title of the detailed annual report for the year ending December 31, 1963, of the activities of the National Bureau of Standards*. The director, A. V. Astin, is assisted by two deputy directors and three associate directors. One deputy director is responsible for basic standards and services, and the other for technological standards and services. New laboratories for the Bureau are under construction at Gaithersburg, Maryland, and one of the associate directors is primarily responsible for the transfer which will shortly take place. The Bureau consists of twenty-four scientific divisions, sixteen of which are at present located in Washington. The remainder constitute the Boulder Laboratories in Boulder, Colorado, which are under the management of R. B. Scott. The total staff of the Bureau numbers about 4,160, of whom some 1,450 are professional physicists, chemists, engineers and mathematicians, and 200 research associates and guest workers. The 1963 programme cost 59 million dollars, and was financed by grants from Congress, payments for specific research and development tasks, and payments by industrial concerns, universities, research institutions and Government agencies for calibrating and testing services.

The report consists of a general review of the Bureau's activities, followed by more detailed reports of the research programmes of the individual divisions arranged so as to bring together related types of activity. In the metrological section, it is reported that a new standard of irradiance has been developed. This consists of a 200-W quartz–iodine lamp with a coiled-coil tungsten filament operating at about 3,000° K, no auxiliary optics being required. In order to calibrate standards to 10^{-7} in. an ellipsometer was used to determine the thickness of the molecular film between gauge blocks when in contact as the film becomes an inherent part of the length standard. The lenses of the 26-in. refracting telescope at the University of Virginia were tested *in situ* by a wave-front shearing interferometer placed at the focus of the telescope, and by applying the 11,530 Å infra-red light produced by a helium–neon gas laser to a modified Michelson interferometer fringes were produced which when converted to visible wave-lengths were observed and photographed over a 200-m optical path. The freezing pressure of mercury at 0° C was determined, and the value obtained, 109,722 ± 30 lb./in.², indicates that this can serve as a calibration fixed point in high-pressure measurement. For the measurement of low pressures, a detailed investigation of capillarity effects on the McLeod gauge has been made, and a search is being undertaken for suitable force-per-unit area techniques to replace the more conventional indirect methods of measurement.

A number of advances in the field of electrical measurement are announced. To meet the need for greater speed and accuracy in the determination of a.c. voltages at audiofrequencies a new d.c.–a.c. comparator was developed and a usable precision of 10 parts per million attained. A permanent adjustable standard of magnetic susceptibility, formed by using the magnetic equivalence of a uniformly polarized volume of paramagnetic material and a solenoid carrying an electric current, was incorporated into a magnetic susceptibility bridge of high accuracy and sensitivity. A new cæsium beam frequency standard, 'NBS-3', was completed, its spectral line width being less than half that of 'NBS-2'. The 'NBS-1' cæsium beam was converted into a thallium beam and approximately the same precision as previously was obtained. In the field of quantum electronics, investigations included the measurement of the velocity of γ-rays by means of the Mössbauer effect, the determination of the fine structure constant using singly ionized helium, and the examination of the mechanisms by which blue fluorescence may be induced in anthracene using the red light of a pulsed ruby laser.

The comprehensive programme of research on the thermodynamic properties of simple light-element compounds important in rocket propulsion was continued. The low-temperature heat-capacity data of some 80 substances taken from the literature were analysed by means of a computer and the thermal functions determined. A computer programme which requires no 'manual' operation is now being developed. The Bureau has continued to act as the world centre for the collection and determination of most of the atomic physics data needed particularly by plasma and astrophysicists. Emphasis has centred on the observation and analysis of the spectra of the rare-earths. A new edition of the extensive solar spectrum is near completion. From an analysis under high resolution of the infra-red spectrum of carbon suboxide (C_3O_2) conclusive evidence has now been obtained that the molecule is a straight chain consisting of three carbon atoms with an oxygen atom at either end.

The solid-state physics programme of measurements of electronic transport, optical characteristics, magnetic resonance and dielectric properties has been supported by theoretical investigations and by crystal growth and structural investigations. The main emphasis was on Ti-O compounds, CdTe, PbF_2 and several azides. Measurements of the Seebeck coefficients of TiO_2 and $SrTiO_3$ down to 15° K have shown that the phonon-drag effect contributes most to the coefficient of rutile at low temperatures, but is almost absent in $SrTiO_3$. Good crystals of CdTe were grown by the Bridgman method. Argon and krypton crystals were grown at temperatures near their triple points, 84° K and 116° K, respectively, and the properties and growth characteristics of these gaseous crystals, which can be regarded as prototype molecular solids, were found to accord closely with those predicted by theory.

The 100-MeV linear accelerator (*Linac*) and the 1·5- and 4-MeV direct accelerators, which are to become operational during 1964 and are housed at Gaithersberg, will enable the Bureau to meet the increased demands for basic experimental data, improved standards and refined measurement techniques in radiation physics. A broad programme of basic research in physical chemistry is carried out by the Bureau. This covers the kinetics of very fast reactions at high temperatures, the photosynthesis of labelled organic molecules, the structure of reactive molecules, surface catalysis, and the interaction of high-energy radiation with organic molecules.

Metal fatigue in aluminium alloys, deformation of metals at low temperatures, anisotropic effects in a series of lead–iridium alloys, the kinetics of metal whisker growth from the vapour phase, electrocrystallization, and the Peltier effect at liquid junctions are some of the items discussed in the metallurgy section. Other sections deal with investigations carried out on natural and synthetic polymers, radio propagation including ionospheric, tropospheric and satellite communication, cryogenic engineering, building research, mathematical processes including machine translation, computer facilities and data processing systems.

* United States Department of Commerce: National Bureau of Standards, Miscellaneous Publication No. 255: *1963 Research Highlights of the National Bureau of Standards*, Annual Report, Fiscal Year, 1963. Pp. ix+246. (Washington, D.C.: Government Printing Office, 1963.) 1 dollar.

During the year under review 1,122 papers and documents were published and in addition some 420 classified and unclassified reports were issued to Government agencies. A comprehensive list of these is given in the appendix to the report. The periodicals published by the Bureau include *Journal of Research*, which is issued in four separate sections—A (Physics and Chemistry) bimonthly, B (Mathematics and Mathematical Physics) quarterly; C (Engineering and Instrumentation) quarterly; D (Radio Propagation) bimonthly—and *Technical News Bulletin*, which is a monthly in which present-day research, development and test activities of the Bureau are summarized. In addition, various non-periodical series publications, the Monograph, Handbook, Miscellaneous Publications, and Technical Notes series, are issued at frequent intervals. Monograph No. 56, *Systems of Electrical Units*, by F. B. Silsbee, is an excellent survey of the various systems of units used in electricity and traces briefly their historical development. *Tensile and Impact Properties of Selected Materials from* 20° *K to* 300° *K* (Monograph No. 63) is concerned with structural materials for use in low-temperature applications, and data relating to their tensile strength, yield strength, elongation, stress–strain curves, and impact properties are given. *Standard X-ray Diffraction Powder Patterns* (Monograph 25) is the twelfth in the series with this title and contains 37 standard patterns of value to chemists in the identification of unknown crystalline materials.

A 16-mm colour film, *Scatter Radar: Space Research from the Ground*, released during 1963, tells the story of the Bureau's new Jicmarca Observatory situated near Lima, Peru. The Observatory has a 22-acre radar aerial and is used to measure at 50 Mc/s the characteristics of ionization in the ionosphere and exosphere. It has made observations of the planet Venus, and will investigate the solar corona and solar gases. The Bureau participated in 18 scientific and technological exhibitions, and as part of the sixtieth anniversary celebrations of the Department of Commerce the Bureau's Washington laboratories were opened to the public for the first time for many years on May 11, 1963. Some 7,000 visitors toured the 100 laboratories and saw the special exhibits on display.

S. Weintroub

ROAD RESEARCH

In recommending that the Road Research Laboratory should be transferred to the proposed Industrial Research and Development Authority, the Trend Committee had reservations as to whether the arrangement should be permanent and suggested that the position should be reviewed after a reasonable interval, with the view of the possible transfer of the management of the Station to the Ministry of Transport. This would be in line with present-day opinion for the strengthening of the scientific resources within the several Departments, but in spite of this the Road Research Report Board in its annual report for 1963* expresses the emphatic view that the value of the Laboratory's research is enhanced by its independence and by the fact that it is seen to be independent by the public and the many authorities and other bodies who benefit from its work. It regards the Laboratory as carrying out its task with conspicuous success within the limits of its resources, but it should be noted that it does not consider that it is the function of a research organization, or within its competence, to apply the results itself, although it admits that a research organization must accept some responsibility for effectively disseminating the results of its researches. The Board reiterates a recommendation it made early in the year, as to the importance that plans should provide for the large staff that will be needed in the near future in view of the great increase forecast for road traffic and road building. The Board welcomes the Laboratory's concern with research on road casualties and urges that prompt action should be taken to apply such measures as research has shown to be appropriate to diminish this continuing loss of life and limb. On lighting problems, in view of the demonstration by the Laboratory's investigations that the accident rate is greater at night than by day and that effective street lighting appreciably reduces the night accident figures, it recommends that an investigation should be made of the effect on accidents and traffic flow of lighting other busy rural roads carrying fast traffic, including motorways. It also welcomes the arrangements now being made in Birmingham and other cities for further trial this winter of the use of dipped headlights in all streets. The large-scale road experiments, which are now an essential part of the Laboratory's research, throw light on many problems of design which face the road engineer and which can be solved only from an examination of results obtained in the prevailing conditions of traffic and climate. It is of the first importance that such experiments should be made and their performance recorded and assessed with a view to the earliest possible application of the results. A further investigation of the effect of frost on the performance of existing road pavements is to be made and a paper on the design of urban sewer systems was published, outlining the recommended procedures for the application of the new design method for surface water sewerage systems: more than a dozen applications have already been received from Local Authorities in England.

The Board notes that the Department of Technical Co-operation has now decided to devote almost one-tenth of its research allocation to provide for the continuation of the activities of the tropical section of the Laboratory. These activities are dealt with more fully in an appendix to the report. They include further investigation of road-making materials from tropical countries with the object of expanding knowledge of overseas soils and of determining the causes of unusual properties, as well as a review of pavement design and soil-moisture movement in tropical and sub-tropical countries. The Board emphasizes the continuing need to make the Laboratory's work better known overseas, and it considers that the primary need in developing countries is knowledge of their own soils and of the other road-making materials available to them. The Board's own report includes the report of the Director of Road Research and appendixes giving details of the committees, staff and publications of the Station during the year. The activities of the Research Station on road systems and layout and parking needs have provided much of the fundamental information required in planning for traffic in towns and elsewhere. Much attention is being given to safety matters and for the first time for 10 years 1962 showed a significant decrease in the proportion of skidding accidents on wet roads. Prevention of some 2,000 accidents is attributed largely to the use of 'dead' rubber for tyre treads and of road materials with a high resistance to polishing under the action of traffic. Research on safety belts and harnesses continued along four main lines, including assistance to the British Standards Institution Committee on seat belts in the specification of a dynamic form of test for safety belts, studies of design, and performance surveys of the usage of the belt, and analyses of

* Department of Scientific and Industrial Research, *Road Research 1963: The Report of the Road Research Board with the Report of the Director of Road Research*. Pp. vi+168+12 plates. (London: H.M. Stationery Office, 1964.) 11*s*. 6*d*.

accidents in which safety belts were worn. Analysis of 600 accidents in which 837 drivers or front-seat passengers were wearing safety belts at the time of the accidents indicated that serious injuries were reduced by about 80 per cent and overall reduction in injuries was about 50 per cent. Six accidents on motorways during the past 2½ years were attributed to spray obscuring a driver's vision and problems involving splashing and production of spray by commercial vehicles are being investigated. A preliminary study has shown that the front wheels are particularly important in producing spray because they generally run in a thicker film of water than the rear wheels, and that the pattern of distribution of spray behind the vehicle depends largely on its shape. Work on road pavements is mainly directed at the construction and observation of full-scale experimental roads, generally on routes carrying heavy traffic, and to theoretical and field studies of the stresses and deflexions in multi-layer pavements and the influence on them of repeated loadings. In the experimental section constructed in 1957 on the A1 at Alconbury Hill the best sections continue to be those with 4 in. asphalt surfaces on a 9-in. lean concrete base and on a 6-in. asphalt base. Studies are in progress on the amount of control testing that should be carried on large road construction projects, to assess the practical limits for the number of tests, the man-power required to carry out the testing, and the cost of testing in relation to the total cost of each project. The first study suggests that tentative proposals made by the Laboratory are likely to be suitable. To determine the effect of wet weather on the construction of earthworks and to provide some indication of the amount of working time likely to be lost through wet weather, records of the utilization of plant at major earthwork sites have been collected to compare the actual performance each day with the performance during dry weather. Weather at the site has been recorded or records are being obtained from nearby stations of the Meteorological Office. Computer programmes are now available for carrying out the calculations involved in the Road Research Laboratory's hydrographic method of sewer design. The Laboratory is also attempting to supply more precise information on the loads imposed on bridges by moving vehicles. This is required in estimating the fatigue life of the structure, and a short-term study is being made of the way in which traffic flow data can be converted into traffic loading data, and a long-term collation of information on vehicle axle weights, using electronic weighbridges at selected sites. The effects of temperature, creep and shrinkage on the performance of a structure are being investigated by measurements on a number of bridges, including the Hammersmith Flyover and the Medway Bridge, and the results have indicated how the behaviour of a structure can be affected by its form and environment.

USE OF WHOLE-BODY COUNTERS IN RADIOLOGICAL PROTECTION

"THE Use of Whole-body Counters in Radiological Protection" was the title of a symposium held at the Middlesex Hospital Medical School on April 7, 1964. It was the eighth in a series sponsored by the Joint Health Physics Committee* and on this occasion was organized for the Committee by the Radiological Protection Service. The proceedings were divided into two sessions, the first being devoted to a review of the development of whole-body counters and an account of experience in their use over a period of more than six years at two centres undertaking this work in the United Kingdom, and the second to reports of some special problems encountered in several laboratories. Mr. W. Binks (Radiological Protection Service) acted as chairman of the first session and Prof. F. W. Spiers (University of Leeds) of the second.

In his opening address to the first session Prof. Spiers (University of Leeds) traced the history of the development of whole-body counters from the early work by Schlundt, Barker and Flinn (1929), and Schlundt, Nerancy and Morris (1933), using ionization chambers, to the highly sophisticated apparatus of the present day utilizing scintillation detectors and multi-channel analysers (Table 1).

From this it could be seen that, after Schlundt *et al.* had made improvements in the ionization-chamber method, there was an additional improvement in sensitivity with the advent of high-pressure ionization chambers, bringing the sensitivity in the region necessary for the measurement of the natural γ-ray emission of the body. The use of large scintillation counters in 1956 brought about a further increase in the sensitivity and it was this order of sensitivity that had provided the health physicist with a powerful tool for measuring body radioactivity far below the maximum permissible values.

Prof. Spiers stressed that, for a high detection efficiency, both high counting rates and large signal-to-background ratio were important, as could be seen from the well-known formula:

$$S.E.\ (\text{as percentage of } S) = \frac{100}{S}\left(\frac{B}{t_B} + \frac{B+S}{t_S}\right)^{\frac{1}{2}} = \frac{100}{(aS)^{\frac{1}{2}}}\left(\frac{1}{t_B} + \frac{1+a}{t_S}\right)^{\frac{1}{2}}$$

(where $S.E.$ is the standard error as a percentage of S, the counts per sec due to the source, B is the counts per sec due to background, $a = S/B$, and background observations are made for t_B sec and source observations for t_S sec). In order to make the standard error small, S should be large, which meant a physically large detector should be used, and a should be increased as far as possible by reducing B.

Table 1. DEVELOPMENT OF WHOLE-BODY COUNTING SINCE 1929

Date	Experimenter and apparatus	Subject observation time	Approximate limit of detection (or standard error): As μg ^{226}Ra equivalent*	Approximate limit of detection (or standard error): As a percentage of total body potassium
1929	Schlundt *et al.*, Ion chamber at 1 atm.		~5	
1933	Schlundt *et al.*, Ion chamber at 1 atm.		~0·2	
1937	Evans, Geiger-Müller tube		0·1	
1947	Hess and McNiff, Ion chamber at 1 atm.		0·03	
1951	Sievert, High-pressure ion chamber	2 h	0·005 (*S.E.*)	~50 (*S.E.*)
1953	Burch and Spiers, Differential high-pressure ion chambers	2 h	0·003 (*S.E.*)	~30 (*S.E.*)
1956	Sievert, High-pressure ion chambers underground	3–4 h	0·001 (*S.E.*)	~10 (*S.E.*)
1956 to 1960	Los Alamos, 4π liquid scintillator (Anderson, 1956)	15 min	~0·0001 (*S.E.*)	1 (*S.E.*)
	Argonne National Laboratory NaI scintillator (Marinelli, 1956)	15 min	~0·0003$_5$ (*S.E.*)	3·5 (*S.E.*)
1960	Leeds, Plastic scintillator apparatus (Bird and Burch, 1958)	15 min	~0·0001$_5$ (*S.E.*)	1·5 (*S.E.*)

* By 'μg ^{226}Ra equivalent' is meant μg ^{226}Ra with all daughter products in equilibrium.

* The Joint Health Physics Committee consists of representatives of the British Institute of Radiology, the British Occupational Hygiene Society, the Central Electricity Generating Board, the Faculty of Radiologists, the Hospital Physicists' Association, the Institute of Physics and the Physical Society, the Radiological Protection Service, the Society for Radiological Protection and the United Kingdom Atomic Energy Authority.

Prof. Spiers referred to a number of different materials, from chalk to lead, which had been used to provide the shield against environmental radiation in order to reduce B (Trott, Parnell, Hodt and Entwistle, 1963, and Wilson, 1964). He considered that attention must also be directed to the problems of other sources of contamination both within the scintillator and its container, also in the bases and resistance chains of the photomultiplier tubes, and other miscellaneous parts (Marinelli, Miller, May and Rose, 1962, and Wilson, 1964). Given a sufficiently sensitive detector and adequate background shielding, statistical accuracy equivalent to about 1 or 2 per cent of the natural ^{40}K content of the body could be achieved. This same order of accuracy was also possible for repeated observations on one person, but there were limitations when determining absolute amounts of radioactivity in the body. Most of the difficulties arose because the activity was distributed about the body and offered a different geometry in each configuration of detector and subject. Moreover, this distribution frequently changed with time after the intake of radioactive material into the body. It was very difficult, therefore, to devise 'phantoms' containing calibrating solutions which approximated at all closely to the *in vivo* distribution, except with radionuclides which dispersed uniformly throughout the whole body. Exceptionally, it might be possible to carry out *in vivo* calibrations with isotopes of the radioactive material concerned, for example, ^{42}K for ^{40}K, and this could increase the accuracy very considerably.

Another important aspect of the accuracy of measurement concerned the overall stability of the apparatus. This became specially important for long observation times and when computer analysis of the results was to be used. One solution to this was to build some form of automatic stabilization into the equipment (Dudley, 1962). As to the choice of detector in any particular instance, this would depend very much on the circumstances and the problem in hand. For rapid screening of large numbers of individuals there was great merit in the use of the large plastic and liquid scintillators, though it must be remembered that time for changing and preparation of the individual was also required, and the actual observation time was only part of the whole operation.

Finally, Prof. Spiers commented that it must be generally conceded that in protection work the sodium iodide crystal detector offered most advantages with regard to higher energy resolution and, therefore, the identification of different radionuclides in the body. Where any large body of people was concerned, it would seem that a simple fast scheme could be worked out using large plastic or liquid scintillators for initial screening purposes. Persons with significant activities could then be passed on to a sodium iodide counter for detailed study.

In his paper entitled "Some Applications of Body Radioactivity Measurements to Radiological Protection at Harwell", Dr. J. Rundo (Atomic Energy Research Establishment, Harwell) stated that there were two applications for whole-body counters at Harwell, namely, the measurement of body radioactivity of persons who had been involved in accidents with radioactive materials and the undertaking of more fundamental studies on the distribution of radioactive material in body tissues and its elimination from the body. The apparatus used had been described in detail elsewhere (Rundo, 1958). During the past five years the number of suspected accident cases examined at Harwell had amounted on average to only 18 a year. By no means all these had been found to be contaminated and the main effort, therefore, had been devoted to careful investigations of a few cases. With regard to observations on the distribution of radioactive material in the body, this could be achieved in three ways, namely: (*a*) by scanning, that is, movement of the detector over the surface of the body; (*b*) by a single large crystal close to an organ of the body; and (*c*) by use of a slit collimator to give a profile curve.

Three cases which illustrated the types of problems encountered in radiological protection were described. All three cases concerned the accidental inhalation of radioactive materials, which Dr. Rundo believed was the predominant mode of entry into the body in most practical circumstances; a view which was later endorsed by others in the discussion. The first case involved ^{90}Sr carbonate (Rundo and Williams, 1961). Measurements were made of body radioactivity, and also of the activity in urine. The significant feature emerging from the results was that if the body radioactivity had been inferred from the initial urine measurements, using data given in the report of Committee II of the International Commission on Radiological Protection (I.C.R.P. II, 1959) for the biological half-life, the estimated body-burden would have been much larger than that actually measured in the whole-body counter. Therefore, it was clear that, wherever possible, it was necessary to have excretion data supplemented by measurements of total-body radioactivity by external counting. The second case (Rundo, 1964) concerned an individual who had inhaled dust generated while grinding and polishing irradiated uranium. The accident was detected when widespread contamination was found in the working area. It was demonstrated that a number of radionuclides had been inhaled, and later it was calculated that the initial dose-rate to the lungs was nearly twice the maximum permissible value of 0·3 rem/week recommended by I.C.R.P., but this decreased by about an order of magnitude in six days. The retention of radioisotopes of Cs, Ce, Ru, and Zr with Nb was followed with the whole-body counter over several hundred days. The whole-body scan showed that, with the exception of ^{137}Cs, all the radionuclides were located in the chest and their activities in that region over a period of time decreased in a manner which was identical with that expected by radioactive decay alone, suggesting that there was little, if any, elimination of these materials from the body. This fact is, of course, quite at variance with the views of I.C.R.P. II that the half-life of particulate material in the lungs is 120 days.

In the third case (Newton, 1963) the accident concerned a man who inhaled dust during maintenance operations on a reactor. The principal contaminants were ^{65}Zn and ^{110m}Ag, identified from examination of a handkerchief used by the man immediately after the accident. His radioactivity was followed by whole-body counting over a period of 2 yr. and profile curves were determined. The profile curves indicated that both ^{65}Zn and ^{110m}Ag were transferred almost completely from the lungs within a few days. A widespread distribution of ^{65}Zn in soft tissues was apparent from the early stages, with an appreciable concentration in the liver during the first 100 days. ^{110m}Ag was concentrated in the liver and was eliminated from that organ with a biological half-life of about 50 days. For both silver and zinc the excretion pattern from the whole body could be described by the sum of two exponential terms. In the case of zinc, 27 per cent was eliminated with a biological half-life of 18 days and 73 per cent with a half-life of 453 days. Most of the silver (about 85 per cent) disappeared very rapidly with a biological half-life of about one day and 15 per cent with a half-life of 52 days, that is, not very different from the rate of elimination from the liver.

In none of the cases described had the individual concerned received a significant radiation dose as a result of the incident. This could have been predicted early in the investigation and the prolonged studies had been made solely to determine the behaviour in the body of the various radionuclides concerned. In answer to a question, Dr. Rundo said that most of the silver and zinc were excreted in the fæces. There was no measurable excretion of silver in urine. He emphasized that excretion patterns varied considerably between individuals, as illustrated by measurements of Furchner, Richmond and Trafton (1962) on four people to whom ^{65}Zn was administered orally.

Table 2. RADIOACTIVITY OF VARIOUS MATERIALS

Material	Radioactivity: Uranium 10^{-12} c./g	Radioactivity: Thorium 10^{-12} c./g	Radioactivity: Potassium 10^{-6} g/g	Primary photon emission in photons/min.g: Uranium	Thorium	Potassium	Total
Brick	75	150	35,000	3·5	10·0	7·4	21·0
Cement	40	70	5,000	1·9	4·7	1·1	7·7
Soil (sample)	40	120	Not measured				
Chalk (North Downs)	10	3	20	0·5	0·2	Very small	0·7

Reviewing the use of whole-body counters at the Radiological Protection Service, Mr. J. Vennart considered that the most interesting feature of the equipment was the construction of the low-background laboratories. Early measurements of the local gamma-ray background in 1956 (Vennart, 1957) had indicated that the chalk underlying the site at Belmont, Surrey, where the Radiological Protection Service was situated, had a very low radioactivity. The reason for this could be seen from information he presented showing the concentrations of the principal naturally occurring radioactive materials, uranium, thorium and potassium (potassium due to the naturally occurring isotope ^{40}K), in a representative sample of brick, cement, soil and chalk and the primary photon emission in photons/min/g in the material from each radionuclide and for the mixture (Table 2). It showed that the total rate of primary photon emission in brick was 30 times greater than in chalk. As soon as this fact was appreciated, a temporary laboratory was built below ground in the chalk and this was still in use at the present time (Vennart, 1963). The detector consisted of four 4½-in. × 2-in. sodium iodide crystals placed in line above the body and in a second counter, recently completed, there were four crystals both above and below the body.

The largest group of people measured had been more than 500 people who had worked in the radium luminizing industry (Vennart, Maycock, Godfrey and Davies, 1964). Twenty of them had been found to have more than the maximum permissible body burden, namely, 0·1 μc. of ^{226}Ra (I.C.R.P. II). The majority contained quite trivial amounts of radium and the important feature was that no one who had luminized exclusively since 1941 contained more than half the maximum permissible body burden. The reason for this might be traced to the fact that it was realized in 1939 that there would be a large increase in the luminizing industry during war-time and, in view of the serious injuries known to have occurred among some of the early American workers concerned with luminizing, the occupation of luminizing in Britain had been brought under the medical supervision of the Ministry of Labour. This supervision, besides including regular medical examinations of the workers, had also resulted in the institution of very simple rules of hygiene in the industry. It was interesting, in view of the present-day efforts in the health and safety field, to see how effective these very simple rules had been. The other large series of measurements had been of fission products in members of the population, principally ^{137}Cs (Maycock, Terry, Vennart and Wise, 1960, and Maycock, McCansh and Vennart, 1962), but also during 1961 of ^{131}I (Vennart, 1962). It had also been possible to measure ^{131}I in the thyroid glands of people living in London following the Windscale Reactor accident in 1957 (Maycock and Vennart, 1958).

During the period that the counter had been in operation (1957–64), body radioactivity of only 85 people had been measured because of incidents involving the dispersal of radioactive materials, and only six of these had more than one-tenth of the maximum permissible body burden of the radionuclide concerned. The radioactivity of the majority of these people was measured because of uneasiness on the part either of the individual himself or of his employer. In other words, they came mainly to be reassured that there was no radioactivity in their bodies. There remained a doubt as to whether it was only the most apprehensive people, or those employed by the most careful employers, who were referred for measurement of radioactivity, and whether more severely contaminated people had escaped attention. Some justification for this assumption might be obtained from the results of measurements of radioactivity carried out on people at present working in the radium luminizing industry, in which they were selected for measurement more or less at random. In this study, 33 people out of a total of 82 measured had contained more than one-tenth of the maximum permissible body burden of radium, which was a much higher proportion than was found in the people referred to the Radiological Protection Service because of incidents involving radioactive material.

These facts suggested that there should be more routine measurements of radioactivity of people working with radioactive materials, but not necessarily with high sensitivity equipment. For the majority of radionuclides which could be measured by detectors placed outside the body, the activities which were of interest could be determined by using very simple apparatus. Significant activities were often several microcuries, not only because the maximum permissible body burdens were large, but also because the radionuclides were often eliminated rapidly from the body and, therefore, the intake of maximum permissible body burdens led to radiation doses which were quite trivial by our present standards (Vennart, 1963). In the discussion which followed about this latter point, it was pointed out that the prevention of intake of radioactive materials by adequate environmental control was also important.

The second session was opened by a paper entitled "The Problem of External Counting of Plutonium at Low Levels *in vivo*", in which Mr. B. Taylor (Atomic Energy Research Establishment, Harwell) described the difficulties of measuring ^{239}Pu *in vivo* by detection of the extremely low-intensity γ-rays emitted. Using a 9-in. × 6-in. sodium iodide crystal, the minimum detectable activity of ^{239}Pu in the lung was about 2–3 μc., while the maximum permissible amount in the lung, corresponding to a dose rate of 0·3 rem/week, was only 16 nc. An alternative method was to measure the *L* X-rays of uranium, which are emitted following the disintegration of ^{239}Pu, with an intensity of about 4×10^{-2} photons per α-particle. These X-rays, of energies 13·6 keV, 16·9 keV and 20·2 keV, had half-value layers in soft tissue of about 0·4, 0·7 and 1·0 cm respectively. The half-value layer in bone was only about 0·03 cm, and the determination of ^{239}Pu in bone at levels near the maximum permissible body burden of 40 nc., therefore, appeared unlikely.

Attempts to measure ^{239}Pu in lung had first been made by Roesch and Palmer (1962), using a thin NaI crystal. In these measurements, a large contribution to the background in the energy band of the *L* X-rays was due to photomultiplier dark noise. The lower background and superior energy resolution obtainable with gas-filled proportional counters had led to the adoption of this type of detector at Harwell. A 6-in.-diameter end-window flow counter constructed from 'Perspex' and containing argon with 10 per cent methane was used with a well-shaped plastic phosphor anti-coincidence shield. The counter background inside a small lead shield 4 in. thick was 1·5 c.p.m. in the energy band 10–22·5 keV, and the best energy resolution achieved at 13·4 keV was 11 per cent, which was close to the theoretical minimum value. Because of the high absorption of the X-rays in body tissues, the effects of variation in distribution of the inhaled ^{239}Pu in the lung, and differences in chest-wall thickness between individuals, had made calibration difficult. However, an estimate of the effective depth of the material might be possible by differential measurements of the three X-rays, since their absorption coefficients are markedly different.

Two further methods of calibration involving human subjects were discussed. The first concerned a case of accidental inhalation of ^{235}U. In this case the amount of the material in the lung could be estimated by measure-

ments of the 186-keV γ-ray it emitted, using a 9-in. × 6-in. sodium iodide crystal detector. Since ^{235}U also emits the characteristic *L* X-rays of thorium, the energies of which are close to those emitted following the disintegration of ^{239}Pu, it was possible to estimate the sensitivity of the proportional counter for ^{239}Pu in lung. Measurements made with the window of the proportional counter close to the chest of the subject had shown that the counting rates were significantly higher than those from two normal subjects with similar potassium and ^{137}Cs contents. The minimum detectable activity was estimated to be 55 nc. of ^{239}Pu for a 100-min measurement. An improvement in sensitivity was expected from the use of a larger multi-wire counter which had just been constructed. Xenon was proposed as the filling gas, though considerable purification from krypton impurity (containing ^{85}Kr) might be required to obtain a sufficiently low background. An alternative method of calibration proposed was the inhalation by volunteer subjects of a 'mock' ^{239}Pu. This would consist of an insoluble mixture of three radionuclides of medium atomic number, which decay by electron capture, giving *K* X-rays of the same energy as the uranium *L* X-rays emitted following the disintegration of ^{239}Pu. Radionuclides which were being considered were ^{85}Sr, ^{93}Mo, ^{103}Pd and ^{103}Ru. Both ^{85}Sr and ^{103}Ru also emit higher-energy γ-rays, thus enabling the lung content after inhalation to be determined by measurements with a sodium iodide crystal detector. An advantage of this method was that reasonably high counting rates might be obtained with the proportional counter, without large radiation doses being received by the volunteer's lungs, since the half-lives of the radionuclides proposed were relatively short.

In his paper entitled "Measurements of Some Long-lived Alpha-Gamma-Emitters in the Thorax" Mr. D. Newton (Harwell) directed attention to the fact that for many α-emitters the maximum permissible amounts in lung, corresponding to a dose rate of 0·3 rem/week, were only a few nc. The detection and estimation of such small amounts *in vivo* might, therefore, be difficult because the γ-radiation accompanying the α-emission is generally of low intensity and in the low-energy region, where the contributions from scattered photons arising from ^{40}K and ^{137}Cs in the body might be difficult to assess. By way of illustration, Mr. Newton described measurements of body radioactivity which were being made on two people who had accidentally inhaled radioactive materials.

The first case involved ^{227}Ac, the long-lived parent of a chain of α-emitters. The parent emitted no detectable γ-radiation itself, and its presence *in vivo* could only be inferred from the γ-rays emitted by its daughters, ^{227}Th (18 days) and ^{223}Ra (11·7 days) *et seq.* The activity in the chest was measured with a single 9-in. × 6-in. sodium iodide crystal placed behind the thorax. The difficulties of calibration were stressed, especially with regard to the excretion of daughter nuclides. For example, it appeared in this case that the ^{223}Ra was excreted more rapidly than the ^{227}Th, but estimation of the equilibrium amounts of these daughters was complicated by the similarity of their spectra and the possibility of their being distributed differently in the chest. Between 200 and 800 days after the incident the chest contents of ^{227}Th and ^{223}Ra were evidently constant at about 1 nc. and 0·6 nc., respectively, showing that there had been no loss of ^{227}Ac during this period, although a small reduction could have been masked by the subject's steeply rising content of ^{137}Cs resulting from nuclear weapons testing. However, measurements of the subject's whole-body radioactivity made during the first 200 days using the four-crystal spectrometer (Rundo, 1958) had indicated that some of the inhaled material had been eliminated more rapidly.

The second case involved a mixture of ^{231}Pa with about 7 per cent of its daughter ^{227}Ac. Measurements with the single large crystal showed that the chest content of ^{231}Pa was unchanged between 7 and 300 days after the incident, at about 10 nc. or two-thirds of the maximum permissible amount in lung. The ^{227}Ac content was apparently about 1 nc. or one-quarter of the maximum permissible amount in lung, but may have decreased very slightly during the period of observation. In conclusion, Mr. Newton said that the investigations had shown that it was possible to measure about a quarter of the maximum permissible amounts in the lung of ^{227}Ac and ^{231}Pa with sufficient accuracy for protection purposes. However, there remained a doubt about the exact location of this material within the chest. In neither case was it certain that the activity was deposited solely in the lungs. If it were instead in the pulmonary lymph nodes, then lower maximum permissible amounts would presumably apply because of the smaller tissue masses involved. In the discussion, attention was directed to the fact that the long biological half-lives of these materials in the lung were contrary to Baird's findings with dogs (Baird, Tombropoulos and Park, 1963), and unexpected from the physiology of the human lung. If the contaminants had been in a soluble form and deposited in bone, this might explain the different results. Was there any information on the chemical form of the materials, or the presence of activity in the fæces? Mr. Newton replied that nothing was known of the chemical form of the ^{227}Ac inhaled by the first subject and, in the second case, the chemical form of the ^{231}Pa was not known with certainty: possible compounds were Pa_2O_5 and $KPaO_3$. None of the parent nuclides had been found in the fæces of either subject, though in the first case ^{223}Ra had been detected after 100 days.

In a paper entitled "Measurement of Fall-out ^{137}Cs in Infants", by F. W. Spiers and A. R. Wilson (University of Leeds), Mr. Wilson described measurements of ^{137}Cs and ^{40}K using a detector consisting of four 6-in. × 6-in. sodium iodide crystals. The crystals were positioned above and below the infant in such a way that the sensitivity of the counter was almost independent of the position and attitude of the infant during the measurement. For a measurement time of 30 min, the standard errors of measuring 1 nc. ^{137}Cs and 8 g potassium in a new-born infant were respectively ±7 per cent and ±10 per cent. It had been possible to estimate the turnover of ^{137}Cs in two cases in which the babies had been fed on dried milk. In calculating the turnover time it had been assumed that the newly born baby had the same ^{137}Cs concentration per unit mass as the mother. The way in which the observed body content of ^{137}Cs changed with time could be accounted for by assuming a biological half-life of 8 days for one baby and 7 days for the other. Both babies had been measured up to about 30 days old. Mr. Wilson considered that it would have been of interest to study breast-fed babies and older children, but it was very difficult to determine the ^{137}Cs intake in such cases.

The way that the ratio $^{137}Cs/K$ changed with time in the two cases was conflicting. In one baby the ratio rose to a maximum in a few weeks, whereas in the other it fell to a minimum at about the same age. Commenting on this in the discussion, Mr. Wilson suggested that the reason for this discrepancy probably lay in calibration and that it was not easy to get a truly representative model when the potassium and ^{137}Cs were varying and also probably undergoing re-distribution in the body. In the discussion, Dr. Rundo briefly described some measurements of body radioactivity which he had made on two children. The ways in which the body content of ^{137}Cs changed with time were consistent with a biological half-life of 10 days for a child measured up to 30 days old and a half-life of 7 days for another measured up to 37 days old. Mr. G. Stott said that he had made measurements of body radioactivity on one child who was 90 days old which showed that the ratio $^{137}Cs/K$ was twice that of adults measured at the same time. The radiation dose received would also be about twice that received by adults.

Mr. C. O. Peabody considered the general philosophy of the use of whole-body counters in radiological protection

in his paper, "The Value of Routine Measurements at the Atomic Energy Establishment, Winfrith". He compared and contrasted the problems and methods of minimizing and measuring exposure to external radiation with those for the internal irradiation produced by radioactive contamination in the body. Where external radiation was concerned the exposure of individual workers was minimized by providing adequate shielding, by controlling working times and by frequent environmental surveys. Finally, the adequacy of protection was further checked by the wearing of personal dosemeters, such as film badges. In the case of internal radiation the risk was minimized by the containment of radioactive material, by adequate ventilation, and by environmental monitoring for contamination on surfaces and in the air. There was, however, no system of routine personal dosimetry for internal radiation which was at all comparable in its simplicity and accuracy with that of the film badge in monitoring external radiation. A case could be made for the need for such a routine system, but it was at present impracticable. The practice generally adopted, and implied in some codes of practice, was that measurements of body radioactivity need be made only when it seemed possible that the person had been exposed to an undue risk of taking radioactive material into the body.

Mr. Peabody went on to consider the problems involved in making routine measurements of body radioactivity. For example, it was necessary to make measurements at realistic intervals of time commensurate with the counting facilities available and with the time for which the subject could be taken away from his work. It was impossible to lay down a standard interval between measurements which would be applicable in all cases, because this depended on the effective half-life of the radionuclide in the body. The situation at Winfrith was that there were about 200 people who were exposed to a possible risk and only about 30 per week could be measured in the whole-body counter there. If all these people were measured continuously, therefore, the interval between measurements would be seven weeks and for many of the radionuclides concerned this would be far too long. Accordingly, a programme of continuous measurement of body radioactivity of all people had not been adopted and measurements had been limited to a representative sample of the people concerned. People were chosen for the sample according to their estimated risk of contamination. Unexposed staff such as office workers were used as controls. So far, no person had been found to contain more than a negligible fraction of the maximum permissible body burden of any radionuclide while, for the majority, the only radionuclides detected were ^{40}K and fall-out ^{137}Cs. The system had proved to be advantageous in that it had found a few cases of personnel contamination which had not been previously suspected and, equally important, it had served to reassure staff and supervisors. In the discussion that followed there were several comments about the time taken to prepare an individual for measurement in a whole-body counter. The need for the individual to take a shower bath depended on whether or not the person had been exposed recently to the risk of contamination. It was agreed that it was always necessary to change into clean and previously monitored clothing.

In dealing with "The Usefulness of Routine Measurements in a Whole-body Counter as a Check on the Effectiveness of Contamination Control", Mr. G. Stott (Dounreay Experimental Reactor Establishment) stated that the principal uses of the whole-body counter at Dounreay had been for routine measurement of body radioactivity of workers, experimental investigations of people who had accidentally acquired radioactive materials in their bodies, measurement of samples taken on environmental surveys and diagnostic tests of thyroid function as a service to ordinary members of the public in the vicinity of Dounreay. There were about 300 people who might be at risk at the Dounreay Experimental Reactor Establishment. These were mostly employed on fuel processing, so the radioactive materials concerned were chiefly fission products. During 1963, when there had been a large increase in fuel processing, extensive air sampling had been undertaken in order to ascertain whether there was any increase in environmental contamination. This showed that the concentration of radioactive materials in the atmosphere had rarely been excessive and the effectiveness of this environmental monitoring with regard to the protection of the workers had been checked by measurements of the body radioactivity in the whole-body counter.

Measurements of ratios $^{137}Cs/K$ (pc./g), taken in 1961 during a slack period, showed values of 81 for the workers and 91 for controls. The corresponding values for 1962–63 were 318 for workers and 293 for controls. There was, therefore, no difference between workers and controls in either period. However, the percentage of workers contaminated with more than 5 nc. of the fission products ^{95}Zn and its daughter, ^{95}Nb, increased from 20 per cent in 1961 (highest value 50 nc.) to 70 per cent in 1962–63 (highest value 40 nc.). The results of air sampling were approximately the same during both periods. Hence, although the usefulness of air sampling was confirmed, in that the body radioactivities due to ^{95}Zn and ^{95}Nb were negligible by comparison with the maximum permissible body burden of 20 μc., the results of air sampling were not sufficiently sensitive to direct attention to the fact that the intake of radioactive materials into the body had been increasing during the period of observations. This was only discovered by *in vivo* monitoring.

Mr. B. E. Godfrey (Radiological Protection Service) discussed the parameters required for estimation of radiation doses following single or protracted intake of radioactive material into the body. He pointed out that, when persons were measured for body radioactivity following accidents, it was seldom possible to determine all the parameters required. For example, the body radioactivity of the individual concerned was very frequently measured some time after the accident had occurred, so that the initial build-up of the radioactive material in the various organs and tissues was not observed. Very often it was not possible to determine the exact distribution of radioactive material in the body and impracticable to make repeated measurements on the individual to find the excretion pattern. In most cases, therefore, it was necessary to adopt some simple model for the distribution of the radioactive material in the body and its elimination. He referred to the model adopted by Vennart and Minski (1962) in which the pattern of elimination is described by a single exponential term and illustrated the use of such a model by describing some cases which had been measured in the whole-body counter at the Radiological Protection Service.

The first example concerned measurements of body radioactivity on three people who had accidentally taken in ^{137}Cs while at work. Measurements had been made over a prolonged period starting a few weeks after the accident and for each individual it was possible to fit the data to a single exponential function. The biological half-lives of ^{137}Cs were found to be 79 days, 118 days and 123 days (Taylor, Taylor and Vennart, 1962). The second example concerned measurements of ^{131}I in human thyroids following the Windscale Reactor accident of 1957, and also following the increase of nuclear weapon testing in 1961. In both cases it had been possible to fit a theoretical expression to the measured points on the assumption that radioactive iodine is eliminated from the thyroid according to a single exponential term (Maycock and Vennart, 1958, and Vennart, 1962). The third example concerned a patient injected with 25 μc. of ^{22}Na in a diagnostic test for exchangeable sodium, whose body radioactivity was later measured in the whole-body counter for a period extending from $2\frac{1}{2}$–$4\frac{1}{2}$ years after the test (Vennart, 1963). The measurements showed that about 0·35 per cent of the injected dose was eliminated from the body very slowly at

a rate which could be described by a single exponential term. The effective half-period of elimination was 513 days, corresponding to a biological half-life of about 1,000 days. The value for the effective half-life was in accord with that of 445 days reported by Richmond (1958) and 475 days reported by Jagger, Hine, Cardarelli and Burrows (1963). The final example concerned two women whose body radioactivity had been measured during the period 5–12 weeks following the administration of ^{131}I in tests for thyroid function. The elimination of ^{131}I from the thyroid could be explained by a single exponential term corresponding to an iodine turnover of about 1·5 per cent per day, a value which is in reasonable agreement with that of 2 per cent per day quoted by Ziliotto (1961), but about twice the values quoted by Rosenburg (1958), Burns, Fish, Hackett and Hickey (1951), and Maurer (1961). However, it was necessary to be cautious in the interpretation of the results because these patients had been diagnosed as having anxiety states following their presentation with symptoms common to thyrotoxicosis. There was a possibility, therefore, that they might have slightly over-active thyroids.

In the discussion on this paper, Dr. Rundo referred to the use of collimated counters to investigate the distribution of radioactive materials in the body. Mr. Vennart doubted whether the degree of collimation would ever be sufficient to determine the activity in different organs of the body, except in very special cases such as the thyroid.

In a general discussion at the end of the symposium the main topic of interest concerned the problems of estimating the activities of β-emitting radionuclides in the body by measurement of bremsstrahlung in whole-body counters. It was clear from this that one of the chief limitations on the estimation of small β-activities was the presence of ^{40}K and ^{137}Cs in the body. Degraded photons from both these radionuclides contribute to the bremsstrahlung spectrum of any β-emitter in the body and due allowance for this must be made when estimating the β-activity. The uncertainty of an estimation of β-activity must, therefore, include the uncertainties of estimating both ^{40}K and ^{137}Cs. Furthermore, estimations of the contributions from ^{40}K and ^{137}Cs involved considerations of several factors, including the weight of the subject and the effect of inhomogeneous distribution (Rundo, 1962), as well as the body content of the radionuclides. Lidén and McCall (1962) had made a careful study of the problem of measuring β-emitters in the body and had estimated the minimum detectable body activity of ^{90}Sr in their apparatus to be 20–25 nc., of which a considerable fraction was due to the uncertainty of estimating the contribution from ^{40}K and ^{137}Cs. It was clear that the error of estimating β-emitters in the body would increase as the ^{137}Cs from fall-out increased. Dr. Rundo said that at present body contents of ^{137}Cs from fall-out were as high as they had ever been and he had recently measured 70 nc. of ^{90}Sr in one person with an estimated standard error of ±30 per cent.

At the conclusion of the symposium Mr. Binks directed attention to a difficulty which faced all those who had to deal with assessments of internal radiation exposure. This was to decide in what circumstances and with what frequency measurements of body radioactivity should be attempted. Clearly measurements need not be carried out in those cases where the amount of radionuclides used was so small that inhalation or ingestion of the whole amount could not lead to significant amounts relative to the maximum permissible body burdens. At higher levels it was not possible to relate the internal hazard with the amount of radionuclide used since other factors, for example, the degree of containment, affected the situation.

It would seem that sample measurements of body radioactivity were necessary to establish the likely levels of uptake into the body. Where a need to carry out assessments of body radioactivity was established, the next question was the frequency of testing. Some of the papers presented during the symposium had indicated how some organizations had attempted to meet these difficulties. Any decisions reached about general policy would greatly affect the future national effort in assessing internal radiation exposures.

MELTING AND FREEZING*

By Prof. A. R. Ubbelohde, C.B.E., F.R.S.

Department of Chemical Engineering and Chemical Technology, Imperial College of Science and Technology, London, S.W.7

MANY present-day problems concerning melting and freezing can be regarded as structural and statistical developments of the Boltzmann expression for the entropy of fusion, S_f:

$$S_f = R \ln W_L / W_S$$

Some authors have postulated a critical melting limit, such that $S_f \rightarrow 0$, and there is then no discontinuous increase of entropy on passing from the solid to the liquid

* Substance of a lecture recently given before the Göttingen Akademie der Wissenschaften, Germany.

state. But notwithstanding theoretical considerations, S_f is, in fact, positive for all cases of melting so far investigated experimentally.

Statistical interpretation of this conclusion about a discontinuous increase of entropy on passing from solid to liquid needs to be linked with modern knowledge about the structure of the two phases. For crystalline states of matter, structural information is often detailed and extensive. On the other hand, our knowledge about the structure of melts tends to be much less specific. Indeed, one outcome of modern investigations of melting is to clarify concepts and conclusions about the structure of the liquid state, in any event near the freezing-point.

A particularly straightforward outcome of the Boltzmann equation is to recognize that the increase of entropy on melting involves some kind of increase of disorder. With crystals of inert gas atoms, the possibilities are reduced to their simplest form. Owing to the change in volume and other rearrangements of atomic positions on melting, we need to consider an increase of vibrational entropy associated with changes in vibrational frequencies. Added to this are the changes in entropy arising from positional disorder associated with movements of atoms to equilibrium positions not on the ideal lattice.

In this simplest case:

$$S_f = S_{\text{vib}} + S_{\text{pos}}$$

A well-known theory of melting due to Lennard Jones and Devonshire[1] postulates $S_{\text{vib}} = 0$ and calculates S_{pos} in terms of one simple type of interstitial positional defect. Aspects of this theory which are particularly suggestive for modern developments include the following:

(1) As the temperature of a crystal increases, melting is the culmination of a normal process of thermal positional disordering. A discontinuous jump of entropy and density on passing from crystal to melt arises because the energy ε required to create a thermal defect decreases as the fraction n/N of defect sites increases. This co-operative interaction between n/N and ε is allowed for in the Lennard Jones–Devonshire theory by assuming a Bragg Williams type of dependence. The melt is thus regarded as a highly defective version of the crystal lattice, which is conveniently termed 'quasi-crystalline'.

(2) At the melting-point, the solid already contains a finite concentration of the same type of defect, the multiplication of which results in the jump from crystal to melt. In the case of crystalline argon, for example, the particular parameters assumed by Lennard Jones and Devonshire lead to a fraction $n/N \sim 0{\cdot}05$ in the solid at T_f.

The general implication is that premonitory formation of thermal defects in the crystals preceding the jump in properties on passing from crystal to melt is a normal feature of positional disordering. The extent of such pre-melting proves to be highly sensitive to the values assumed for specific parameters such as repulsion potential energy. Pre-melting phenomena are thus likely to vary in prominence in different kinds of crystals.

(3) Models for positional disorder with co-operative inter-action between the energy of defect creation ε and the fraction of defect sites n/N can be formulated, which are less naïve than the Bragg Williams procedure. Dislocations can be treated as co-operative defects, such that at T_f the crystal contains only a small fraction, and the melt a fraction near to unity[2]. Mathematical aspects of such a model are less amenable to elegant formulation than the Bragg Williams co-operative interaction used by Lennard Jones and Devonshire. For example, in a model for dislocation melting of metals[3,4], the necessary approximations are considerably harsher. It is interesting to note that this particular model leads to the conclusion:

$$S_f = S_{\text{pos}}\ (1{\cdot}08\ \text{e.u.}) + S_{\text{vib}}\ (0{\cdot}69\ \text{e.u.})$$

Dislocation models for melting may become important for their thermodynamic consequences, such as the finite contribution from S_{vib}. They may also become important in pointing to possible ways of bringing together thermodynamic with mechanical theories about melting. Some of the transport properties of liquid crystals[5], for example, may require dislocation theory for their interpretation. The Lindemann theory of vibrational instability, and other theories of shear instability, must essentially be recognized as mechanical theories of melting. It seems likely, though I will not attempt to justify the statement here, that for most crystals:

$$T_f\ (\text{mech.}) > T_f\ (\text{thermodynamic})$$

On the other hand, crystals of certain globular molecules become plastic[6] below T_f; for these, possibly:

$$T_f\ (\text{mech.}) < T_f\ (\text{thermodynamic})$$

(4) Theories of the increase of positional disorder on melting are directly applicable when this is the only mechanism of disordering. Unfortunately, crystals of the inert gases which are the best examples constitute only a minute part of the enormous diversity of crystal structures. More complex mechanisms of disordering must be considered when the structure of the crystals is less simple than those of inert gases. One fairly simple extension is found with molecular crystals, in which the units of structure are quasi-spherical, as, for example, in the group CH_4, CF_4, CCl_4, SiH_4. In such crystals, the molecular axes are found to assume specific orientations at low temperatures. However, these orientations randomize in the crystals above a transition temperature T_c below the melting-point T_f. The disordering of molecular axes takes place with an uptake of entropy of orientational disorder S_{orient} frequently by way of a λ-transformation in the crystals. (Much interesting work on structural aspects of λ transformations is making use of investigations on single crystals. These emphasize the importance of domains in such co-operative changes[7a]; but since their connexion with melting is indirect they will not be detailed here). In the range between T_c and T_f crystals in which the units of structure have disordered molecular axes behave as though these units of structure are spherical or 'globular'. The Lennard Jones–Devonshire calculations about melting can be extended to cover such cases likewise[7b] so that a reasonable theoretical discussion can now be presented of mechanisms of melting represented by the possibilities:

$$S_f = S_{\text{vib}} + S_{\text{pos}} + S_{\text{orient}}$$

A great merit of models of disordering on melting, of the type discussed, is that they serve as a workable norm, which makes the discussion of even more complex mechanisms of melting much clearer. As a start, it may be noted that even with more complex mechanisms of melting, X-ray investigations show that the melts are always positionally disordered with respect to the crystals. Consideration of these more complex mechanisms can be based on the simplifying assumption that operations of disordering are separable, that is:

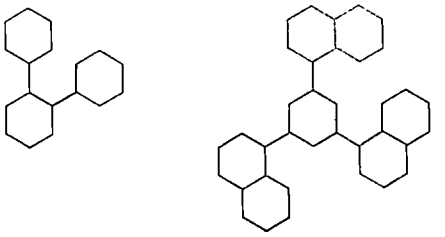
$$S_f = S_{\text{vib}} + S_{\text{pos}} + S_{\text{orient}} + S \ldots \text{additional mechanisms}$$

Additional Mechanisms of Melting

A characteristic feature of the theories just referred to is that the melt is treated as a highly defective crystal. The fact that the structure of the melt is referred to the crystal lattice warrants the description 'quasi crystalline'. In addition to their statistical theromodynamic significance, quasi crystalline models for melts are well known

and often used in their application to the calculation of transport properties of liquids. An increasing variety of melts is beginning to be recognized, however, for which a quasi-crystalline structure is grossly inadequate as a basis for calculation. Probably the longest known instance is the class of molecular crystals formed by flexible molecules, such as *n*-alkanes and their derivatives. When these flexible molecules are widely separated from one another, as in the dilute vapour phase, they assume various configurations of approximately equal energy, as a result of rotations about single C—C bonds. It used to be thought that stretched configurations were quite common even in dilute vapours, but actually collision processes in the gas suggest[8] that the molecules when widely separated from one another are predominantly crumpled, apparently so as to minimize Van der Waals potential energy terms. On passing from vapour to melt, the proportion of stretched configurations increases, but at all temperatures the liquid contains a mixture of forms. On passing from melt to crystal, in many cases a unique fully stretched configuration is selected for packing into the crystal lattice. The process of crystallization of the melt acts as a kind of molecular sieve. In such cases, an additional term appears in the summation of mechanisms of fusion which now reads:

$$S_f = S_{\text{vib}} + S_{\text{pos}} + S_{\text{orient}} + S_{\text{config}}$$



With large flexible molecules the number of configurational options can become very large, so that the increase of configurational entropy may swamp the more familiar mechanisms of fusion. This situation, which leads to convergence or limiting melting-points however large the molecule, is of great importance for the thermodynamic and mechanical properties of melts of thermo-plastic high polymers. Melting mechanisms of such solids will not, however, be detailed further here. From another aspect, these melts provide a clear instance of liquids the structure of which cannot even approximately be represented by reference to a crystal lattice. They are in fact anti-crystalline.

In discussing these and other types of melts that are definitely not quasi-crystalline it is sometimes convenient to regard them as generated from a hypothetical quasi-crystalline melt of the same molecules, which itself is formed from the crystals by one of the Lennard Jones operations already mentioned, that is:

$$\text{crystal} \xrightarrow{\text{(positional + orientational defects)}} \text{quasi-crystalline melt} \xrightarrow{\text{(configurational randomization of molecules)}} \text{Anti-crystalline melt}$$

Considerable thought and experimentation are being devoted at the present time to melts the structure of which departs progressively from a quasi-crystalline model, as they are cooled down to, and below, the freezing-point. Particular reference may be made to a number of different types of melts in which it seems likely that a fraction of the molecules pack into more or less transient clusters, of which the relaxation time for formation or dispersion is notably larger than the reciprocal of the hopping frequency for individual molecules in the quasi-crystalline melt. Reasons for such clustering can be quite diverse[9]. For example, in melts of H_2O hydrogen bonding appears to be the predominant cause. Melts of molecules with marked tendency to enmesh may form clusters even when only Van der Waals forces are operative. Particular attention to this simple geometrical possibility has been paid in some of our investigations on various polyphenyl molecules, including striking instances such as *o*-terphenyl (I) and *tri*-α-naphthylbenzene (II)[10].

Ionic melts with non-spherical anions such as silicates or nitrates provide further possibilities. In this very brief summary, I will only refer to some of the leading

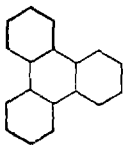
I II

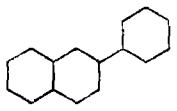
thermodynamic and structural considerations about consequences of cluster formation, regarded as a departure from quasi-crystalline structure of the melts. Essentially what is involved is the examination of the structure of melts in a region of temperatures on either side of and near the freezing-point T_f. As it happens, this is facilitated by the fact that when anti-crystalline features become prominent in the structure of a melt, it tends to supercool more readily. The group of problems to be discussed can conveniently be referred to as 'pre-freezing' effects.

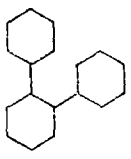
Conventional X-ray diffraction investigations in their present stage are of little use for revealing marked fluctuations in packing density in a melt, since the data are computed in terms of a single smoothing parameter, the radial distance r starting from any one centre. On the other hand, in simple cases transport properties such as viscosity yield useful information. Experimentally, this property has the advantage that its measurement can often be extended into supercooled regions well below T_f. Theoretically, viscosity is a convenient property for investigating anomalies of liquid structures, since if the molecules aggregate in any special way in small regions in a melt the bulk of which is quasi-crystalline, these aggregates or clusters can be treated like colloidal particles. This is because they are compelled to move together in fluid-flow so long as the relaxation time for their formation or dispersion is large compared with the relaxation time for the bulk of the same melt which is effectively quasi-crystalline. Following a theorem originally due to Einstein, the presence of such particles blocks a fraction φ of the 'fluid' volume. Provided that $\varphi \leqslant 0{\cdot}3$ approximately:

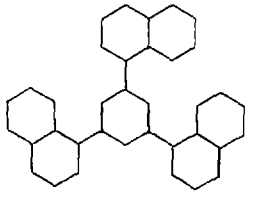
$$\frac{\eta_{\text{actual}}}{\eta_{\text{ideal}}} = 1 + 2{\cdot}5\varphi + 7\varphi^2 \qquad (1)$$

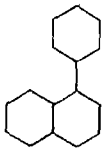
when the particle shape is spherical. In applying this expression to investigate cluster formation in melts, the assumption made is to treat the fluid as quasi-crystalline, with values of η_{ideal} obeying an Arrhenius type of expression:











$$\eta_{\text{ideal}} = A + B \exp(-E\eta/T) \qquad (2)$$

which is in fact followed closely not too near T_f by very many melts.

This particular approach to the examination of clustering receives considerable empirical support from viscosity data for a wide range of polyphenyl liquids. For simple polyphenyls, such as benzene, diphenyl, *p*-terphenyl, triphenylene and fluorene, the straight-line Arrhenius expression is followed quite closely over an extensive range of temperatures. On the other hand, when the repulsion envelopes of polyphenyls have marked re-entrant portions, as in the case already qnoted, large excess viscosities become apparent as the melt is cooled down to T_f and below it. At T_f some typical values of φ_f in the melt at the freezing-point are given in Table 1.

Although viscosity is a property which can be widely applied in this way, other more discriminating methods for examining the marked fluctuations of molecular packing which may be present in a melt are obviously desirable to elucidate non-quasi-crystalline structure. In brief:

Table 1. VOLUME FRACTION φ_f BLOCKED FOR FLOW BY CLUSTERING AT T_f

Molecule	T_f° C	φ_f
Triphenylene 	198·1	Nil
2-phenyl-naphthalene 	—	0·038
o-terphenyl 	55·5	0·58
1-3-5 tri-*α*-naphthylbenzene 	197·3	0·40
1-phenyl naphthalene 	Glass	0·55 even at 25° C

(1) Other transport properties such as heat and mass diffusion have been much less investigated than viscosity, particularly in the pre-freezing region. Anomalies in thermal conductance have been reported for *n*-alkanes and also for *o*-terphenyl[11] near T_f.

(2) In favourable cases, optical methods can be used. For example, in melts of alkanes detailed investigation of the infra-red absorption spectra should reveal any trends in the proportions of various configurational isomers, on approaching and traversing T_f. Similarly for melts of pyridine and *o*-chlorophenol changes in the Rayleigh line 'wings' as the temperature approaches and traverses T_f (ref. 12) can probably be attributed to cluster formation. Again, the ultra-violet absorption band E_2 of melts of alkali nitrates normally shows a shift of the position of the band peak with volume, and thus with temperature, in a uniform linear trend. But in certain mixtures which remain molten down to sufficiently lower temperatures, accelerated shifts are found. The onset of these roughly coincides with the temperatures at which the viscosities of the melts begin to show marked enhancement above the linear dependence indicated by equation (2) and may be plausibly attributed to the formation of transient clusters of higher density. The effects are particularly striking in mixed melts of nitrates which behave as practically ideal binary systems with respect to molar volumes[13].

In conclusion, the role of pre-freezing anomalies in the statistical thermodynamics of melting may be briefly indicated. As is well known, packing of the molecular units of structure on a regular three-dimensional crystal lattice leads to a reduction in enthalpy of the magnitude H_f per mole. At or below T_f, this lowered enthalpy outweighs the higher entropy of the melt so that the free energy $G_S = H_S - TS_S$ of the crystal is lower than that $G_L = H_L - TS_L$ of the melt, and the crystal is the stable phase. Consideration of fluctuation theory leads to three refinements of this classical thermodynamic statement about melting.

(1) Even the crystal shows a proportion of defect sites in thermal equilibrium. The proportion n/N of such sites at T_f is large enough to become obvious as a pre-melting effect only for exceptional crystal structures.

(2) Micro-regions with crystalline arrangement can exist in equilibrium in the melt and constitute the so-called crystal nuclei. Their concentration and size are determined *inter alia* by the temperature and by the interface energy σ_{SL} between the looser packing of the quasi-crystalline melt, and the denser packing in the micro-crystalline region.

(3) Starting with any one unit of structure in the melt, and packing successive units as close to it as possible, will generally lead to reductions in enthalpy comparable with H_f in magnitude. But unless this packing is made on a regular crystal lattice as in (2), as the aggregate or cluster grows it soon becomes necessary to include clefts or voids. For this reason, normally the decrease in enthalpy falls off more or less steeply to zero as the size of an aggregate increases, except for crystalline lattice packing. The greater freedom of arrangement in a melt may, however, permit molecules of exceptional shape, or with exceptional types of intermolecular force fields to pack closely in a cluster that is definitely anti-crystalline. This may permit favourable reductions in enthalpy for aggregates considerably larger than, say, in melts of inert gas atoms. In such cases, fluctuation theory indicates that such clusters will be formed progressively as the melt is cooled. Formation of anti-crystalline clusters appears to be a common cause for marked pre-freezing anomalies in certain types of melts. Reference has already been made to favourable examples in the polyphenyls. Anomalous packings not represented in the crystal state are likewise encountered in ionic melts. A striking instance has recently been reported in mixed systems of thallium and potassium halides[14]. New methods of study are likely to reveal many other examples.

CRYSTAL STRUCTURE OF HYDROXYAPATITE

By Dr. M. I. KAY and Prof. R. A. YOUNG
Georgia Institute of Technology, Atlanta, Georgia
AND
Dr. A. S. POSNER
Hospital for Special Surgery, Cornell University Medical College, New York

APATITES and related compounds are of fundamental importance in several areas, including the structural chemistry of hard tissue. Hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$) is the first compound to be examined in a programme which calls, in part, for detailed refinements of several of these materials.

The space group and unit cell dimensions are, respectively: $P6_3/m$ and $a = b = 9{\cdot}432$, $c = 6{\cdot}881$ as determined by Posner, Perloff and Diorio[1].

Neutron diffraction data were obtained at Oak Ridge National Laboratory on mineral hydroxyapatite mined in a Holly Springs, Georgia, foliated talc and serpentine quarry. The crystals were found on layers of foliated talc in serpentine as described by Mitchell, Faust, Hendricks and Reynolds[2]. Chemical analysis of a typical specimen gave the fluorine content as $0{\cdot}28 \pm 0{\cdot}01$ per cent by weight. The neutron data consist of 253 reflexions in the $hk0$ and hkl zones. The $|F|^2$ values are available on request. The X-ray data were those collected by Posner, Perloff and Diorio[1] on synthetic crystals with an integrating Weissenberg camera.

It was assumed that the previously determined structure[1] was correct except for the missing hydrogen atom. The overall structure of hydroxyapatite was discussed in ref. 1 and is indicated in Fig. 1 with the new results incorporated. Interest here centres on the OH's which occur in columns parallel to c. The main lines of the columns pass through the centres of Ca triangles which are on the mirror planes at $z = 1/4$ and $z = 3/4$. Successive triangles are rotated 60° about c. Fig. 2 illustrates both these features and some disorder features discussed later.

In a Fourier difference projection down the c axis the neutron data showed the hydrogen to be at $x = y = 0$. Line sections at $x = y = 0$ using X-ray and neutron data showed the oxygen to be displaced about 0·3 Å from the mirror plane at $z = 1/4$ (Fig. 1). This result leaves only 0·7 Å between half oxygens and implies a configuration in which only one of two possible positions is filled near each mirror plane. The close possible approach of the hydrogens ($< 0{\cdot}85$ Å) implies short-range ordering of the hydroxyls, a not unusual event for other groups (see, for example, the disordered structure of $NaNO_2$ (ref. 3)). Least-squares refinements on several models were carried out with the Busing, Martin and Levy programme[4]. Attempts to refine with no mirror plane ($P6_3$) ended in failure. By refinement on scale factors of hydrogen atoms it was shown that, within experimental error, none of the OH's straddles the mirror plane. The diffraction data thus lead to two models which are indistinguishable on the basis of these data alone: (1) in the 'disordered column'

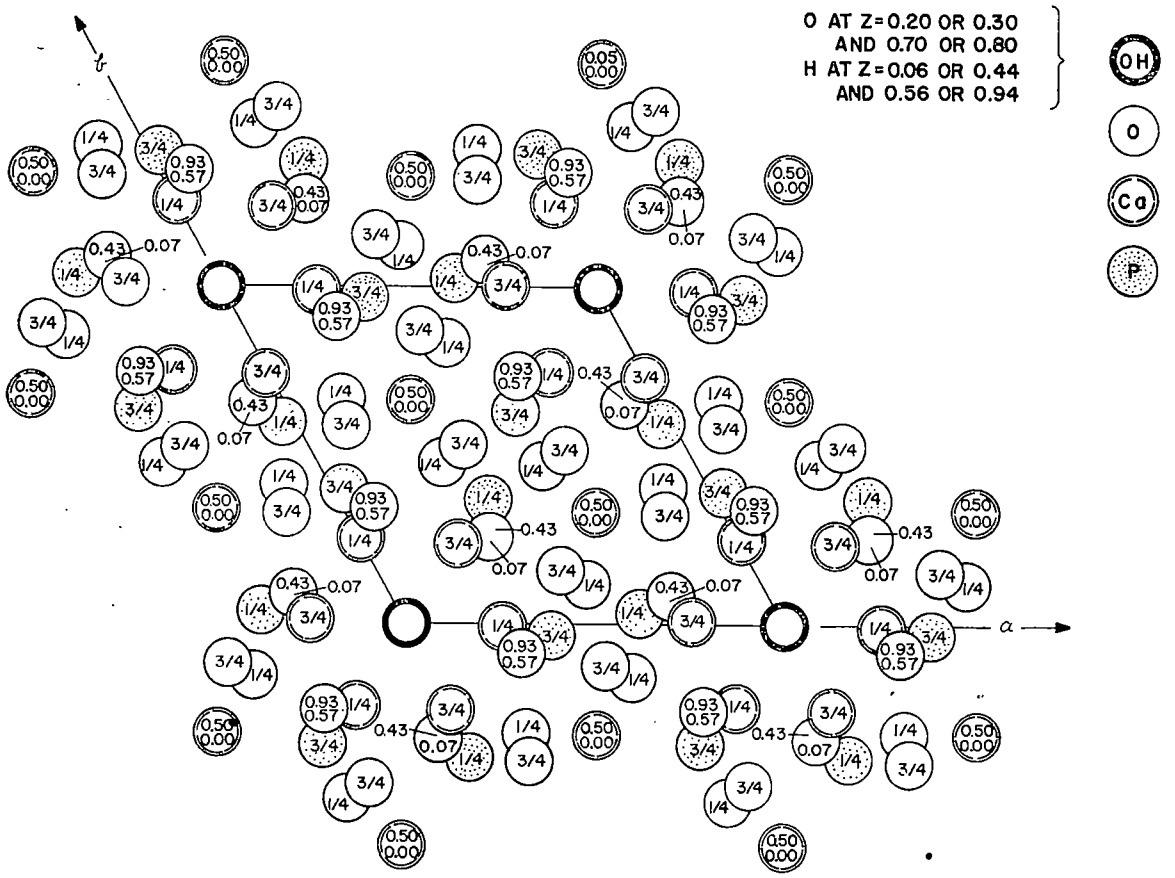

Fig. 1. Hydroxyapatite structure projected on x, y plane

model the orientation of the OH's is reversed at various places within a column; (2) in the 'ordered column' model all the OH's in a given column are oriented the same way, but the choice of orientation is random.

A refinement of the X-ray data gave results very similar to the neutron data. The old X-ray results (based on refinements with isotropic temperature factors), new X-ray results and neutron diffraction results are presented in Table 1. A diagram of the structure is presented in Fig. 1 and the close approaches are given in Table 2.

The final $R = \frac{\Sigma \, | \, |F_0| - |F_c| \, |}{\Sigma \, |F_0|} = 0{\cdot}075$ for the X-ray results and $R' = \frac{\Sigma \, | \, |F_0|^2 - |F_c|^2 \, |}{\Sigma \, |F_0|^2} = 0{\cdot}055$ for the neutron data after correction for extinction. The extinction correction used was the rough approximation:

$$|F_{corr}|^2 = |F_{obs}|^2 (1 - (5{\cdot}6 \times 10^{-6})I)$$

I is the number of counts in the peak. The correction was almost a factor of two for some reflexions. Thus there are some systematic errors in the neutron data. However, it is not expected that these errors affect positions by more than a few thousandths Å. The effects of extinction should be mitigated by the fact that, when the correction was large, the complete extinction correction was added to the standard deviation of the observed data in the least-squares refinement. Where the correction was moderate, one-half the correction was added to the standard deviation.

Correlations among parameters presented no difficulties; the largest correlation coefficient, that between β_{11} of the hydroxyl oxygen (O_H) and β_{11} of the hydrogen, was only 0·76.

It is interesting to note that, if refinement of the structure with an isotropic temperature factor and the X-ray data is carried out with the hydroxyl oxygen at 0·25 (that is, on the mirror plane), the ultimate agreement factor is the same as is obtained when the correct configuration is used; the positional error is suggested only by an unusually large β_{33} on the hydroxyl oxygen. The experimental evidence of the new, disordered positions for the hydroxyl oxygen, whether arising from ordered or disordered columns, is found partially in the X-ray difference map but more strongly in the neutron data. The latter give a hydrogen position that is consistent only with the new structure. This position of the hydrogen atom confirms Elliott's[6] polarized infra-red results indicating that the O—H bond direction is parallel to the c-axis.

The dimensions for the $PO_4^{\equiv}$ group are given in Table 2. Considering the standard deviations, the differences in P—O length are not considered significant, but the $PO_4^{\equiv}$ tetrahedron is probably slightly distorted.

In the discussion here, some conclusions depend on the thermal vibration parameters. While the value of these

* A standard deviation of 0·5 per cent in cell edge was assumed and probably overstates the error.
Note 1—If the lighter atom 'rides' on the heavier, the result is given in parentheses.
Note 2—Lengths repeated by symmetry.
Note 3—O_{III} is related to $O_{III'}$ by a mirror plane at $z = 1/4$.

may be somewhat in doubt, because of the over-simplified extinction correction and other systematic errors, the general trend of them is probably correct and their expected errors should not alter the conclusions. As evidence, compare the X-ray and neutron thermal parameters in OH.

The O—H distance was corrected[7] for thermal vibration on the assumption that the H 'rides' on the O. The result of 0·999 Å may be slightly large, but it is barely one standard deviation larger than the 0·984 obtained in $Ca(OH)_2$ by Busing and Levy[8].

The most significant results are found in the geometry of the O—H group, determined by means of the neutron diffraction data, and in the relationship of that group to its surroundings. The O of the O—H groups is located about 0·3 Å (on the average) above or below the triangle of Ca_{II}^{++} on the mirror plane at $z = 1/4$ and again at $z = 3/4$. The geometry is approximately similar to that found in $Ca(OH)_2$, but each side of this Ca_{II}^{++} triangle is 4·09 Å as compared to 3·59 Å in $Ca(OH)_2$. The Ca_{II}—O_H distance of 2·38 Å is, however, quite comparable to the Ca—O distance, 2·37 Å, in $Ca(OH)_2$. In other words, compared with the similar configuration in $Ca(OH)_2$, the Ca triangle in hydroxyapatite is pulled apart and the O—H drops closer to the Ca plane while essentially the same Ca—O distance is maintained. It will be noticed from the root mean square thermal vibration amplitudes of the hydroxyl group in the c direction, 0·18 Å (0·17 for O and 0·19 for H), that the OH group is able to move rather freely along the c-axis. This freedom would be expected as, being nearly perpendicular to the Ca_{II}—O_H direction, such motion may become relatively large without appreciably changing the Ca_{II}—O_H length. Perpendicular to the c-axis, however, the root mean square amplitude of thermal motion is 0·10 Å for O_H but 0·22 Å for H. Large rocking motion of the H about the O or the centre of mass of the system is thus indicated. Such large librational motion is consistent with the generally open nature of the structure in the neighbourhood of the H.

In the disordered column model a special structural circumstance may occur at one-half of the points where the direction of the O—H group is reversed. Fig. 2 indicates some of the possibilities. If OH groups were to extend toward each other from the average structure mirror planes at $z = 1/4$ and 3/4, the H's would be too close together. Thus it would appear that an OH should be missing at each such point. Such a site could either be vacant or contain a fluorine ion, F. Some fluorine has always been found in mineral hydroxyapatite. An F at the centre of the Ca triangle might be expected to have at least a slight attraction for the H of neighbouring OH's. Thus the presence of the F impurity might even be expected to produce disorder within the column and would, at the least, accommodate it. Because this disordered column model seems to provide such a convenient structural location and function for the fluorine impurity, one is tempted to prefer the disordered column over the ordered column model. From similar reasoning for the case of the fluorine-free synthetic apatite (for which only X-ray data are now available), it would seem that either vacancies must exist at these reversal points or the ordered column model should apply. Present data are inadequate for the determination of structural detail as fine as a reversal mechanism which need operate only in a small percentage of the unit cells, not all. Indeed, probably undetectable with present data, and, therefore, not yet to be ruled out, are conceivable reversal mechanisms involving: (1) an occasional O—H placed across the pseudo-mirror plane, or (2) an occasional O—H pair pointing generally toward each other from adjacent pseudo-mirror planes, but making a substantial angle with the c-axis in order that the H's do not approach each other too closely. Further neutron diffraction investigations relative to this structural detail are to be undertaken. Infra-red investigations now being done by ourselves and others[9] on details of the O—H stretching region of the spectrum may also illuminate this point.

It is felt that, in contrast to disordered OH in hydroxyapatite, the F in fluorapatite is probably at $z = 1/4$, where present structure determinations[10] place it. (The crystal structure of fluorapatite is at present under investigation with precision X-ray techniques.) This structural difference may be the principal cause of the increased relative stability of fluorapatite, particularly if the disordered column, rather than the ordered column, model is the correct one. In biological apatites, significance of this stability difference has been shown recently by *in vivo* bone apatite growth-rate investigations[11,12]. There, fluoride-containing bone apatite grew more rapidly and to larger crystallite size than did the fluoride-free specimens.

In summary, the crystal structure of hydroxyapatite has been determined from X-ray and neutron diffraction data. The result agrees generally with the earlier determination by Posner, Perloff and Diorio[1]. However, the O—H groups are disordered about the mirror planes at $z = 1/4$ and 3/4 with the oxygens about 0·3 Å from the mirror planes. The O—H direction always points away from the mirror plane. It is assumed that this feature may be correlated with the relative instability of hydroxyapatite as compared to fluorapatite.

We thank Drs. H. A. Levy and W. R. Busing, who placed their equipment and time at our disposal for the collection and reduction of the neutron data, and the Oak Ridge National Laboratories. We also thank Ephraim Segerman for advice concerning the ordered column model, Mr. Alan Friedman for help in carrying out some of the calculations, Mrs. Charlene Lampkin of Lockheed-Georgia Corporation for running refinements on the IBM 7094 computer, and Prof. W. E. Moody for obtaining the crystal.

THE LIMESTONE ASSIMILATION HYPOTHESIS

IN a recent communication describing the synthesis of feldspathoids by feldspar-carbonate reactions, R. D. Schuiling[1] discussed the limestone-syntexis hypothesis, which proposes that rock-types under-saturated in silica can form from silica-over-saturated magmas by assimilation of limestone, and he stated that, from a physico-chemcial point of view, there was no essential difference between this process and one involving the assimilation of sialic material by a carbonatite magma. He remarked that: "Nobody, however, seems to have tried to verify experimentally such proposed processes". The purposes of this communication are: (1) to direct attention to an extensive series of experiments by Stansfield[2] which were aimed directly at testing assimilation hypotheses, and which included investigation of the extent and products of assimilation of limestone by various igneous melts; (2) to outline some of our own experiments[3,4] which are concerned with the origin of carbonatites and associated alkalic rocks and, inevitably therefore, with the limestone assimilation hypothesis as well; (3) to comment on some points of Schuiling's communication.

Stansfield[5] advanced field and chemical evidence to support his conclusion that the okaite at St. Joseph du Lac, Quebec, had originated by assimilation of Grenville limestone by a magma of unknown type (possibly peridotite), and he suggested that, in general, rock magmas which yield melilite and monticellite on crystallization have dissolved considerable amounts of limestone. He later[2] conducted a series of fusion experiments in which ten different igneous rocks were made to assimilate materials representing pure sediments. The igneous rocks varied in composition from granite to peridotite, and the sedimentary materials were calcite, kaolin, and glass sand. The igneous rocks and calcite were mixed in various proportions, and the mixtures were fused in 57 experiments at temperatures ranging from 1,270° C to 1,470° C. Most of the products of the experimental assimilation of calcite contained glass, and all were characterized by melilites. No feldspathoids were developed. The experiments thus support the hypothesis that melilitic rocks may be derived by limestone assimilation, but provide no evidence for the hypothesis that feldspathoidal magmas or rocks can be produced in the same way. Stansfield concluded tentatively that 10 or 15 per cent may be the limit of foreign rock matter which can be assimilated by natural magmas.

The frequent association of alkalic igneous rocks and carbonate rocks is thoroughly documented, but the present status of the limestone assimilation hypothesis is somewhat more uncertain than it was when Shand[6] stated the case in 1946. This is due in no small measure to the accumulation of evidence confirming that most carbonatites have characteristics distinguishing them from sedimentary, metamorphic, or xenolithic limestones[7-9]. The discovery of Wyllie and Tuttle[10] that relatively low temperature melts in the system CaO—CO_2—H_2O are capable of precipitating calcite through a wide pressure range has provided experimental verification for the magmatic origin of carbonatites where the field evidence is consistent with such an origin. Following these results, our experimental work has been extended into a number of carbonate–silicate systems aimed at elucidating the relationships between carbonate rocks and the associated alkalic igneous rocks. One approach adopted has been to add mineral molecules such as nepheline, albite, and orthoclase to the synthetic carbonatite magmas with compositions on the join $CaCO_3$—$Ca(OH)_2$. At the other end of the composition joins so obtained, we have information about the effect of adding $CaCO_3$, $Ca(OH)_2$, or mixtures of these components, on the melting relationships of nepheline, albite, and orthoclase, respectively, in the presence of water vapour under pressure.

These experiments confirm that less than 5 weight per cent of the silicate molecules dissolve in the synthetic carbonatite magma at 1 kilobar pressure, before liquidus temperatures rise steeply from the low-temperature part of the liquidus[3], with melilite being a prominent crystalline phase. The wide stability range of melilite, in terms of both compositions of mixtures and of temperature, is a notable feature of the systems[4]. At the other ends of the composition joins, the sequence of phase assemblages produced by adding CaO-rich material to the feldspathic melts indicates that desilication does occur. The assemblage albite + liquid is first replaced by wollastonite + plagioclase + liquid, and further addition of lime then stabilizes nepheline, but not in the presence of liquid. More CaO-rich subsolidus assemblages contain the silica-undersaturated phases melilite, rankinite and larnite. Phase assemblages involving orthoclase are replaced initially by assemblages with leucite and then kalsilite. Relationships in the nepheline join are complicated by the formation of phases with the cancrinite and nosclite structures.

The work completed in the feldspar composition joins shows that they are divided into three parts. At the feldspathic ends of the joins, solidus temperatures in the presence of water vapour under pressure are moderate, and at the synthetic carbonatite ends of the joins, melting temperatures are even lower. In the central portions of the joins, however, melting temperatures are higher than at either end of the join. This means that addition of CaO-rich material to a feldspathic liquid causes crystallization of the liquid before desilication proceeds very far, and development of feldspathoids results from sub-solidus reaction.

We are dealing with sections through a six-component system, and the actual phase assemblages encountered are complex. The phases present were identified by optical methods, and by X-ray powder diffraction patterns. The petrographic microscope is an indispensable instrument in phase equilibrium investigations, and we have found it unwise to rely on X-ray diffraction patterns for the recognition of phases.

Schuiling's experiments[1] were conducted at 1,000° C at 1 atmosphere, and ours were conducted at temperatures between 550° C and 950° C at 1 kilobar pressure, with 25 weight per cent water added to the mixtures[3,4]. Schuiling reported that his reactions "proceed rather rapidly", whereas our subsolidus reaction rates were slow, and we were not confident that equilibrium had been achieved in some mixtures even after runs of 3 weeks' duration. The difference may be due in part to our lower temperature range, but probably a more important factor is the difference between the two experimental approaches. $CaCO_3$ dissociates at 894° C at atmospheric pressure, and it is therefore likely that in Schuiling's experiments the calcite or dolomite dissociated while the mixtures were being heated to 1,000° C. The reactions which then occurred during the 25 h of the experiments were reactions between the feldspars and oxides rather than the listed reactions between feldspars and carbonates. In order to investigate the reaction between feldspar and calcite at 1 atmosphere pressure, the mixture should be heated at a temperature of less than 894° C. In our closed-system experiments, the carbon dioxide released during the reactions mixed with the water vapour and remained in the system, and the vapour, or gaseous phase, was an essential phase in each reaction. This is a significant

difference between the two experimental approaches, because we have found that in systems containing a vapour phase composed essentially of water and carbon dioxide, the nature of reactions may be controlled as much by variations in the composition of the vapour phase as by variations in temperature and pressure[4]. One example is relevant to the process of limestone assimilation.

Wyllie and Tuttle[11] have shown experimentally that carbon dioxide is only slightly soluble in feldspathic and granitic liquids. They showed further that the effect of adding carbon dioxide to hydrated feldspathic or granitic liquids is to extract the water from the liquid, thus raising its solidus temperature considerably and causing crystallization by a quenching process. The process of limestone assimilation necessarily involves the release of large quantities of carbon dioxide and the crystallization so induced in a granitic magma would offset the tendency of the assimilation process to yield a desilicated magma.

Thus, for two different reasons based on two different sets of experiments, it appears to us that assimilation of limestone by a granitic magma would lead to crystallization of the magma, with the concomitant development of some lime silicates (wollastonite in our experiments) and the formation of slightly undersilicated rocks only locally, in the vicinity of the limestone undergoing assimilation. There is petrological evidence that such processes do occur on a local scale. A third serious problem facing the syntexis hypothesis concerns the availability of heat for the assimilation process. This has been discussed at length by Bowen[13], and it appears that this heat must be supplied by crystallization of the magma.

In discussing the limestone assimilation hypothesis there is an important distinction to be drawn between the formation of an under-silicated, alkalic magma, and the formation of an under-silicated, alkalic rock from a magma which is forced to crystallize as syntexis proceeds. We agree with Schuiling's conclusions[1] that the production of leucite and nepheline from feldspars by reaction with carbonates is an experimentally proved possibility. The process of desilication of a magma, however, is limited by the three factors which have been discussed here, and we believe, therefore, that the development of an alkalic magma by limestone syntexis is unlikely. The formation of alkalic, silica-under-saturated rocks in reaction zones at limestone contacts with silica-saturated igneous rocks is to be expected. Continued sub-solidus reaction between contiguous limestone and igneous rock could produce more feldspathoids in the igneous rock, but there is no evidence known to us that sub-solidus reactions of this kind occur extensively in nature.

After a detailed review of the literature it appears to us that there is little convincing evidence to support the view that limestone assimilation has led to the formation of alkalic magmas, or even of alkalic igneous rocks except as contact phenomena. As Schuiling has remarked, the regional association of alkalic rock-types and carbonatites is indeed suggestive, but reasonable attempts have been made to explain this association by many processes other than that of assimilation of sialic material by carbonatite magma or that of assimilation of limestone by magmas[7–9,14]. In the limestone assimilation hypothesis attention is directed to addition of CaO-rich material and desilication of the magma. In the associations involving carbonatites, on the other hand, there is evidence suggesting that, for the development of some alkalic rocks, migration of alkalis may be as significant as desilication processes.

There are so many processes possible on paper which could conceivably account for the petrology and field relations of the associations of alkalic igneous rocks and carbonate rocks that the need for experimental testing of the various hypotheses is urgent. We conclude that evidence from our high-pressure phase equilibrium investigations weighs against the limestone assimilation hypothesis, but this conclusion may have to be modified in the light of future results, and by more detailed investigations by Schuiling on specific reactions performed at atmospheric pressure.

Several years ago a young geologist in a lecture at a congress proposed a theory highly differing from earlier views expressed by Eskola. A member of the audience wished to defend these earlier views and tried to enlist the help of Prof. Eskola, who stoically remarked: "I proposed this theory fifty years ago, and it is about time to have a new theory instead". Watkinson and Wyllie, in their comments on one point of my communication[1], seem to feel the same with regard to the limestone assimilation hypothesis, which has reached about the same age, and which is, according to them, only "one of the many processes possible on paper which could conceivably account for the petrology and field relations of the associations of alkalic igneous rocks and carbonate rocks". They thereby reduce the only theory which really has been demonstrated in the field with a degree of certainty, scarcely ever achieved by petrological observation, to the common level of guesses, unsupported by facts.

I am grateful for their remarks about Stansfield's experiments, which had escaped my attention, and which on the whole seem to have received only scant or no attention at all by such proponents of the limestone–syntexis theory as Daly and Shand.

Stansfield's experiments[2] at temperatures between 1,270° and 1,470° C with mixtures of igneous rocks and limestone produced melilite-bearing assemblages and are accepted by Watkinson and Wyllie as evidence that melilitic rocks may be derived by limestone assimilation. It would seem logical then if they would accept my experiments at 1,000° C (geologically speaking, a more acceptable temperature) with mixtures of, admittedly simplified, igneous rocks and carbonates producing feldspathoid-bearing assemblages as supporting evidence that feldspathoidal rocks may also be derived by limestone assimilation. Instead, they try to show that, as the carbonates I used in my experiments are probably dissociated before any appreciable reaction occurs (the same applies *a fortiori* to Stansfield's experiments), there would be a significant difference in the reaction mechanism of the experiments of Watkinson and Wyllie and mine. As reaction mechanisms are not well understood anyhow, and as it is, also, not very clear in what way Nature works, a more fruitful approach is from the thermodynamical side. This has the additional advantage that we can state quantitatively what Watkinson and Wyllie state qualitatively by say-

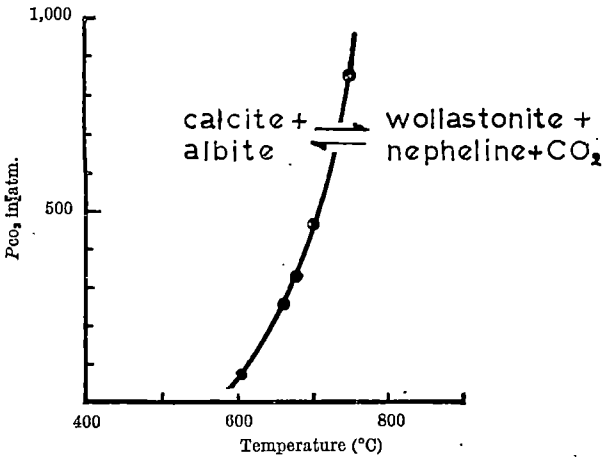

Fig. 1. Computed equilibrium curve for the reaction: calcite + albite ⇌ wollastonite + nepheline + CO_2 ↗

ing that "the nature of reactions may be controlled as much by variations in the composition of the vapour phase as by variations in temperature and pressure".

We have calculated the equilibrium curve of the reaction:

albite + calcite → nepheline + wollastonite + CO_2 ↗

by starting with the known curve for:

quartz + calcite → wollastonite + CO_2 ↗

and the value of $*\mu_d^5 = -2{,}500 - 0{\cdot}05\,T$ cal. for the reaction:

½ nepheline + quartz → ½ albite[3]

With the aid of these data and those for the fugacities of carbon dioxide at high pressures and temperatures[4], we can calculate the curve given in Fig. 1; any mixture of albite + calcite under conditions on the right-hand side of this curve will react to nepheline + wollastonite, independent of any supposed reaction mechanism and total composition of the vapour phase.

In fact, runs of three weeks produced the association:

nepheline + wollastonite

at 605° and 650° C at 1,000 atm. vapour pressure starting from mixtures of $Ca(OH)_2$ (portlandite) and albite; apparently the small, but not infinitely small, partial pressure of carbon dioxide (present in occluded air, solved in the water, and undoubtedly too in the $Ca(OH)_2$ at the moment the gold capsules were sealed) was not sufficiently high to prevent complete reaction. Analogous experiments with microcline + portlandite at 605° and 650° C at 1,000 atm. vapour pressure produced only small amounts of leucite + wollastonite at 605° C, but reaction was complete at 650° C. This is in agreement with the fact that $*\mu$ of the reaction:

quartz + leucite → potash feldspar

is significantly greater than the $*\mu$ of the corresponding reaction:

quartz + ½ nepheline → ½ albite,

which means that in carbonate–feldspar mixtures nepheline will form at lower temperatures than leucite, or at higher pressures of carbon dioxide at the same temperature. We may thus expect to find in Nature the association:

nepheline–sanidine–wollastonite

but not the chemically equivalent association:

leucite–albite–wollastonite[3]

The second line of reasoning of Watkinson and Wyllie against the concept of the limestone assimilation hypothesis consists in stating that the addition of carbon dioxide (which of necessity must be released on reaction with carbonates) results in the crystallization of the 'granitic' liquids by a quenching process. The word 'quenching' may be a somewhat unfortunate choice of term, as it is normally used only for rapid cooling; in their instance it is meant as "bringing about rapid crystallization by the addition of carbon dioxide", if I have understood these authors' use of the term correctly. Their argument gives rise to some speculation. From the pioneering experimental work of Wyllie and Tuttle[5–7] on the system $Ca(OH)_2$—$CaCO_3$—H_2O, petrologists have probably gained the impression that the composition of carbonatite magma would lie somewhere near the eutectic of portlandite and calcite, which is scarcely probable, as portlandite has never been found as a constituent of carbonatites; that it has never been found can be interpreted best by saying that carbonatites are probably high up on the calcite side of the join $Ca(OH)_2$—$CaCO_3$, which means that their melting temperatures are more probably of the order of 1,000° C instead of eutectic temperatures about 700° C, depending on the presence of impurities.

When such a carbonatite melt encounters water-rich sialic material, the addition of water will leave us with a magma which has acquired a large amount of superheat thanks to its new composition. We may thus say that Watkinson and Wyllie's argument works one way when applied to assimilation of limestone by sialic magma, and the other way when applied to Holmes's[8] hypothesis of assimilation of sialic material by carbonatite magma. If the system is open with respect to carbon dioxide, the argument becomes immaterial.

I see no reason why carbonatites and alkaline rocks should ever acquire their high explosiveness because of high pressure of carbon dioxide, unless such pressures are developed at the loci of magma-generation; it is not reasonable to assume that they should (against what is certainly a carbon dioxide pressure gradient), attract carbon dioxide from their surroundings. We see no other possibility but that they generate it themselves by the breakdown of carbonates; the equilibrium pressure of carbon dioxide for calcite at 1,000° C is only ~3 atm. (ref. 9); on the other hand, the equilibrium pressure of carbon dioxide for a reaction like calcite + albite → nepheline + wollastonite + carbon dioxide will be of the order of 10^4 atm. at the same temperature. Only by carbonate–silicate reactions (including the formation in melilite, monticellite, larnite, etc., mentioned by Watkinson and Wyllie) can we explain high pressures of carbon dioxide, and I am therefore still in favour of the limestone–syntexis theory, or its alternative, sial–syntexis by carbonatite magma.

This does not mean that I wish to exclude other petrogenetical processes, like alkali-transfer; I have repeatedly[10–12] invoked alkali-migration as a petrogenetical process.

I thank Mr. Vink for assistance in the computation of the equilibrium curve of Fig. 1.

INACTIVATION OF CHYMOTRYPSIN IN AQUEOUS SOLUTION BY ATOMIC HYDROGEN

By Dr. LORNA K. MEE
Department of Radiotherapeutics, University of Cambridge
AND
Dr. GIL NAVON and Prof. GABRIEL STEIN
Department of Physical Chemistry, Hebrew University, Jerusalem

A COMPARISON of the effect of heat, chemicals and ultra-violet light with that of ionizing radiations on the kinetic parameters of chymotrypsin indicated the varying mechanisms of different degrees of specificity by which these agents produce the inactivation observed[1]. Ionizing radiations act on solutes in dilute aqueous solution through labile reactive intermediates produced in the water and it is often difficult to determine which of the intermediates is responsible for a particular reaction. A recent extension[2] of the work of Butler and Robins[3] suggests that the mechanism of inactivation of trypsin in dilute solution by ionizing radiations is likely to include an effective process of reduction as well as oxidation. The lack or reversal of the oxygen effect on other enzyme systems[1,4–6] indicates that reductive processes may be involved in inactivation by ionizing radiations.

Recently a method was developed[7] for the quantitative study of the reactions of hydrogen atoms with acceptors in aqueous solution, using a high-frequency electrodeless discharge to dissociate pure hydrogen gas into hydrogen atoms and passing these, under carefully controlled conditions, into aqueous solution. It was shown that the reactive species is identical in its reactions to hydrogen atoms produced by ionizing radiations or by ultra-violet light. In this method, however, hydrogen atoms are the only reactive species present, so that their specific action may be examined separately[8].

The present work attempts to establish whether hydrogen atoms have a specific effect on chymotrypsin by examining the effects on the kinetic parameters of the enzyme. Data on spectroscopic changes were used to support the kinetic evidence.

α-Chymotrypsin, obtained from Worthington Biochemical Corporation, was a crystalline preparation from bovine pancreas, the substrate, *N*-acetyl-l-tyrosine ethyl ester (ATEE), was from British Drug Houses, Ltd., and all chemicals were of analytical reagent quality.

Solutions of the enzyme were prepared in triple distilled water and the *p*H adjusted to *p*H 3 with dilute hydrochloric acid and to *p*H 6 with sodium hydroxide. The protein concentration was determined on the basis of a molar extinction coefficient of $2{\cdot}07 \times 10^3$ at 280 mμ. The solutions were treated with atomic hydrogen by first passing hydrogen gas through the system to eliminate oxygen and then lighting the discharge when hydrogen atoms passed through the solution. Control solutions were treated similarly, but without lighting the discharge. The esterase activity of chymotrypsin was determined, using ATEE as substrate, by a continuous potentiometric titration method as described previously[1,9]. The Michaelis constant, *Km*, and the maximum velocity, *V*, were determined from plots of reciprocal reaction velocities against reciprocal substrate concentrations, *S*, giving a linear dependence: $\frac{1}{V} = \frac{Km}{V}\frac{1}{S} + \frac{1}{V}$ (ref. 10). The inter-

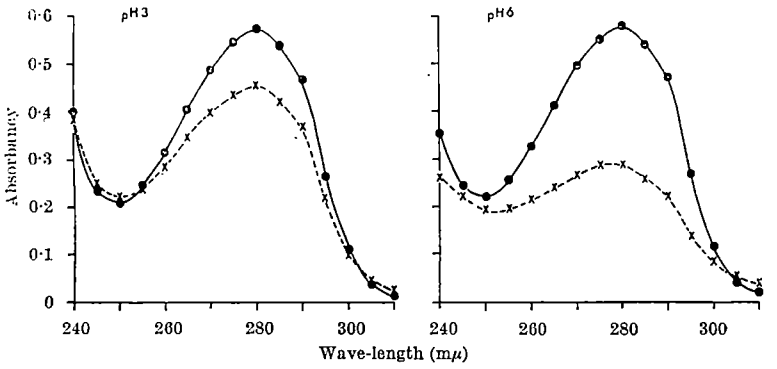

Fig. 3. Effect of hydrogen atom treatment of chymotrypsin in solution (2×10^{-5} M) on the absorption spectrum. ●, Control; ×, hydrogen atom treated—dose 8×10^{-4} moles/l.

cept on the vertical axis gives $1/V$ and on the horizontal axis $-\frac{1}{Km}$.

The Lineweaver–Burk[10] plots show that at *p*H 3 (Fig. 1) and *p*H 6 (Fig. 2) V is decreased considerably without change in Km, indicating that treatment of the enzyme with hydrogen atoms produces an all-or-none loss of activity. Fig. 3 shows the change in the absorption spectrum of chymotrypsin. The absorption peak at 280 mμ, which is contributed mainly by tryptophan residues in chymotrypsin, decreases considerably under the action of hydrogen atoms, but changes in other parts of the spectrum are relatively small. The decrease in activity and changes in the absorption spectrum are comparable with those obtained with trypsin at a similar concentration, *p*H and total dose of hydrogen atoms[11].

The inactivation of chymotrypsin by hydrogen atoms resembles the inactivation of the enzyme by heat, urea or 2537 Å ultra-violet light, which produce changes in V alone[1]. Ionizing radiations, longer wave-lengths of ultra-violet light[1] and Fenton's reagent[12] produce changes in Km, as well as in V, indicating the formation of partially damaged molecules, whereas the action of peroxides—peracetic acid[1] or hydrogen peroxide[12]—produces changes in Km without change in V. The radicals and molecular products resulting from the irradiation of water, which might be involved in the inactivation of chymotrypsin, include solvated electrons, e^-_{aq}, hydrogen atoms, hydrogen peroxide, as well as some molecular, non-reactive hydrogen. Initially, most of the reducing species are in the form of e^-_{aq}, which can be converted into hydrogen atoms at acid or neutral *p*H values; in the presence of oxygen, O_2^- and HO_2 radicals are formed from e^-_{aq} and hydrogen atoms depending on the *p*H. The reaction of e^-_{aq}, hydrogen and O_2^- with the enzyme may all result in reduction, HO_2, OH and H_2O_2 in oxidation. By virtue of their strong H—OH bond formation (~118 kcal/1 mol), OH radicals may attack and oxidize indiscriminately peripheral bonds, such as CH bonds, on the enzyme, modifying it without complete inactivation. Fenton's reagent, which produces OH radicals, acts similarly, only some of the reacting radicals producing complete inactivation: peroxides appear to cause mainly peripheral modification.

The results presented here are consistent with the assumption that hydrogen atoms, which are produced also in solutions irradiated with ionizing radiations, may specifically inactivate chymotrypsin, their reaction with it being more selective than that of the more reactive oxidizing OH radicals. Hydrogen atoms appear to attack specifically disulphide bonds in trypsin[11] and some evidence has been obtained for a similar effect in chymotrypsin.

The observations on the changes in the absorption spectrum of chymotrypsin support the conclusion of a selective attack by hydrogen atoms. The 280-mμ peak, which is contributed mainly by tryptophan residues in chymotrypsin, is decreased considerably, without significant changes in the absorption spectrum elsewhere. Compared with this selectivity, X-ray irradiation causes some decrease at 280 mμ, but increase at other wave-lengths[1], which may be accounted for by light scattering from aggregates formed[13] and result possibly from peripheral oxidative attack on other parts of the molecule.

For ionizing radiations, energy transfer within the protein molecule specifically to certain bonds, such as disulphide, has been postulated to account for efficient inactivation[14]. The present results and other recent work[15,16] indicate that this assumption may not be necessary and that the observed selectivity may be accounted for by specific reductive processes, mediated by radicals.

We thank Prof. J. S. Mitchell for having enabled us to carry out this co-operative work and for his advice. One of us (L. K. M.) was supported by a travel grant from the British Empire Cancer Campaign for Research, making it possible for her to accept the hospitality of the Department of Physical Chemistry of the Hebrew University of Jerusalem. This work was supported by the Biology Division, U.S. Atomic Energy Commission.

RADIOACTIVE STRONTIUM CONTENT OF RAINFALL

By Dr. E. BAKÁCS-POLGÁR and I. KURCZ-CSIKY
State Institute of Hygiene, Budapest, Hungary

THE development of a simple procedure for the convenient determination of strontium in rainfall, the essence of which was the successful separation of strontium from barium by methods more simple than the usual ones, has already been reported[1].

The determination of radioactive barium is necessary for the estimation of the time of nuclear explosion, for directly after such an explosion the amount of barium-140 atoms present in the atmosphere is 1870 times that of strontium-90. This ratio changes constantly on account

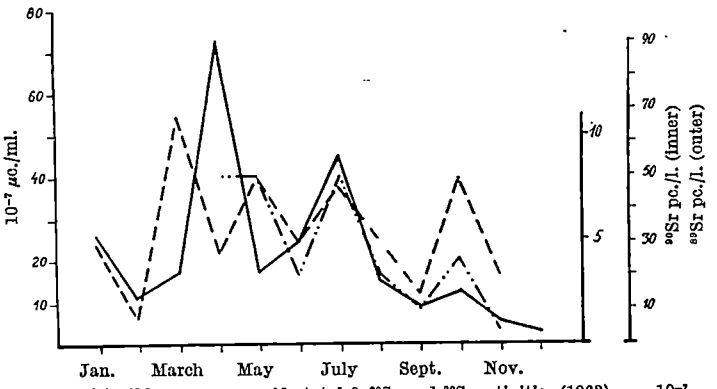

Fig. 1. Monthly average specific total-β, ^{89}Sr and ^{90}Sr activities (1963). —, 10^{-7} μc./ml.; — — —, ^{90}Sr pc./l.; — · · —, ^{89}Sr pc./l.

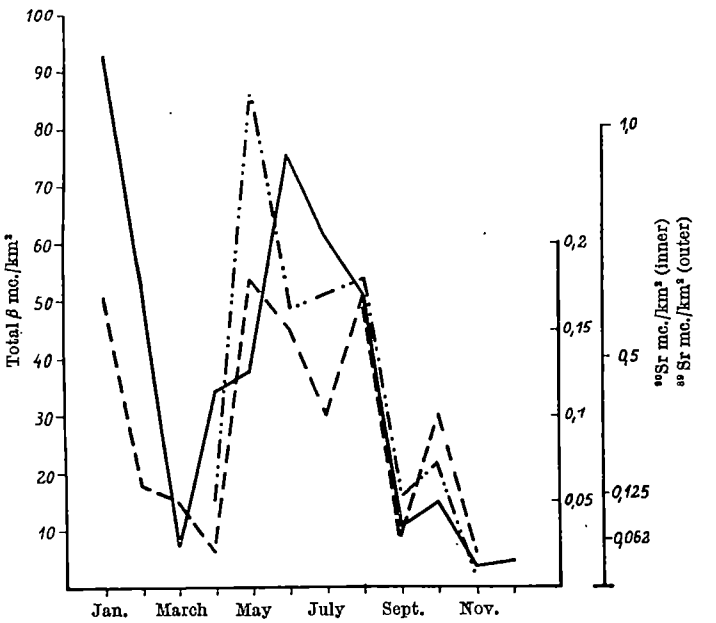

Fig. 2. Total-β, ^{89}Sr and ^{90}Sr activities, carried to the ground by rainfall (mc./km²) (1963). —, total β; — —, ^{90}Sr; — · · —, ^{89}Sr

of the different half-lives. The time of the explosion can be calculated from the ratio of both elements present in the atmosphere at the time of any measurement. The half-life of radioactive barium is 12·8 days; hence the determination of the quantity of this element would be of some value only soon after an explosion. However, if the aim of an investigation is to examine monthly average values—as it is in the case recorded here—then this possibility may be disregarded. So the course of separation by chemical means is substantially shortened by the omission of the separation of barium.

To 3 l. of filtered water is added some strontium carrier and evaporated to about 200 ml. For the elimination of foreign activities 5 mg Fe^{III} (as ferric chloride), and for the masking of calcium a calculated amount of ethylenediamine tetraacetic acid (EDTA), are added. The solution is made alkaline and the precipitated hydroxides are filtered off. Strontium is precipitated as carbonate. This precipitate is dissolved in hydrochloric acid, neutralized and precipitated in a weakly acetic acid medium as the oxalate. The precipitate is collected on a filter candle, washed and dried, and its weight and activity measured; the latter only after a period of about three weeks. This interval is necessary to make possible the recovery of radioactive equilibrium between strontium-90 and yttrium-90, which is, as a matter of course, disturbed by the process of chemical separation. For the improvement of radiochemical purity it is convenient to repeat the separation.

Since strontium-90 is always accompanied by some strontium-89 and yttrium-90, any measurements on strontium activity will give the sum of the three respective activities. For the individual measurement of the activities of single isotopes, yttrium should be separated from strontium to render possible determination of its activity. This activity represents also at the same time the activity of strontium-90, since with radioactive equilibria the activities of parent and daughter elements are equal. The activity of strontium-89 is calculated by difference.

The principle of the separation of yttrium is briefly as follows:

(1) Yttrium is separated from strontium most frequently by means of the differential solubility of the hydroxides of both elements. However, for this type of separation the oxalates must be decomposed first. Oxidation of the oxalates is effected by evaporation with concentrated nitric acid. It is convenient to repeat the separation via the hydroxides several times. Yttrium is separated at last from boiling N/10 nitric acid medium as the oxalate. The precipitates separating at different temperatures will contain different quantities of water of crystallization. The composition of the precipitate separating at 100° C corresponds to the formula: $Y_2(C_2O_4)_3 \cdot 2H_2O$ (ref. 2). In the given circumstances any traces of strontium present in the system do not precipitate.

(2) Attempts have been made to circumvent the evaporation of concentrated nitric acid by solving the task of separation on the basis of the differential solubilities of the oxalates, rather than that of hydroxides as is generally used. (Particulars of these experiments will be published elsewhere.) Yttrium oxalate separates from dilute nitric acid medium, whereas strontium remains dissolved. Separation was also found to be more conveniently achieved at 40° C, rather than at 100° C, since in the former case a precipitate composed of $Y_2(C_2O_4)_3 \cdot 10H_2O$ will separate.

Yttrium oxalate is collected as usual on a filter candle, washed with cold water, dried with alcohol and ether, and its activity measured. The activity values are plotted on semi-logarithmic paper as a function of time. The activity value extrapolated to zero supplies the activity at the time of separation. The activity values measured at different times will lie only on the same straight line, if the separated yttrium is radiochemically pure.

At the beginning of the year of these experiments procedure No. 1 was used; however, in the second half of the same year the more simple method No. 2 was applied for the separation of yttrium.

The results of measurements effected during January–December 1963 are summarized in Table 1. Besides the specific activities of strontium-89 and strontium-90, the

Dec. 1963							2·5	3·89

quantity of monthly rainfall per square metre is given, as well as the amount of strontium-89 and strontium-90 expressed in mc./km². The ratio $^{89}Sr/^{90}Sr$ is also registered. This ratio can also be applied to some extent for the estimation of the time of an explosion; but it does not give such an exact result as does the ratio $^{140}Ba/^{90}Sr$, partly because the half-life of barium-140 is shorter ($T\frac{1}{2}$ = 12·8 days) than that of strontium-90 ($T\frac{1}{2}$ = 50·3 days), partly because the ratio $^{89}Sr/^{90}Sr$ amounts to 185 at the moment of an explosion; however, the ratio $^{140}Ba/^{90}Sr$ is as high as 1840. Activity of strontium-90 of stratospheric origin may also be misleading.

In Fig. 1 the monthly total specific β-activity values of atmospheric origin are summarized in units of 10^{-7} μc./ml. as well as the monthly specific activities of strontium-89 and strontium-90, respectively, in pc./l. From April onwards the curves follow similar courses, hence the strontium-89 content of the atmospheric rainfall changes in proportion with the total activities. It is striking that the strontium-89 and strontium-90 contents of rainfall in November are practically equal—a fact which can be attributed to the stopping, at that time, of nuclear explosions.

In Fig. 2 the sums of total specific β-activities as well as the monthly averages of strontium-89 and strontium-90 activities are compared. It may well be seen that the January rainfall practically washed out the atmosphere, and strontium-90 activity, as well as all other β-activities, which have been falling to the ground, are similarly high. The February rainfall brought scarcely any activity to the ground. The spring maximum presents itself in May, but for radioactive strontium it is far better expressed than for the total activities, and, in fact, the total β-activities carried to the ground with the rainfall in June are very much greater than those during the spring. The autumn minima present themselves markedly and can be attributed not only to the usual seasonal fluctuation, but also to the stopping of the nuclear weapon experiments. The relatively high October values must probably be regarded as a consequence of stratospheric penetration.

From November 1962 onwards, the radiostrontium content of atmospheric rainfall was checked with the method developed by us.

All investigations carried out by us so far show partly that only a very minute fraction of the activity of atmospheric rainfall is derived from both dangerous isotopes; partly it was generally experienced because in the first place the amount of strontium-89, but also a certain amount of strontium-90, changes proportionally to the total β-activity of the atmospheric rainfall. This partially supports the fact, well known from the literature, that the radioactive strontium content of fall-out is present chiefly in soluble form, namely, the measurement of total activity is carried out with shaken-up water samples rather than with samples which had been previously filtered, whereas strontium contents were determined out of filtered water. On the other hand, it is shown that, in the course of wide-range, present-day determinations, the estimation of total activities supplies practically reliable and satisfactory results.

METABOLISM OF COUMARIN BY A MICRO-ORGANISM: O-COUMARIC ACID AS AN INTERMEDIATE BETWEEN COUMARIN AND MELILOTIC ACID

By Dr. CARL C. LEVY
Dermatology Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland

IT has been shown in an earlier work[1] that a species of *Arthrobacter*, isolated from soil and utilizing coumarin as the sole carbon source, deposited l-tyrosine in the culture medium. In the course of an investigation attempting to find intermediates in this conversion, a highly specific enzyme, NADH : *o*-coumarate oxidoreductase, was partially purified from extracts of the organism[2]. This enzyme was found to catalyse the stoichiometric reduction of *o*-coumaric acid to melilotic acid with the concomitant oxidation of NADH[2]. The evidence linking both *o*-coumaric and melilotic acids to coumarin, however, was based primarily on the spectral changes coumarin underwent during enzymatic attack, and secondarily, on the high degree of specificity exhibited by NADH: *o*-coumarate oxidoreductase towards *o*-coumaric acid. This was so in spite of the fact that the organism from which the enzyme was obtained had been grown exclusively on coumarin. The purpose of the present work is to demonstrate the occurrence of both *o*-coumaric and melilotic acids in the culture medium of the organism, and by isotope dilution experiments to show the order of their appearance as actual degradation products of coumarin.

The conditions of culture and the means of gathering the organism have been described elsewhere[1,2]. Similarly, methods for the preparation of crude enzyme extracts, as well as the partial purification of NADH : *o*-coumarate oxidoreductase also have been described[2].

Two litres of culture medium taken from a 16-h old culture were reduced by vacuum distillation to 50 ml., filtered, and the filtrate acidified to *p*H 1. The phenolic constituents of the media were extracted 3 times with 50 ml. portions of diethyl ether, and the combined ether extracts brought to a small volume. This material was chromatographed overnight on Whatman 3 *MM* paper using 1-propanol–15 N NH_4OH (7:3) as developing solvent. When viewed under ultra-violet light (267 mμ), the dried chromatogram exhibited a number of fluorescent and quenching bands. Of particular interest were a yellow fluorescent band (R_F 0·42) and an absorbing or quenching one (R_F 0·70). Both bands were eluted from the paper with water and the fluorescent band was co-chromatographed with an authentic sample of *o*-coumaric acid in three different solvent systems, giving a single spot in each one (1-propanol–15 N NH_4OH (7 : 3), R_F 0·47; 2-propanol–15 N NH_4OH–water (8:1:1), R_F 0·35: methylethylketone-water–diethylamine (921:77:2), R_F 0·15). Similarly, the quenching band, when co-chromatographed in the above-mentioned solvent systems with authentic melilotic acid, gave a single spot in each case (1-propanol–15 N NH_4OH, R_F 0·70; 2-propanol–15 NH_4OH–water, R_F 0·60; methylethylketone–water–diethylamine, R_F 0·38).

The ultra-violet absorption spectra in acid and alkali of the yellow band were identical with those of *o*-coumaric acid in similar solvents. In a like manner, the ultra-violet spectra of the quenching band were identical with those of melilotic acid under acidic and alkaline conditions. From the foregoing, it is concluded that the yellow fluorescent band contained *o*-coumaric acid whereas the absorbing or quenching band contained melilotic acid.

Once having established that both *o*-coumaric and melilotic acids were intermediates in coumarin degradation, the sequence in which these compounds arose was determined by isotope dilution investigations. Crude

extracts of the organism were incubated with buffer and coumarin-^{3}H (Volk Radiochemical Co.) both in the presence and absence of NADH.

Both reaction mixtures were kept at 30° for 1 h, and at various time-intervals (see Tables 1 and 2). 1-ml. aliquots were withdrawn and placed in a 15-ml. centrifuge tube containing 0·2 ml. of 2 N HCl. The precipitated protein was removed by high-speed centrifugation and the clear supernatant solution extracted three times with equal volumes of diethyl ether. The combined ether extracts were evaporated to a small volume and applied on Whatman 3 *MM* paper. One μmole each of unlabelled *o*-coumaric and melilotic acids were applied over the ether extract and the mixture chromatographed overnight using 1-propanol–15 N NH_4OH as developing solvent. Both *o*-coumaric and melilotic acids were detected and eluted as described earlier. These compounds were then re-chromatographed in two additional solvents (2-propanol–15 N NH_4OH–H_2O and then methylethylketone–H_2O–diethylamine) to constant specific activity. The eluate removed from the last chromatogram of each compound was taken to dryness and the residue dissolved in 2 ml. of absolute methanol. An aliquot of this solution was counted in a Tri-Carb scintillation counter. In the absence of NADH, the activities found in each of the compounds (at the time intervals shown) are recorded in Table 1.

Table 1. Products of the Enzymatic Degradation of Coumarin-^{3}H in the Absence of NADH

Product	Incubation time (min)			
	10	20	30	60
	(c.p.m.)			
o-Coumaric acid	16,000	38,000	63,000	170,000
Melilotic acid	2,200	3,800	4,200	4,000

The reaction mixture consisted of 750 mμmoles of coumarin-^{3}H, 1·5 ml. of crude enzyme (15 mg protein) and 3·4 ml. of 0·05 M phosphate buffer, *p*H 7·3, in a total volume of 5·0 ml.

Approximately 12 per cent of the original activity administered as coumarin-^{3}H ($2·6 \times 10^6$ c.p.m.) was recovered in the combined activities of both acids. It is apparent, however, that only a small percentage of this was actually present in melilotic acid, the greatest amount being found in *o*-coumaric acid. Moreover, the data in Table 1 indicate that the reaction giving rise to melilotic acid was, in fact, finished at the end of 20 min, presumably because of the utilization of endogenous NADH. Undegraded coumarin accounted for some 40 per cent of the remainder of the original activity, and the rest was lost, probably by mechanical means, through three chromatographic runs. When NADH was included in the reaction mixture, the results (Table 2) were strikingly different.

Table 2. Products of the Enzymatic Degradation of Coumarin-^{3}H in the Presence of NADH

Product	Incubation time (min)			
	10	20	30	60
	(c.p.m.)			
o-Coumaric acid	46,000	90,000	140,000	250,000
Melilotic acid	50,000	150,000	320,000	580,000

The reaction mixture consisted of 750 mμmoles of coumarin-^{3}H, 1·5 μmoles of NADH, 1·5 ml. of crude enzyme (15 mg of protein) and 2·9 ml. of 0·05 M phosphate buffer, *p*H 7·3, in a total volume of 5·0 ml.

At the end of the first 10 min of incubation, both compounds were labelled to about the same extent, but 10 min later the activity in melilotic acid had surpassed that within *o*-coumaric acid. Finally, at the end of an hour, there was somewhat over twice the activity in the former compound as in the latter. It should be noted, moreover, that the counts within each of the acids was greater than in the previous experiment. In fact, the combined total activity within the two compounds accounted for about 60 per cent of the original activity. Another important difference between these two experiments is that with NADH added, coumarin had been completely utilized. This indicates that, with respect to the degradation of coumarin, the absence of NADH is rate-limiting. When boiled enzyme was used, either in the presence or absence of NADH, coumarin remained undegraded. The evidence presented above suggests that *o*-coumaric acid is one of the early products formed during coumarin degradation, and that it is the reduction of this compound in the presence of NADH which gives rise to melilotic acid. This view is further substantiated by the results of the next series of investigations summarized in Tables 3 and 4.

Table 3. Conversion of *o*-Coumaric-^{3}H Acid to Melilotic-^{3}H Acid

Enzyme	*o*-Coumaric-^{3}H acid (c.p.m./μmole)	Melilotic-^{3}H acid (c.p.m./μmole)
Crude extract	$2·8 \times 10^4$	$2·63 \times 10^4$
$NADH_2$–*o*-coumarate oxidoreductase (30-fold purified)	$2·8 \times 10^4$	$2·7 \times 10^4$

When crude extract was used, the reaction mixture consisted of the following; 2·1 μmoles of *o*-coumaric-^{3}H acid; 1·5 ml. (15 mg of enzyme protein) of enzyme; 4·0 μmoles of NADH and 5·5 ml. of 0·05 M phosphate buffer, *p*H 7·3. The entire mixture was contained in a total volume of 10 ml. In the second experiment (that is, with partially purified enzyme) all constituents of the reaction mixture were the same as in the first, except that 1·0 ml. of enzyme was used. Both reaction mixtures were incubated at 30° for 30 min and then the reactions stopped by the addition of 1 ml. of 6 N HCl. The protein was removed by centrifugation and the phenolic constituents of each reaction mixture were removed by ether extraction. The ether extracts were each chromatographed through 3 solvent systems (as described in the text) until melilotic acid reached constant specific activity.

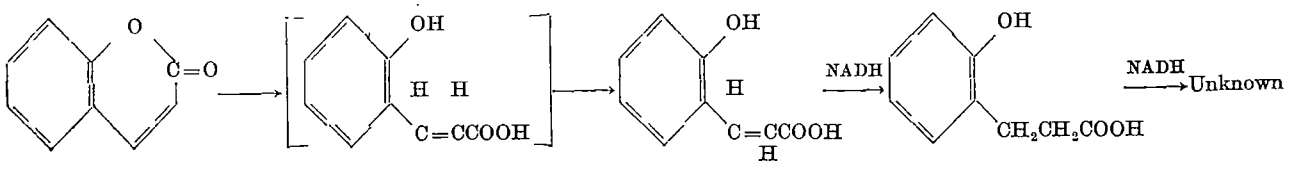

Table 4. Irreversibility of NADH–*o*-Coumarate Oxidoreductase with Melilotic Acid as Substrate

Enzyme	Melilotic acid (c.p.m./μmole)	*o*-Coumaric acid (c.p.m.)
Crude extract	$1·8 \times 10^4$	12
$NADH_2$–*o*-coumarate oxidoreductase (30-fold purified)	$1·8 \times 10^4$	55

The reaction mixture consisted of 1·5 μmoles of melilotic-^{3}H acid; 1·5 ml. of crude extract (15 mg of enzyme protein); 3·0 μmoles of NAD and 500 μmoles of phosphate buffer *p*H 7·3 in a total volume of 10 ml. In the partially purified system only 1·0 ml. of enzyme was used; all other constituents were the same. Both reaction vessels were incubated at 30° for 2 h and the reactions stopped by the addition of 1 ml. of 6 N HCl. The phenolic constituents of the reaction were extracted with ether. To each ether extract, 1 μmole of *o*-coumaric acid was added, and the mixtures chromatographed as described in the text. The *o*-coumaric acid was eluted from the last chromatogram with methanol and counted. The data in the table under *o*-coumaric acid represent counts above background.

In the first study (Table 3), *o*-coumaric acid of known specific activity was incubated either with crude extract or with thirty-fold purified NADH : *o*-coumarate oxidoreductase[2]. In both cases the specific activity of the melilotic acid recovered from the reaction mixture was the same as that of the substrate, *o*-coumaric acid. With both preparations, between 70 and 80 per cent of the *o*-coumaric acid present initially was utilized at the end of 30 min. Only with the crude preparation, however, were products (that is, quenching bands on the first chromatogram) other than melilotic acid seen. These were derived, presumably, from the further degradation of melilotic acid. When the reverse of this system was examined, that is, when melilotic acid of known specific activity was incubated with either crude enzyme or a partially purified preparation in the presence of NAD, 90 per cent of the melilotic acid could be recovered at the end of a 2-h incubation period. No trace of *o*-coumaric acid could be found. Nor on addition of unlabelled *o*-coumaric acid to ether extracts of the reaction mixture and chromatography afterwards could any significant counts above background be found in the *o*-coumaric acid present on the chromatogram (Table 4). The enzyme system, NADH : *o*-coumarate oxidoreductase, appears then to be an irreversible one, that is, melilotic acid in the presence of NAD and enzyme could not be oxidized to *o*-coumaric acid.

When, however, melilotic acid was incubated with crude extract and NADH, and the reaction followed spectrophotometrically at 340 mμ, NADH was found to be rapidly oxidized. Subsequent chromatography of the reaction mixture revealed that essentially all the melilotic acid had disappeared and that a new quenching or absorbing band was present. The compound within this band gave a positive test with Evans's reagent for dihydroxyphenols and had after elution about the same R_Fs in the solvents used by Coulson and Evans[3] reported for 2,3-dihydroxyphenylpropionic acid. The exact nature of this compound and the enzyme affecting its transformation from melilotic acid is presently now being investigated.

Coumarin *cis*-Coumarinic acid *o*-Coumaric acid Melilotic acid

Fig. 1. Scheme for degradation of coumarin

Melilotic acid, as a degradation product of coumarin, has been reported by a number of workers in a variety of biological systems[4–6]. It has been shown, for example, by Kosuge and Conn[4] that melilotic acid arose in the sweet clover as a result of the reduction of coumarin to dihydrocoumarin with the subsequent hydrolysis of this latter compound. In a microbial system, on the other hand, Fernley and Evans[5] felt that melilotic acid was derived from coumarin via *cis*-coumarinic acid although no enzymatic evidence for this transformation was presented. In the work recorded here, both *o*-coumaric and melilotic acids have been identified in the culture medium of an organism growing on coumarin. Further, by isotope dilution techniques, the labelling pattern of the two compounds obtained from enzymatic degradation of coumarin-^{3}H indicates quite clearly that *o*-coumaric acid is formed before melilotic acid and that, in fact, it is the reduction of the former compound which gives rise to melilotic acid. Earlier attempts to show the reverse of this reaction, that is the ability of the enzyme NADH–*o*-coumarate oxidoreductase to catalyse the oxidation of melilotic acid with the concomitant reduction of NAD, were unsuccessful[2]. These results were borne out when melilotic-^{3}H acid was used as a substrate for the enzyme. In the presence of NAD and enzyme, even after a 2-h incubation period, some 90 per cent of the melilotic-^{3}H acid could be recovered.

The results of these investigations suggest a tentative scheme (Fig. 1) for the degradation of coumarin. The first reaction would be, presumably, the hydrolytic cleavage between the oxygen and carbon atoms of the pyrone ring. Since coumarin is *cis*-coumarinic lactone, the product of this first reaction would be *cis*-coumarinic acid, a compound which, in fact, cannot exist as the free acid. Moreover, at neutrality, the partially purified NADH : *o*-coumarate oxidoreductase does not catalyse the reduction of coumarin[2], so that the ring opening reaction is probably accompanied by some kind of isomerization in which *cis*-coumarinic acid is transformed to its trans isomer, *o*-coumaric acid. This compound is reduced to melilotic acid in the presence of NADH: *o*-coumarate oxidoreductase and NADH. In turn, melilotic acid is converted by another enzyme, also utilizing NADH as a co-factor, to an as yet unknown compound.

METABOLISM OF EHRLICH ASCITES CARCINOMA CELLS GROWN IN MICE ON A MEAT DIET

By JUDITH ILAN* and ROSE M. JOHNSTONE

McGill–Montreal General Hospital Research Institute, Montreal, Canada

IT has been reported[1] that mice kept on a diet of fresh or boiled meat eventually develop an anæmia. In young mice the anæmia is accompanied by depressed growth and osteoporosis[2]. The typical course of infection with *Plasmodium vinckei* is suppressed in mice kept on this diet[1]. In normal mice the cæcum is packed with *Trichomonas muris*, but in these anæmic animals the flagellates are scarce[3].

Our aim was to determine whether mice confined to a diet of meat for six weeks could support tumour growth. Eighteen such animals as well as eighteen controls from the same batch were injected intraperitoneally with Ehrlich ascites cells. Eight days later the mice were killed, the ascitic fluid collected and the volume of packed cells determined in each group. In the control mice the average volume of packed cells per mouse was 3·2 ml., whereas in mice on the meat diet the average volume was 1·7 ml.

In view of the foregoing finding, possible metabolic differences between Ehrlich ascites cells grown in mice fed meat, and cells derived from mice on a normal diet, were investigated. Respiration, glycolysis and fatty acid oxidation were not significantly different in the two types of Ehrlich ascites cells. The incorporation of compounds labelled with carbon-14 into proteins of the Ehrlich ascites cells was examined in the two types of cells (Table 1). The methods used for preparing and incubating the cells have been described previously[4]. The incorporations of carbon-14 labelled precursors into proteins and nucleic acids were made as described previously[5] using the extraction procedure of Schneider[6].

From the results in Table 1, it is apparent that there is a reduced incorporation of carbon-14 from formate into protein of cells grown in mice on a meat diet. This effect is peculiar to formate as it is not observed when the amino-acids glycine-1-^{14}C, methionine methyl-^{14}C or serine-U-^{14}C are added to the medium.

It is known that formate is incorporated into proteins as serine[7]. Since incorporation of carbon-14 from formate but not from serine is reduced in cells from mice on a meat diet, it seemed possible that serine synthesis was reduced in these cells. To measure serine synthesis the

Table 1. INCORPORATION OF ^{14}C FROM FORMATE-^{14}C, SERINE-U-^{14}C, METHIONINE-METHYL-^{14}C AND GLYCINE-1-^{14}C INTO PROTEIN

Radioactive precursors added	Cells from mice on normal diet. c.p.m./mg protein	Cells from mice on a meat diet. c.p.m./mg protein
Formate 1 mM 120,000 counts/min/μmole	641	388
Serine 2 mM 16,700 counts/min/μmole	142	193
Methionine 2 mM 41,700 counts/min/μmole	166	206
Glycine 2 mM 16,700 counts/min/μmole	210	209

0·1 ml. of packed cells was incubated for 2 h at 37° C in Krebs-Ringer bicarbonate buffer, *p*H 7·4, containing 10 mM glucose[5] and 1 mM glutamine, with a gas phase of O_2/CO_2 (95:5). Each figure given is the average of at least six separate determinations. For each experiment, cells from three to six mice of each type were pooled.

* Present address: Department of Biochemistry, Columbia University, New York, N.Y.

acid-soluble fraction containing nucleotides and amino-acids was extracted from the cells with 6 per cent cold trichloroacetic acid after incubation with formate-^{14}C (ref. 5). To separate nucleotides from amino-acids the trichloroacetic acid extract was first extracted with ether to remove the acid and a portion of the latter was passed through a column (1 cm × 1 cm) of 'Dowex-50' in the H+ form (12 per cent cross-linked, 200–400 mesh). The resin was washed extensively with water to remove nucleotides and then washed with 4 ml. of 2 N ammonium hydroxide[5]. It has previously been shown that serine is the only amino-acid formed from formate-^{14}C under the present experimental conditions and is eluted from the resin with NH_4OH (ref. 5).

The results in Table 2 show that serine synthesis from formate-^{14}C is appreciably reduced in cells from mice on a meat diet.

Table 2. Incorporation of ^{14}C from Formate-^{14}C into Free Serine and Soluble Nucleotides

	Serine c.p.m./mg dry wt. of tissue	Nucleotides c.p.m./mg dry wt. of tissue	Nucleic acids c.p.m./mg dry wt. of tissue
Cells from mice on meat	125	348	349
Cells from control mice	226	327	366

Conditions as in Table 1. No. of determinations and pooling of cells as in Table 1.

Since formate is incorporated into nucleotides and nucleic acids as well, we examined the incorporation of formate into these substances in the two types of Ehrlich ascites cells. The results in Table 2 show that formate-^{14}C incorporation into nucleotides and nucleic acids is not reduced in cells from mice on a meat diet.

To ascertain whether the inhibition in the incorporation of formate-^{14}C into protein and serine was peculiar to ascites cells grown in animals on a meat diet or whether it occurred in other tissues as well, formate-^{14}C utilization by kidney cortex slices, liver slices and spleen slices were examined.

In the livers of mice on a meat diet incorporation of formate-^{14}C into all fractions was lower than in controls. This may be due to the fact that the livers were very fatty[8]. In Table 3 it is apparent that the incorporation into nucleic acids in kidney was appreciably lower in meat-fed animals. It seems that in contrast to tumour cells where biosynthesis of serine from C_1 units is most sensitive to the diet, nucleic acid biosynthesis is more vulnerable

Table 3. Incorporation of Formate-^{14}C into Protein, Serine, Nucleotides and Nucleic Acids of Mouse Spleen and Kidney Slices

		Protein c.p.m./mg protein	Serine c.p.m./mg dry wt. of tissue	Nucleotides c.p.m./mg dry wt. of tissue	Nucleic acids c.p.m./mg dry wt. of tissue
Normal mice	Spleen	98·0	28·3	22·8	50·6
	Kidney	53·6	37·6	79·2	36·8
Mice on meat	Spleen	100·0	38·5	29·5	46·1
	Kidney	40·8	44·3	85·0	24·6

Tissue slices were incubated for 2 h at 37° C in Krebs-Ringer phosphate buffer, *p*H 7·4, with a gas phase of pure oxygen. Other conditions were as in previous experiments. Each figure represents an average value of at least four determinations.

in kidney. In spleen, little alteration from normal utilization of formate-^{14}C is observed in mice on a meat diet.

It has been shown[8,9] that both the anæmia and osteoporosis are prevented and cured by the addition of calcium salts to the meat diet. The addition of copper, as the sulphate salt, both prevented and cured the anæmia and partially prevented the osteoporosis. Manganese partially prevented the osteoporosis. We therefore examined the effects of these ions on formate-^{14}C incorporation into the protein of these cells. The presence of the ions did not enhance formate incorporation into protein.

Serine synthesis is the only aspect of C_1 metabolism, so far examined, which is affected in the tumour cells by the dietary regimen of the host. Although formate utilization for serine and purine synthesis has a common pathway so far as the formation of $N^{5,10}$-methenyl-tetrahydrofolic acid (THFA.) is concerned, for serine synthesis this compound must be further reduced to methylene-THFA[10]. It may be that the requirements for this last step are different in tumours from those in normal tissue and that the dietary deficiency brings about a decreased availability of the factors involved in the reduction of the formyltetrahydrofolic acid derivative.

We thank Prof. J. H. Quastel for his advice and help. This work was supported by the National Cancer Institute of Canada.

RECOMBINATION BETWEEN PROTAN AND DEUTAN GENES; DATA ON THEIR RELATIVE POSITIONS IN RESPECT OF THE G6PD LOCUS

By M. SINISCALCO* and G. FILIPPI
Department of Genetics, Faculty of Science, University of Rome, Italy
AND
B. LATTE
Ospedale Civile, Nuoro, Italy

VAN DER DONCK and Verriest[1] have reported the occurrence of two normal sons in a sibship which included two deuteranopic and one protanomalous son. They concluded that this situation could be best explained by assuming that the mother of the propositi was a double heterozygous (in repulsion phase) at the deutan and protan loci, and that the two normal sons therefore had to be considered as recombinants.

Kalmus[2] emphasized the importance of such a finding in relation to the debated hypothesis[3] that the genes for protan and deutan colour blindness pertain to different loci, and, on the basis of the available data on the linkage relationship between either of these genes and that responsible for the G6PD-deficiency[4–6], he put forward the hypothesis that the sequence of the three corresponding loci along the X-chromosome should be:

Deutan.....G6PD.....Protan

During a large-scale collection of data in Sardinia for the mapping of the X-chromosome[7,8,10], we have recently observed an extremely interesting pedigree (Fig. 1) that

* Present address: Department of Human Genetics, University of Leiden, Holland.

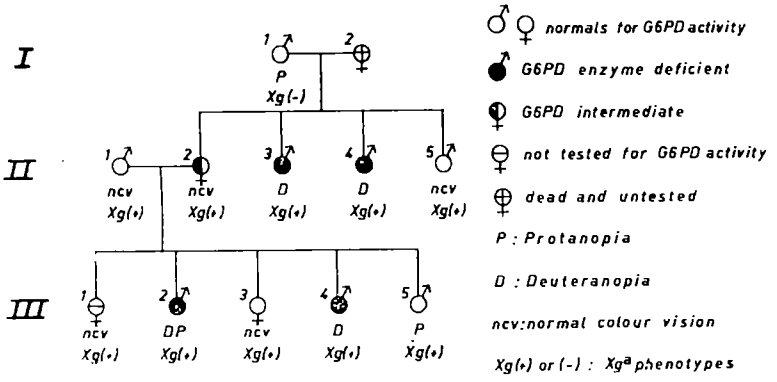

Fig. 1. Pedigree AH3–Irgoli (Sardinia)

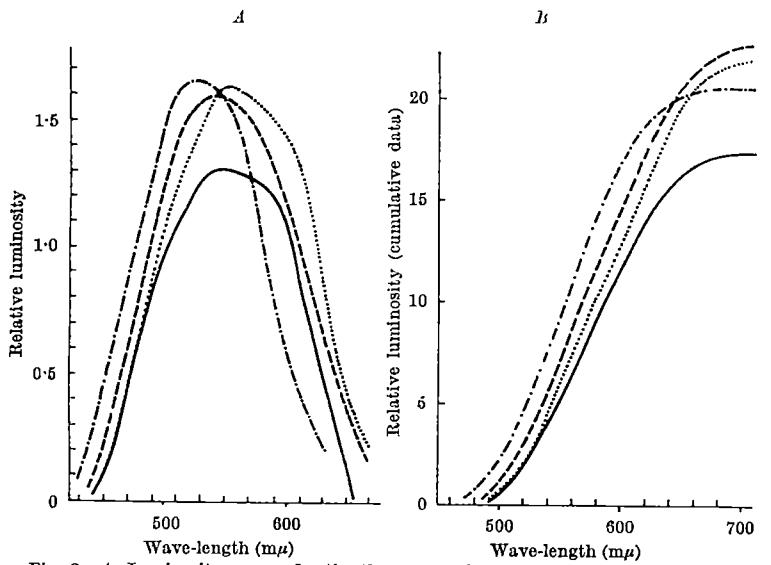

Fig. 2. *A*, Luminosity curves for the three colour-blind sibs and a normal control. Relative luminosity is expressed in logarithmic units. Each curve is the average of three separate sets of measurements; *B*, The data in *A* converted into cumulative curves. ·····, Normal control; —·—·—, III_5; – – – –, III_4; ——, III_2

throws light on this particular issue and strongly supports Dr. Kalmus's conclusions.

The propositus in our pedigree was a protanope child (III_5) with normal G6PD activity. The family was further investigated in the hope that it would yield data concerning the linkage comparison between protan and Xg^a loci.

To our surprise the next child examined in the same sibship (III_4) was found to be a definite deuteranope and to be G6PD-deficient. Among the maternal uncles two were deuteranope and enzyme deficient (II_3 and II_4) and one was normal for both traits. The maternal grandfather (I_1) was protanope and G6PD normal like his youngest grandson (the propositus III_5). Thus there was no doubt that the mother (II_2), who had normal colour vision and showed intermediate G6PD activity, must have carried on one of her X-chromosomes the genes for deuteranopia and G6PD-deficiency and, on the other, that for protanopia together with the normal G6PD allele.

However, when the eldest son (III_2) was examined, he was found to be enzyme deficient, like his deuteranopic uncles and younger brother, but showed colour vision defects of a peculiar nature[9]. He was repeatedly tested with the H.R.R. and the Ishihara plates as well as with the Farnsworth dychotomique test, and always gave ambiguous results, in the sense that each time he made mistakes typical for protanopia and/or for deuteranopia.

The same answer was obtained when later on he was tested with the 100 Hue–Farnsworth–Munsell test and with the Anomaloscope of Nagel (Ophthalmological Clinic of the University of Rome).

Finally, a scotopic luminosity curve was performed on each of the three sons, and on a normal control, at the National Institute of Optics at Arcetri (Florence).

As may be seen from Fig. 2, the curve for the protanope child (III_5) shows low red luminosity values and a shift of the maximum towards a shorter wave-length, whereas the curves of the deuteranope child (III_4) and of the normal control were very similar, as was expected. The curve for the eldest son (III_2) is peculiar in that it overlaps with that of the normal control in the green-blue area, it shows a markedly reduced luminosity in the green-yellow area, and it approaches the shape of the protanope curve in the red area. The differences and similarities in shape of these four curves may perhaps be better appreciated if they are transformed into cumulative curves (Fig. 2*B*).

The obvious conclusion from all this is that the eldest son is carrying the genes for both protan and deutan colour blindness, and this implies that his X-chromosome is the result of a recombination between deutan and G6PD genes on one side and the protan gene on the other.

The discovery of a second family showing recombination between deutan and protan genes therefore confirms the duality of the corresponding loci and makes very likely the conclusion that their degree of linkage is rather loose. If this is so it follows also that the locus for G6PD-deficiency must be located between them since it is known, from independent investigations, that the G6PD gene behaves as if very closely linked to both the colour-vision genes though seemingly somewhat closer to the deutan locus[4–7].

Table 1 summarizes our own data bearing on this particular point. The linkage between G6PD and deutan loci is very close indeed and that between G6PD and protan loci seems slightly looser, but certainly not so loose as one would expect if the G6PD locus were located on the other side of the deutan locus.

Table 1. Linkage Data for G6PD-Deficiency, Deutan and Protan Colour-blindness
(Sardinian data only)

Type of comparison	No. of families	Scorable nco	Sib. co	Log scores[13] $\text{Log}_{10}\frac{\text{Prob F/rec}}{\text{Prob F/(rec = 0·5)}}$ rec = 0·5	0·10	0·20	0·30	0·40
G6PD/Deutan	57	179	3	+33·5	+31·1	+23·6	+15·5	+6·6
G6PD/Protan	10	26	1	+4·8	+4·5	+3·5	+2·4	+1·2

Rec, recombination frequency; nco, non cross-over; co, cross-over
The estimate of recombination frequency between G6PD and deutan genes is less than 4 per cent, with very narrow confidence intervals; that between G6PD and protan genes is 5 per cent but with much broader confidence intervals. For a complete evaluation of these data see ref. 8.

Thus a tentative conclusion is that the sequence of the three loci in question may be:

Deutan.....G6PD.....Protan
c.o.v. < 0·04 • c.o.v. ≥ 0·05

It is interesting to note that the pedigree described here is informative also for the Xg^a locus[10], the maternal grandfather being Xg^a negative and an illegal paternity being obviously out of the question because of the segregation of protanopia down to the third generation. Thus it would appear that in this family the Xg^a locus, which has

recombined twice with protan and once with deutan, must be located nearer to the deutan locus than to protan, and yet far enough from both deutan and the G6PD loci, with which it is known to recombine quite freely in Sardinia[7,8]. The sequence of the four genes appears to be:

Xg^a.....Deutan.....G6PD.....Protan
c.o.v. ~ 0·40 c.o.v. < 0·04 c.o.v. ≥ 0·05

These conclusions, which are now supported by data based on 34 new pedigrees involving 3 generations, all with known phases, do not accord with those drawn by other workers from the data collected in Israel[12] and in Greece[12], where the sequence of the genes controlling the Xg^a blood group, G6PD-deficiency and deutan colour blindness has been given as

Xg^a.....G6PD.....Deutan
c.o.v. ~ 0·27 c.o.v. ~ 0·05

Whether this disagreement is due to chance, or to genetic heterogeneity, or to chromosomal rearrangements, remains to be seen. Alternative interpretations are to be discussed in detail elsewhere[7,10].

This work was supported by grants from the Rockefeller Foundation and the Italian National Research Council. We thank Prof. A. Wirth and Prof. F. Bozzoni for their advice, and for help in evaluating the colour vision data, and Prof. V. Ronchi for the luminosity measurements in Fig. 2.

ABILITY OF TAMARINS TO PRODUCE AND RESPOND TO ERYTHROPOIETIN

By Prof. E. A. MIRAND, Dr. T. C. PRENTICE and Dr. J. T. GRACE, jun.
Roswell Park Memorial Institute, New York State Department of Health and State University of New York, Buffalo, New York

EVIDENCE for the existence of a humoral erythropoietic factor is ascribed to Carnot and Déflandré[1], who, in 1906, stated that the serum of rabbits which had been made anæmic by bleeding was capable of stimulating erythropoiesis when administered to normal rabbits. For several decades investigators attempted to confirm and elaborate on these findings with mixed success. Experiments performed by various authors (refs. 2–10) and others provided new interest in and strong support for the existence of a humoral erythropoietic factor produced in response to induced hypoxia. This humoral factor (or factors) controlling erythropoiesis, erythropoietin (EPF), can be recovered from body fluids, plasma, urine and milk of a number of animals (rabbits, dogs, monkeys, rats, sheep, guinea-pigs and mice) in which hypoxia has been produced by abrupt bleeding, by ropeated injections of phenylhydrazine, and by hypoxic hypoxia, or by the administration of excessive amounts of cobalt[1–10]. (*Addendum*. Recent data show that testosterone can stimulate and œstrogen can inhibit the production of erythropoietin in tamarins.)

Despite the work on EPF during the past decade, there was a paucity of investigations on primates[11–14]. It was thought worth while, therefore, to determine whether the small sub-primate, *Tamarinus nigricollis* (white-lipped tamarin), could produce detectable EPF with and without the presence of the kidneys, and respond to exogenous EPF from human and rabbit sources.

(*a*) Plasmas were obtained from non-nephrectomized *Tamarinus nigricollis* which had been bled to hæmatocrit-levels of 30, 25 and 20 per cent. Bilaterally nephrectomized tamarins were made anæmic by bleeding at several intervals after surgery. 24–30 h after surgery, when the hæmatocrits reached 25–20 per cent, the animals were bled. Plasmas from non-anæmic bilaterally nephrectomized tamarins were collected for controls at 24 and 30 h after surgery. These plasmas were assayed for EPF in polycythæmic mice.

(*b*) Intact and bilaterally nephrectomized tamarins were given 10 per cent oxygen for 8–120 h and 24–30 h, respectively. After each interval, tamarins were bled promptly after leaving the chamber. The plasma from these animals was stored at −20° C and assayed later in polycythæmic mice.

(*c*) Rabbit EPF prepared from the plasma of phenylhydrazine-treated rabbits by the method of Lowy *et al.*[15] was injected into tamarins. Each tamarin received subcutaneously 1–2 ml./100 g of rabbit EPF for 7 days.

(*d*) Human EPF extract was prepared from the urine of patients with hypoplastic anæmia. This extract was injected into tamarins in the same manner as rabbit EPF.

The criteria of erythropoietic response have included increased values of red blood cells, hæmoglobins, hæmatocrits, reticulocytes, increase in erythroid bone marrow elements, or measurement of the amount of iron-59 incorporated into circulating red blood cells in a given interval of time. To determine the erythropoietic response in groups (*a*) and (*b*), plasma was assayed in polycythæmic mice[16] and 48-h iron-59 uptake by the blood was determined[17]. Any mouse losing weight or having a hæmatocrit value less than 60 per cent on completion of the assay was discarded. The polycythæmic mouse iron-59 uptake assay method, though it did not allow absolute measurements of EPF concentrations, was sufficient to detect relative increases of plasma EPF levels. The erythropoietic response in tamarins receiving rabbit EPF or human EPF was determined by injecting 1 μc. of iron-59 intravenously into tamarins and measuring iron-59 uptake by the blood over 48 h after the last injection.

Jacobson *et al.*[5,18] reported the absence of EPF production in animals which had been bled after bilateral nephrectomy and proposed the kidney as the site of EPF formation. Mirand *et al.*[19], Naets[20], and Reissmann *et al.*[21] have confirmed and extended these findings in non-primate animals.

Table 1 demonstrates the effect of bleeding on the plasma EPF levels of non-nephrectomized tamarins. Note that the level of EPF was related to the severity of the anæmia as indicated by an 8·45 per cent 48-h uptake of iron-59 in the blood of polycythæmic mice. This was 70 times greater than the normal value, 0·12 per cent, obtained from plasma from non-anæmic, non-nephrectomized tamarins.

Table 1. Effect of Bleeding on Plasma Erythropoietin Production in Non-nephrectomized Tamarins

Material injected*	Assay in polycythæmic mice: No. of mice	48 h ^{59}Fe uptake by the blood	Ht.
(A)			
Plasma from anæmic tamarins (30 ht.)	5	4·07 ± 1·3	65
Plasma from anæmic tamarins (25 ht.)	5	6·57 ± 2·8	62
Plasma from anæmic tamarins (20 ht.)	5	8·45 ± 1·4	65
(B)			
Plasma from non-anæmic tamarins	5	0·12 ± 0·02	64

* Mice received a single injection of 0·5 c.c. intraperitoneally.

The results in Tables 1 and 2 indicate that the kidney of the tamarin played an integral part in EPF production. The 48-h uptakes of iron-59 in the blood of polycythæmic mice which received plasma from anæmic bilaterally nephrectomized tamarins bled to hæmatocrit levels of 25 and 20 per cent were comparable to the uptakes of iron-59 in non-anæmic, bilaterally nephrectomized and non-anæmic, non-nephrectomized tamarins.

Table 2. Effect of Bleeding on Plasma Erythropoietin Production in Bilaterally Nephrectomized Tamarins

Material injected*	Assay in polycythæmic mice: No. of mice	48 h ^{59}Fe uptake by the blood	Ht.
(A)			
Plasma from anæmic bilaterally nephrectomized tamarins (24 h, † ht. 25)	5	0·22 ± 0·05	67
Plasma from anæmic bilaterally nephrectomized tamarins (30 h, ht. 25)	5	0·16 ± 0·02	67
Plasma from anæmic bilaterally nephrectomized tamarins (30 h, ht. 20)	5	0·17 ± 0·06	65
(B)			
Plasma from non-anæmic bilaterally nephrectomized tamarins (24 h, ht. 41)	5	0·22 ± 0·03	70
Plasma from non-anæmic bilaterally nephrectomized tamarins (30 h, ht. 40)	5	0·12 ± 0·01	68
Plasma from non-anæmic non-nephrectomized tamarins (ht. 41)	5	0·12 ± 0·02	64

* Mice received single injection of 0·5 c.c. intraperitoneally.
† Time tamarins bled after bilateral nephrectomy.

Although the kidney of the tamarin played an integral part in EPF production, erythropoietic activity had not been detected in tissue extracts prepared from kidneys of normal or hypoxic tamarins. A survey of other tissues yielded negative results. Gordon *et al.*[7], Reissmann and Nomura[22], and Mirand[23] had observed this for other species. As in the case of other hormones, this may be due to lack of storage.

Osnes[24], from investigations with irradiated mouse kidneys, proposed that the juxtaglomerular apparatus was the source of EPF. Hirashima and Takaku[25] had also suggested this site in the kidney. Their conclusions were based on an increased granulation in the juxtaglomerular apparatus following bleeding or as a result of severe hæmolysis and a reduction in granulation in the juxtaglomerular apparatus during hypertransfusion.

The evidence of renal EPF production in experimental animals was reinforced by observations in man. Patients with hypernephroma or renal cysts had been shown to develop secondary polycythæmia[26–28].

Plasma from non-nephrectomized tamarins exposed to 10 per cent oxygen for 8–120 h was assayed for EPF in polycythæmic mice. Note that the findings in Table 3 demonstrated that the uptake of iron-59 increased steadily from the eighth hour and still persisted at high levels at 120 h. In some instances, the values obtained were 100 times greater than normal values. The persistence of high levels was in contrast to our findings in the rat[6,19,29] and rabbit[30], where we saw a drop in EPF levels after 48 and 72 h respectively.

Jacobson *et al.*[5,18], using cobaltous chloride or bleeding as a stimulus, were not able to demonstrate significant levels of EPF in the plasma of bilaterally nephrectomized animals. As indicated previously, Jacobson postulated that the kidney was the sole source of EPF production. Mirand *et al.*[6,19,29] confirmed this finding in bilaterally nephrectomized rats, when cobaltous chloride or bleeding, but not when hypoxic hypoxia, was used as a stimulus. Since then, Jacobson[31] and others have confirmed the hypothesis that although the kidney appeared to be the principal site of production of EPF, there may be an extrarenal site(s) of such production as indicated by the ability of bilaterally nephrectomized animals to produce EPF to a hypoxic stimulus. Moreover, Fisher *et al.*[32] demonstrated a slight response of the bilaterally nephrectomized rat to cobalt, and felt that this was further evidence of the existence of an extrarenal site(s) of EPF production.

The data in Table 4 demonstrated the existence of an extrarenal site(s) for EPF production in bilaterally nephrectomized tamarins subjected to hypoxic hypoxia. The tamarin contained significant levels of plasma EPF in the absence of the kidneys but at a much lower level. It was interesting to note that the amount of plasma EPF produced in the rat in absence of the kidneys appeared to be greater than that in the tamarins[6].

Although it has been shown that exogenous EPF obtained from the plasmas of anæmic hypoxic or hypoxic hypoxic tamarins will stimulate erythropoiesis in tamarins, findings from our laboratory also showed that tamarins can respond to human and rabbit EPF.

From Table 5 it can be seen that EPF from human urine stimulated erythropoiesis in tamarins. Tamarins received urine from hypoplastic anæmic patients and after the last injection a 48-h uptake of iron-59 by the blood was determined. In six different experiments, all blood uptakes of iron-59 exceeded normal values. Tamarins responded to plasma EPF from phenylhydrazine-treated rabbits. The uptakes of iron-59 were not as high as in those animals which received EPF from human urine. Regardless of the source of exogenous EPF injected, the increase in erythropoiesis as determined by uptake of iron-59 by the blood was maintained as long as EPF was given. Normal erythropoiesis was evident 7 days after administration of EPF was stopped.

These results demonstrated the effectiveness of exogenous EPF from non-primate and primate sources to stimu-

late erythropoiesis in the tamarin. Moreover, our findings concurred with Van Dyke's data indicating that EPF of primate origin was not required for stimulation of erythropoiesis in cynomolgus monkeys[14]. Osmond *et al.*[33] indicated some species differences in the response to EPF. This finding was not confirmed in these experiments.

SYNERGISTIC ACTION OF PENICILLINS AND CEPHALOSPORINS AGAINST *Pseudomonas pyocyanea*

By Dr. L. D. SABATH and Prof. E. P. ABRAHAM, F.R.S.
Sir William Dunn School of Pathology, University of Oxford

MANY strains of *Pseudomonas pyocyanea* show an unusually high resistance to penicillins and cephalosporins, and also produce enzymes which inactivate these substances[1,2]. An inducible β-lactamase (*EC* 3.5.2.6) from one such strain of *Ps. pyocyanea* (NCTC 8203) has been examined in this laboratory[3]. The behaviour of this enzyme towards a number of derivatives of 6-aminopencillanic acid (6-APA) and 7-aminocephalosporanic acid (7-ACA) was found to differ greatly from that of penicillinases from *Staphylococcus aureus* and *Bacillus cereus*[4,5]. One example of this difference was the ability of methicillin ((6-[2 : 6]dimethoxybenzamido)penicillanic acid) and cloxacillin (6-(5-methyl-3-*o*-chlorophenylisoxazole-4-carboxamido)penicillanic acid) to act as powerful competitive inhibitors of the hydrolysis of susceptible derivatives of 6-APA and 7-ACA by the enzyme from *Ps. pyocyanea*, though they themselves were not hydrolysed at an appreciable rate. It thus seemed likely that methicillin and cloxacillin would delay the disappearance of hydrolysable derivatives of 6-APA or 7-ACA from whole cultures of this strain of *Ps. pyocyanea* in which the derivatives had induced β-lactamase formation.

Small inocula of penicillinase-producing staphylococci have been reported to be as sensitive to benzylpenicillin as penicillinase-negative strains[6], and the growth of heavy inocula of staphylococci in the presence of methicillin or oxacillin has been shown to occur only after the accelerated disappearance of the antibiotic[7]. In a serial dilution test with *Ps. pyocyanea* (NCTC 8203) the minimum inhibitory concentrations of benzylpenicillin and cephalosporin *C* were found to be reduced by 64-fold or more when the inoculum size was reduced 10^6-fold from a $0{\cdot}5 \times 10^{-2}$ dilution of an overnight culture[3].

Experiments were done with *Ps. pyocyanea* (NCTC 8203) to determine: (1) whether large inocula of this organism grow in the presence of concentrations of benzylpenicillin or cephalosporin *C* which are higher by several orders of magnitude than those required to suppress the growth of many other Gram-negative bacteria, or only after much of the antibiotic has been destroyed by enzymatic hydrolysis; (2) whether methicillin or cloxacillin in concentrations that are themselves antibiotically ineffective, can potentiate the effect of penicillins and

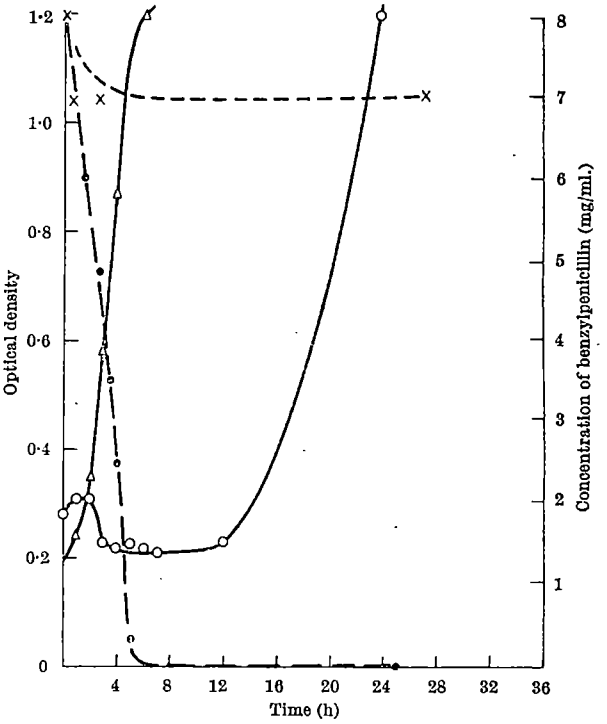

Fig. 1. Growth of *Ps. pyocyanea* and disappearance of benzylpenicillin from the culture. △, Control culture (no antibiotic); ○, growth after addition of benzylpenicillin (8 mg/ml.); ●, concentration of benzylpenicillin in the culture; ×, concentration of benzylpenicillin in sterile control

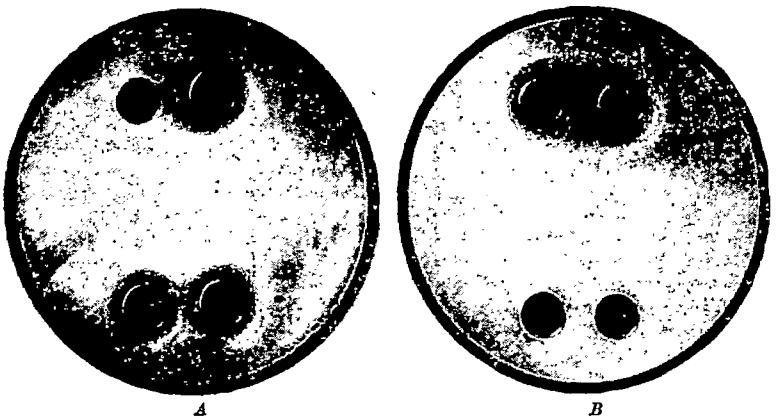

Fig. 2. Synergism on agar plates seeded with *Ps. pyocyanea*. Solutions of the substances studied were placed in holes cut in the agar. (*A*) Top pair: left, methicillin (1 mg/ml.); right, cephalosporin *C* (16 mg/ml.); bottom pair: each cephalosporin *C* (16 mg/ml.). With the top pair synergism is revealed by an eccentric zone of inhibition. The bottom pair show inhibition but no synergism. (*B*) Top pair: left, methicillin (4 mg/ml.); right, cephalosporin *C* (16 mg/ml.). Bottom pair: each cephalosporin *C* (4 mg/ml.). With the top pair synergism is revealed by eccentric and merging zones of inhibition. The bottom pair show no inhibition

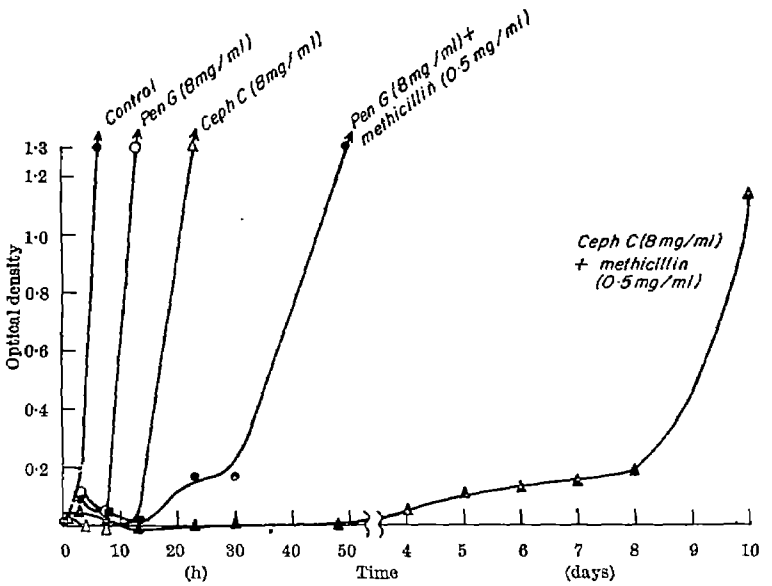

Fig. 3. Effect of benzylpenicillin (pen. *G*) alone, cephalosporin *C* alone and mixtures of these substances with methicillin on the growth of *Ps. pyocyanea* in inverted 'T' tubes

cephalosporins that are susceptible to hydrolysis by the β-lactamase (that is, act synergistically with them); (3) whether such synergism, should it occur, could be correlated with a decrease in the rates of destruction of the latter antibiotics.

A 10 per cent (v/v) inoculum of an overnight culture of *Ps. pyocyanea* was made in 'Oxoid' nutrient broth (10 ml. total volume) containing benzylpenicillin (8 mg/ml.) in inverted 'T' tubes (40 ml. capacity). The tubes were rocked 50 times/min at 35° C. Simultaneous measurements were made at intervals of bacterial growth (in terms of optical density, in a Spekker absorptiometer with a neutral grey filter, *H*508) and of the amount of antibiotic remaining. The latter was estimated enzymatically. Samples (0·5 ml.) of the whole culture were mixed with 0·5 ml. of a solution of crude β-lactamase from *B. cereus*[4] and 1 ml. of water in the reaction vessel (30° C) of a *p*H stat set to maintain the initial *p*H of the mixture (7·1 ± 0·2) by automatic addition of 0·1 N sodium hydroxide. The equivalents of alkali required to hold the *p*H constant during the reaction (which was always complete within 4 min) represented the equivalents of benzylpenicillin remaining in the sample. In a similar experiment with cephalosporin *C* (4 mg/ml.) a solution of preformed cephalosporinase[3] was used for estimation of the remaining antibiotic. In each experiment bacterial growth or antibiotic concentration in parallel control tubes, containing bacteria, benzylpenicillin, or cephalosporin *C* alone in broth, was estimated in a similar manner.

Fig. 1 shows that the rate of disappearance of benzylpenicillin in the presence of the inoculum of *Ps. pyocyanea* increased with time and became very much faster than that in the control; but that rapid bacterial growth did not begin until after the antibiotic level had fallen to a value below that at which it was detectable by the method used (50 μg/ml.). A single reading at 25 h would have suggested that this strain of *Ps. pyocyanea* was resistant to 8,000 μg/ml. of benzylpenicillin, although growth did not in fact occur at that concentration. When cephalosporin *C* was used in place of benzylpenicillin rapid growth was also delayed until the antibiotic concentration had fallen to less than 50 μg/ml.

Synergism was looked for in three systems involving: (1) diffusion on agar plates; (2) tube dilutions; (3) growth in inverted 'T' tubes.

(1) In the agar plate system Petri dishes were filled with 10 ml. of an 'Oxoid' nutrient agar seeded with 2 per cent (v/v) of an overnight culture of *Ps. pyocyanea* (NCTC 8203). Pairs of holes, each 1·5 cm (centre-to-centre) from its mate, were punched with a sterile cork borer of 7 mm diameter. One hole of each pair was filled with methicillin or cloxacillin (1 to 4 mg/ml.) and the other with cephalosporin *C* (1–16 mg/ml.). Synergism shown by two of a number of mixtures of cephalosporin *C* and methicillin is illustrated in Fig. 2.

(2) Tube dilution tests were performed by addition of 0·5 ml. of 'Oxoid' broth containing a 10^{-4} dilution of an overnight culture of *Ps. pyocyanea* (NCTC 8203) to 0·5 ml. of the same broth containing various concentrations (two-fold dilutions) of either a hydrolysable derivative of 6-APA or 7-ACA alone or of one of these derivatives together with an inhibitor (methicillin or cloxacillin).

Table 1. Activities against *Ps. pyocyanea* (NCTC 8203) of Mixtures of Hydrolysable Penicillins or Cephalosporins with β-Lactamase Inhibitors

Hydrolysable antibiotic	Inhibitor	Inhibitor concentration (μg/ml.)	M.I.C. of hydrolysable antibiotic (μg/ml.)
Benzylpenicillin	None	—	4,000–8,000
Benzylpenicillin	Cloxacillin	10	4,000
Benzylpenicillin	Cloxacillin	100	1,000
Benzylpenicillin	Cloxacillin	1,000	60
Cephalosporin *C*	None	—	1,000–4,000
Cephalosporin *C*	Cloxacillin	10	500
Cephalosporin *C*	Cloxacillin	100	500
Cephalosporin *C*	Cloxacillin	1,000	120
Cephalothin	None	—	4,000
Cephalothin	Methicillin	10	4,000
Cephalothin	Methicillin	100	250
Cephalothin	Cloxacillin	10	1,000
Cephalothin	Cloxacillin	100	500
Cephalothin	Cloxacillin	1,000	120
Cephaloridine	None	—	4,000
Cephaloridine	Methicillin	10	1,000
Cephaloridine	Methicillin	100	60
Cephaloridine	Cloxacillin	10	1,000
Cephaloridine	Cloxacillin	100	60
Cephaloridine	Cloxacillin	1,000	30

The tubes containing antibiotics and bacteria were read after 16–18 h. The lowest concentration of antibiotic to prevent visible growth completely, or permit only faint surface growth, was considered the minimum inhibitory concentration (M.I.C.). Controls (without antibiotic) showed marked turbidity and heavy surface growth. Neither of the inhibitors caused any detectable inhibition of bacterial growth when used alone in the concentrations listed. Under the conditions used the M.I.C. for methicillin alone was 4 mg/ml. and that for cloxacillin was 8 mg/ml.

The tubes were incubated at 37° C for 16–19 h before being read. Synergism was observed in these tests (Table 1). At concentrations in which they had no observable antibacterial effect alone, methicillin and cloxacillin increased the apparent antibacterial activity of benzylpenicillin, cephalosporin *C*, cephalothin (7-(2-thienylacetamido-cephalosporanic acid), or cephaloridine (the pyridinium (C_A) analogue of cephalothin) by as much as a factor of 100.

(3) The growth of *Ps. pyocyanea* (NCTC 8203) in inverted 'T' tubes containing 'Oxoid' broth and several derivatives of 6-APA and 7-ACA, alone and in pairs, was followed by measurements of optical density. The inoculum was 1 per cent (v/v) of an overnight culture in 'Oxoid' broth and the tubes were rocked at 35° C. The growth curve in the presence of methicillin (500 μg/ml.) was superimposable on that of the control shown (no antibiotic) while either benzylpenicillin (8,000 μg/ml.) or cephalosporin *C* (8,000 μg/ml.) caused some delay in growth (Fig. 3). However, addition of methicillin (500 μg) to a tube containing benzylpenicillin or cephalosporin *C* resulted in marked potentiation of the effect of either of the latter antibiotics alone. In all these cases the organisms which finally grew out were no more resistant than the parent strain to derivatives of 6-APA and 7-ACA when tested by the tube dilution method. The synergistic effect was also demonstrable at lower concentrations of cephalosporin *C* (800 μg/ml.) and methicillin (250 μg/ml.) (Fig. 4). Fig. 5 shows the relationship between bacterial growth (solid lines) and cephalosporin *C* levels (broken lines), the concentration of the latter in the medium being estimated from measurements of extinction at 260 mμ. In the presence of methicillin (500 μg/ml.) the concentration of cephalosporin *C* fell no more rapidly than in sterile control medium without bacteria and was still 3,000 μg/ml. after 7 days. No measurable growth had occurred by 7 days in the 'T' tube containing both cephalosporin *C* and methicillin.

A similar experiment was done in which cephalosporin *C* was replaced by benzylpenicillin. The growth curves

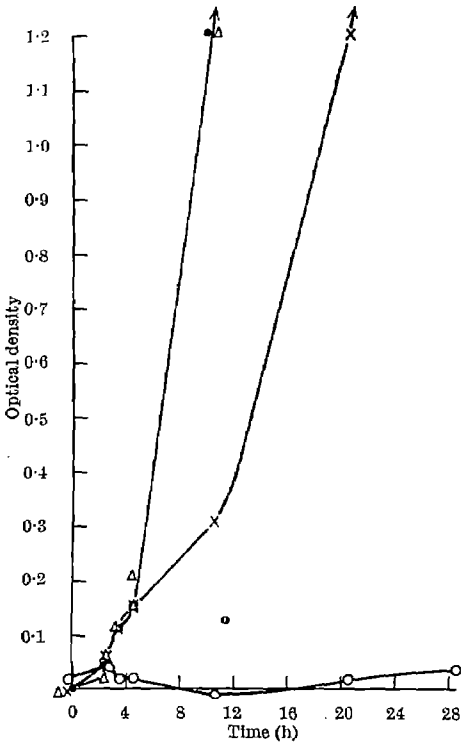

Fig. 4. Effect of: ×, cephalosporin *C* (800 μg/ml.) alone; △, methicillin (250 μg/ml.) alone; and ○, a mixture of the two antibiotics in these concentrations on the growth of *Ps. pyocyanea* in inverted 'T' tubes. ●, control culture growth without antibiotic

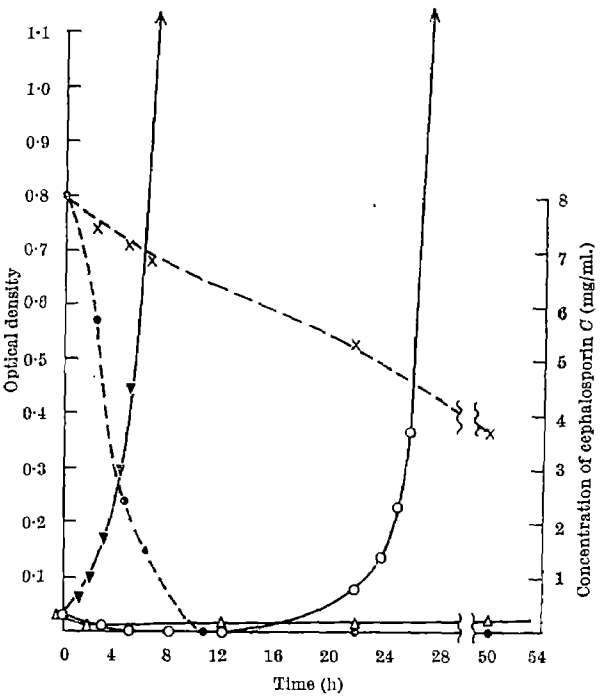

Fig. 5. Growth of *Ps. pyocyanea* and changes in the concentration of cephalosporin *C*. ▼, Growth in control culture; ○, growth after addition of cephalosporin *C* (8 mg/ml.); ●, concentration of cephalosporin *C* in the same culture; △, bacteria in the presence of cephalosporin *C* (8 mg/ml.) plus methicillin (0·5 mg/ml.), ×, concentration of cephalosporin *C* in the presence of bacteria and methicillin. In the presence of methicillin alone (0·5 mg/ml.) growth was similar to that in the control culture

were similar to those in Fig. 5 and the concentration of benzylpenicillin had fallen from 8,000 μg/ml. to less than 50 μg/ml. before heavy growth was detected after 10 h, in the tube without methicillin. In the presence of methicillin (500 μg/ml.) a detectable level of benzylpenicillin was maintained much longer than in the culture without methicillin. The delay in rapid growth produced by the mixture of benzylpenicillin and methicillin paralleled the delay in the disappearance of benzylpenicillin from the medium. In some cases relatively small increases in optical density occurred before rapid growth took place, but it is not known whether these changes were associated with cell multiplication.

These results indicate that synergistic antibacterial action against *Ps. pyocyanea* (NCTC 8203) can be obtained by use of a β-lactamase inhibitor (methicillin or cloxacillin) with any one of several derivatives of 6-APA or 7-ACA which are susceptible to enzymatic hydrolysis. The results of concurrent measurements of growth and antibiotic levels are consistent with the suggestion that there is synergism due to a delay in the destruction of the hydrolysable antibiotic. The biochemical basis for such an effect would reside in the existence of essentially non-hydrolysable competitive inhibitors (methicillin and cloxacillin) which have very much higher 'affinities' for the active centre of the β-lactamase from *Ps. pyocyanea* (NCTC 8203) than have the hydrolysable substrates and which do not themselves prevent the growth of *Ps. pyocyanea* in concentrations approaching those required to saturate the enzyme. The values of *Ki* (dissociation constant of the enzyme inhibitor complex) for methicillin and cloxacillin are 10^{-7} M and 10^{-8} M respectively, and the values of *Km* (Michaelis constant) for benzylpenicillin, cephalothin, cephaloridine and cephalosporin *C* are 10^{-5} M, 10^{-4} M 10^{-4} M and 10^{-3} M, respectively, while the minimum inhibitory concentration of methicillin and cloxacillin is about 10^{-2} M[3].

It is possible that the type of synergism found in the laboratory with this strain of *Ps. pyocyanea* will not be

demonstrable in patients even with strains which behave similarly *in vitro*[8]. The antibiotic levels at which synergism was shown to occur are still enormous compared with the levels at which these antibiotics are effective against 'susceptible' bacterial species. Such levels would not be reached systemically in man, except at unusual doses, and the antibiotics concerned would therefore not be expected to compete with polymyxin *B* and colistin in the chemotherapy of systemic infections. However, the concentrations used are easily achieved in the urine of patients receiving methicillin[9], cloxacillin[10], benzylpenicillin[11] and cephalosporin *C* (ref. 12) because of the active urinary secretion of these drugs. In the management of chronic pseudomonad infections of the urinary tract, or in patients with severely impaired renal function, for which the use of polymyxin *B* and colistin is not generally favoured, a synergistic combination of these non-toxic drugs could conceivably have application.

An earlier suggestion was made that synergism observed with cephalosporin *C* and benzylpenicillin against one penicillinase-producing strain of *Staph. aureus* might be due to competitive inhibition of the penicillinase by cephalosporin *C* (ref. 13), but this explanation of the phenomenon appeared to be unlikely after a study of the relative affinities of the antibiotics concerned for a staphylococcal penicillinase[4]. More recently, it has been reported that methicillin and cloxacillin are inhibitors of penicillinase produced not only by *Ps. pyocyanea*[2] but also by a number of other Gram-negative bacteria[14–16]. Synergism has been shown to occur with these substances and benzylpenicillin or ampicillin against some strains of *K. aerogenes*, *E. coli* and *Proteus* sp., but it was thought to be inadequate for clinical application[15,16].

The question arises whether different derivatives of 6-APA and 7-ACA will show differences in affinity for β-lactamases from other organisms, particularly those from Gram-negative bacteria, which are greater than those so far encountered. However, an affinity for an accessible enzyme which is high compared with that of an antibacterial substrate is only one of the properties which may be required of a competitive inhibitor in this context.

A second is an affinity for the enzyme which is high in relation to the antibacterial activity of the inhibitor. 'Cephaloram' (7-phenylacetamidocephalosporanic acid) has strong affinity for penicillinase from *Staph. aureus* (Ki $0{\cdot}43 \times 10^{-7}$ M) relative to benzylpenicillin ($Km = 2{\cdot}5 \times 10^{-6}$ M) and a high resistance to hydrolysis by it[4]. But its antistaphylococcal activity alone is high (minimum inhibitory concentration, 10^{-6} M) and in concentrations that are less than one-quarter of its minimum inhibitory concentration 10 per cent or more of the enzyme would be uncombined with this inhibitor, however low the concentration of substrate. In this respect the situation is therefore less favourable for synergism than that with methicillin or cloxacillin and the enzyme from *Ps. pyocyanea*, in which the corresponding values for uncombined enzyme would be about 0·004 and 0·0002 per cent respectively. A third property, the ability of the inhibitor to reach the enzyme, becomes significant when the enzyme is intracellular.

We thank the Lilly Research Laboratories for a sample of 'Cephalothin', the Glaxo Laboratories, Ltd., for a sample of 'Cephaloridine', Dr. G. G. F. Newton for helpful suggestions and Mr. J. O. Isaacs for his assistance.

SYNCHRONOUS AND DICHOTOMOUS REPLICATIONS OF THE *Bacillus subtilis* CHROMOSOME DURING SPORE GERMINATION

By MICHIO OISHI, HIROSHI YOSHIKAWA and PROF. NOBORU SUEOKA
Department of Biology, Princeton University, New Jersey

GERMINATION of bacterial spores provides an unusual opportunity for analysing the process of development of a metabolically active state from an inert or dormant state[1]. The mode of chromosome replication during spore germination, therefore, should be of particular interest because of the possibility that during germination the sequence of transcription and translation of genes may reflect the sequence of gene replication. In this article, the process of gene replication during spore germination of *Bacillus subtilis* will be described. The main findings are as follows: (1) The chromosome in the spore is in completed form; (2) On germination, the genes replicate in definite sequential order from one end of the chromosome (origin) to the other (terminus), the same as in vegetative cells; (3) In an enriched medium, a dichotomous replication occurs, as in the exponential phase in the same medium.

Sequential replication of the bacterial chromosome in an exponentially growing population has been described in *Bacillus subtilis*[2] and in *Escherichia coli*[3,4]. In *Bacillus subtilis*, genetic markers on the chromosome have been shown to replicate in a definite order[5,6]. The result is most consistent with the replication model shown in Fig. 1. Thus, the replicating chromosome of *B. subtilis* has one replicating point when cells are grown in a standard medium (Table 1) with a generation time of approximately 40 min. The replication order of markers was followed by measuring the frequency of markers in the exponential growth phase by genetic transformation. Based on the replication order, a genetic map of *B. subtilis* was constructed[5] (Fig. 2). The theoretical basis for marker frequency analysis will be given elsewhere[8]. This single-fork replication is, however, not true when the cells are dividing rapidly in an enriched medium. An indication of multifork replication was first noted by an unusually high ratio, four, of *ade*/*met* in an enriched medium (Table 1) with a generation time of about 20 min (ref. 9), in contrast to the ratio of two in a standard medium[5,8]. A hypothetical

Table 1. Composition of Standard and Penassay Media

Standard medium* (1 l.)		Penassay medium (1 l.)	
K_2HPO_4	14·0 g	Bacto-beef extract	1·00 g
KH_2PO_4	6·0 g	Bacto-yeast extract	1·00 g
$(NH_4)_2SO_4$	2·0 g	Bacto-peptone	3·33 g
Na_3-citrate.$2H_2O$	1·0 g	Bacto-dextrose	0·67 g
$MgSO_4.7H_2O$	0·2 g	NaCl	2.33 g
Glucose	5·0 g	K_2HPO_4	2·46 g
Casamino-acids	0·05%	KH_2PO_4	0·88 g
L-Tryptophan	50 μg/ml.		
	pH 7·0		pH 7·0

* Similar to Anagnostopoulos and Spizizen (ref. 7), except 0·05 per cent casamino-acids instead of 0·02 per cent.

model of chromosome replication for this situation is shown in Fig. 3, and this special case of multifork replication is called 'dichotomous replication'[9]. Multifork replication has also been reported for *Escherichia coli* when cured from thymine deprivation[10]. Synchronous replication and an unequivocal demonstration of dichotomous replication of the *B. subtilis* chromosome are reported here for the case of spore germination in an enriched medium, and their implication for gene expression during spore germination and for the regulation of chromosome replication are discussed.

Experimentally, heavy spores of strain *W*168, which had been formed in a deuterium oxide medium, were germinated in a light-enriched medium (Penassay medium, Table 1) containing radioactive phosphorus. During the germination of spores, replication of deoxyribonucleic acid (DNA) was followed by cæsium chloride density gradient centrifugation in a swinging bucket rotor. The dichotomous replication gives a unique prediction of the distribution of markers in heavy, hybrid and light DNA peaks as a function of the stage of chromosome replication and the position of the marker on the chromosome (Fig. 4). The experimental results are in complete agreement with the prediction.

A wild-type strain *W*168 of *B. subtilis* was used as the DNA-donor strain. Two triple mutants, *leu-met-ade* (Mu8u5u16) and *leu-met-thr* (Mu8u5u5), were used as recipient strains. These markers were obtained by an ultra-violet–penicillin method. Markers *leu* and *met* in the two strains were identical. Heavy deuterated spores of strain *W*168 were produced by shaking the culture at 37° C. in the following medium (D_2O-spore medium). The mixture of 7·0 g K_2HPO_4, 3·0 g KH_2PO_4, 1·0 g $(NH_4)_2SO_4$, 0·1 g $MgSO_4.7H_2O$, 0·5 g Na_3-citrate.$2H_2O$, 2·5 g glucose and 2·5 g potato extract (Difco Lab., Detroit, Michigan) was dried *in vacuo*, dissolved in 500 ml. of D_2O (99·7 per cent, General Dynamics Corp., San Carlos, California) and sterilized by passing through a 'Millipore' membrane filter (pore size 0·45μ). Strain *W*168, first grown on a D_2O agar medium, was inoculated in 2 ml. of the above D_2O-spore medium. The overnight culture was transferred to 500 ml. of a fresh D_2O-spore medium and incubated at 37° C for 10 days with constant shaking. The spores formed were collected by centrifugation and washed once with water. The crude spores were then incubated with 25 ml. of sterile water containing 1 mg/ml. of egg white lysozyme (Worthington Biochemical Corp., Freehold, New Jersey) for 60 min at 37° C. 'Duponol' was added to the suspension (final concentration, 2 per cent), incubated for 30 min at 37° C, and washed four times with sterile water. The spores thus purified were suspended in 3·3 ml. of sterile water (3·01 × 10^9 spores/ml., optical density (*O.D.*) at 650 mμ, 17·55) and kept in a refrigerator. In a growth flask, 1·2 ml. of the spore suspension (3·61 × 10^9 spores) was added to 28·8 ml. of a 1·22 per cent Penassay medium (Difco antibiotic medium 3) containing 10 mc. of ^{32}P-phosphate (final 0·33 mc./ml.) and incubated at 37° C with constant shaking. The optical density of the culture was followed by Klett–Sommerson colorimeter with a red filter (No. 66).

Samples of 5–6 ml. were withdrawn from the culture at various times and immediately heated at 60° C for 10 min in a water bath to stop DNA synthesis. The samples were chilled, centrifuged and the cells resuspended in 0·9 ml. of a saline versene solution (0·15 M NaCl and 0·1 M versene, *p*H 8·0) and incubated with 1 mg/ml. of lysozyme at 37° C for 30 min. 'Duponol' (final concentration 2 per cent) was added and incubated further at 37° C for 30 min; 0·5 ml. of the lysate was mixed with 4·76 g CsCl and 3·24 ml. *tris*-versene buffer (0·01 M *tris*-hydroxymethylaminomethane and 0·001 M versene, *p*H 8·4). The mixture was centrifuged at 35,000 r.p.m. for 63–74 h at 25° C in a Spinco '*SW*39' rotor. Single drops were collected through the bottom of centrifuge tubes in sterilized tubes; the dripping rate was adjusted by hydropressure to about a drop each 2 sec. The total number of drops was 105–135 per centrifuge tube. Each fraction was diluted immediately with 1 ml. of sterile saline citrate solution (0·15 M NaCl and 0·015 M sodium citrate), and stored at 4° C.

Transforming activities were assayed by a modified method of Anagnostopoulos and Spizizen[7] using stored recipient cells. The stored competent recipient cells were prepared and used as follows: 2 ml. of cell suspension grown overnight in a standard medium (Table 1) with appropriate supplements (100 μg/ml. for amino-acids and 50 μg/ml. for adenine) were diluted in 40 ml. of the same medium and incubated at 37° C with shaking. When the growth approached the stationary phase, the total cell suspension was transferred to 360 ml. of a medium (Medium *T*) containing 0·01 per cent casamino acids, 5 μg/ml. of L-tryptophan and L-histidine, and 50 μg/ml. of adenine (otherwise same as standard medium). After 90 min incubation at 37° C with shaking, the cells were collected by centrifugation at room temperature and immediately suspended in 40 ml. of the same

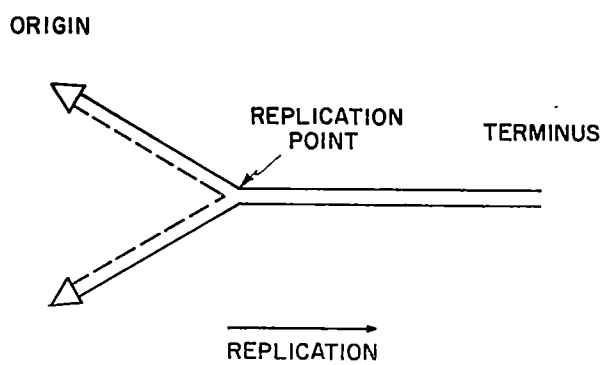

Fig. 1. A replication model of the chromosome. The solid line represents the old strand and the broken one the newly synthesized strand. This model does not differ, in principle, from a circular chromosome model in which replication stands at a fixed point and proceeds in one direction

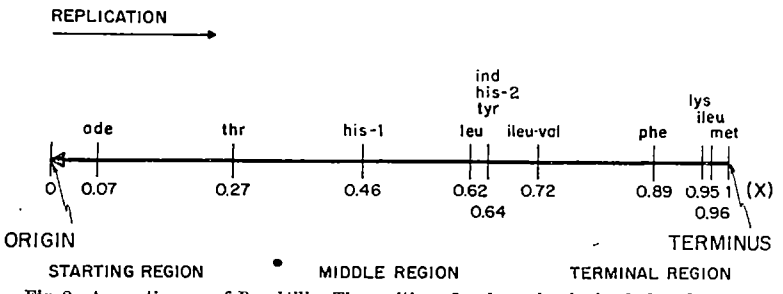

Fig. 2. A genetic map of *B. subtilis*. The position of each marker is simply based on the average of the results so far obtained by marker frequency analysis. Minor adjustments are expected in the future. For example, the *met* marker is assumed to have a position 1·00, which makes the *ade* position 0·07. Equally possible are the situations in which *ade* is located at 0·00 and *met* 0·93, or more generally, *ade* is in 0·00–0·07 and *met* in 0·93–1·00. The distance between *ileu* and *met* may be closer than indicated in the map because a linkage has been found for them by joint transformation (ref. 5). In our previous communication (ref. 5), the *his* 2-*ind*-*tyr* group was mislocated, for *his* 1 and *his* 2 were unjustifiably assumed to be identical. A detailed account of the map will be given elsewhere (ref. 17)

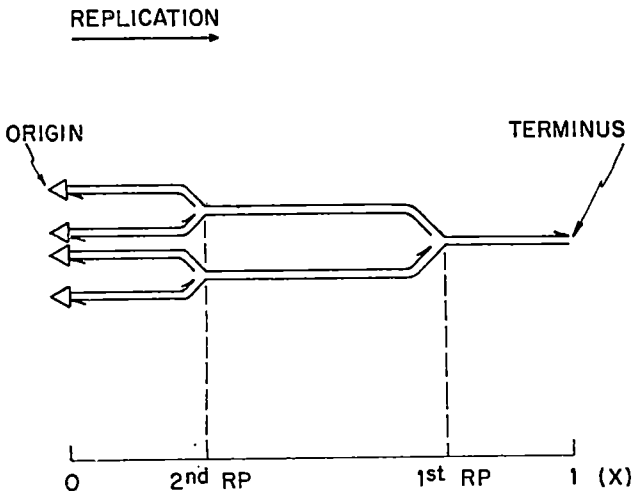

Fig. 3. A schematic representation of dichotomous replication of the chromosome. Before the first replication position (RP) reaches the terminus, the second RP starts from the origin. In an exponentially growing population, the simplest steady state can be set if the distance between the first and second RP's occupies half the chromosome and each replication point proceeds at a constant rate (ref. 8). In reality the two replication points at the second RP may not necessarily be at the same position

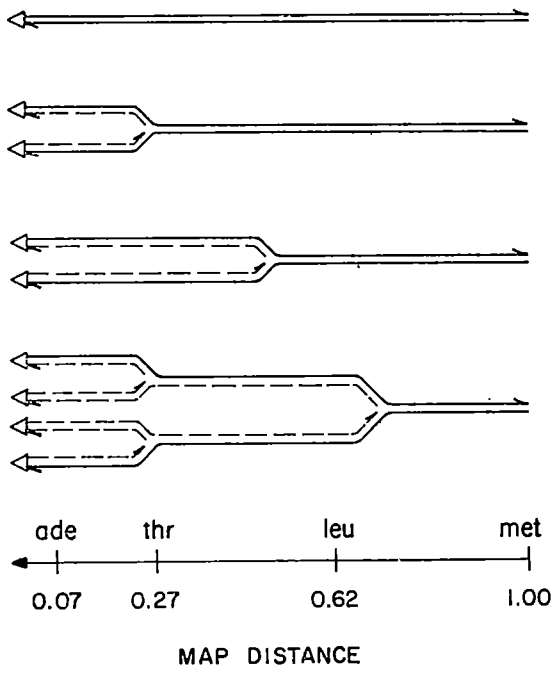

Fig. 4. A schematic presentation of successive stages of chromosome replication during germination of D_2O-spores in a ^{32}P-Penassay medium. The solid line represents the heavy non-radioactive strand and the broken one the newly synthesized strand (light and radioactive)

medium containing 4 per cent (w/v) glucose. 1-ml. aliquots of the thick cell suspension were poured into test-tubes, soaked in liquid nitrogen and kept frozen for at least 10 min. Then the tubes were transferred to a refrigerator adjusted at −80° C and stored at that temperature. For transformation, the tubes were transferred to a water bath (37° C) and thawed for 3 min with gentle shaking: 0·2 ml. of this cell suspension was diluted with 0·8 ml. of Medium *T* (minus glucose) containing DNA and incubated for transformation for 40 min at 37° C with constant shaking before the addition of DNase. Within our limited experience, no appreciable loss of transforming activities of competent recipient cells stored by this procedure was observed after one month's storage at −80° C.

In order to get radioactive profiles, 0·4 ml. aliquot of each fraction, 3 drops of a 0·5 per cent solution of salmon sperm DNA and 0·4 ml. of cold 20 per cent trichloroacetic acid were added. After keeping it in ice water for 30 min, the precipitate was collected on a membrane filter ('S and S', type *B*–6) and washed twice with about 30 ml. of 10 per cent cold trichloroacetic acid. The radioactivity was measured by a liquid scintillation technique.

The change in optical density of the spore suspension during germination and the schedule of sampling are shown in Fig. 5. The marker and phosphorus-32 radioactivity profiles of samples No. 1, No. 3, No. 4 and No. 5 are given in Fig. 6. Fig. 6*A* shows that the *ade* marker is mostly transferred to the hybrid peak while all the other markers (*thr*, *leu* and *met*) stay completely in the heavy peak. This is in perfect agreement with the replication order of markers which is shown in Fig. 2. Moreover, the results show that the chromosome in the spore has a complete non-replicating form and the synchrony of chromosome replication is excellent in this case. The result shown in Fig. 6*B* for sample No. 3 gives the most critical evidence for dichotomous replication of the chromosome. Thus the *ade* marker is distributed more or less equally in both hybrid and light peaks, while the *met* marker still remains totally in the heavy peak and the *leu* marker in the heavy and hybrid peaks.

On the basis of the dichotomous replication model (Figs. 3 and 4), the relative amount of phosphorus-32 radioactivity in the hybrid and light peaks allows us to calculate the position of replication points on the chromosome. In the case of sample No. 3, the calculated position of the first replication point on the chromosome is at 0·66 and the second replication points (or replication position) at 0·16. This predicts that the *leu* marker on the profile should be more in the hybrid than in the heavy peak (Fig. 2), which is exactly the picture. Data for later stages of germination are given in Figs. 6*C* and *D*. A sign of degeneration of synchrony is clear in the later stages.

The established order of chromosome replication during spore germination should provide a basis for our understanding of the developmental process. A basic issue here is whether or not the order of transcription and translation of genes during the germination process follows the order

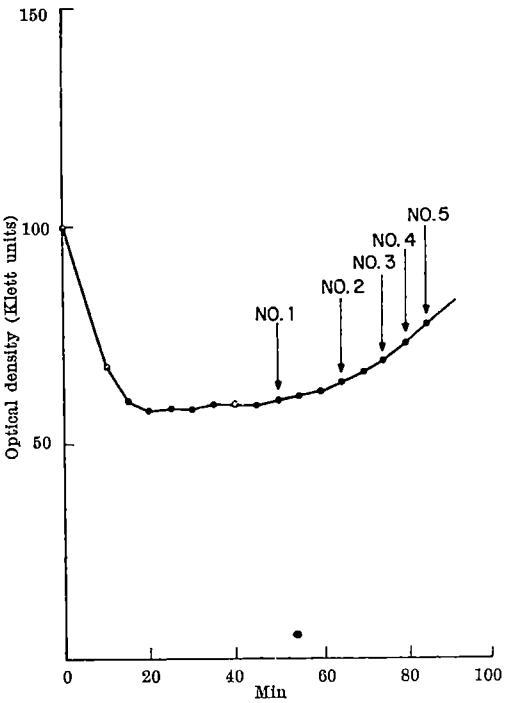

Fig. 5. Germination of *B. subtilis* D_2O spores. Spores were germinated in a Penassay medium at 37° C with constant shaking. Samples were taken at the time indicated and immediately heated at 60° C. for 10 min to stop further DNA replication. The volumes of samples taken were 6 ml. for No. 1, No. 2 and No. 3 samples, and 5 ml. for No. 4 and No. 5 samples. These samples were then lysed and analysed by CsCl density gradient centrifugation as described in the text

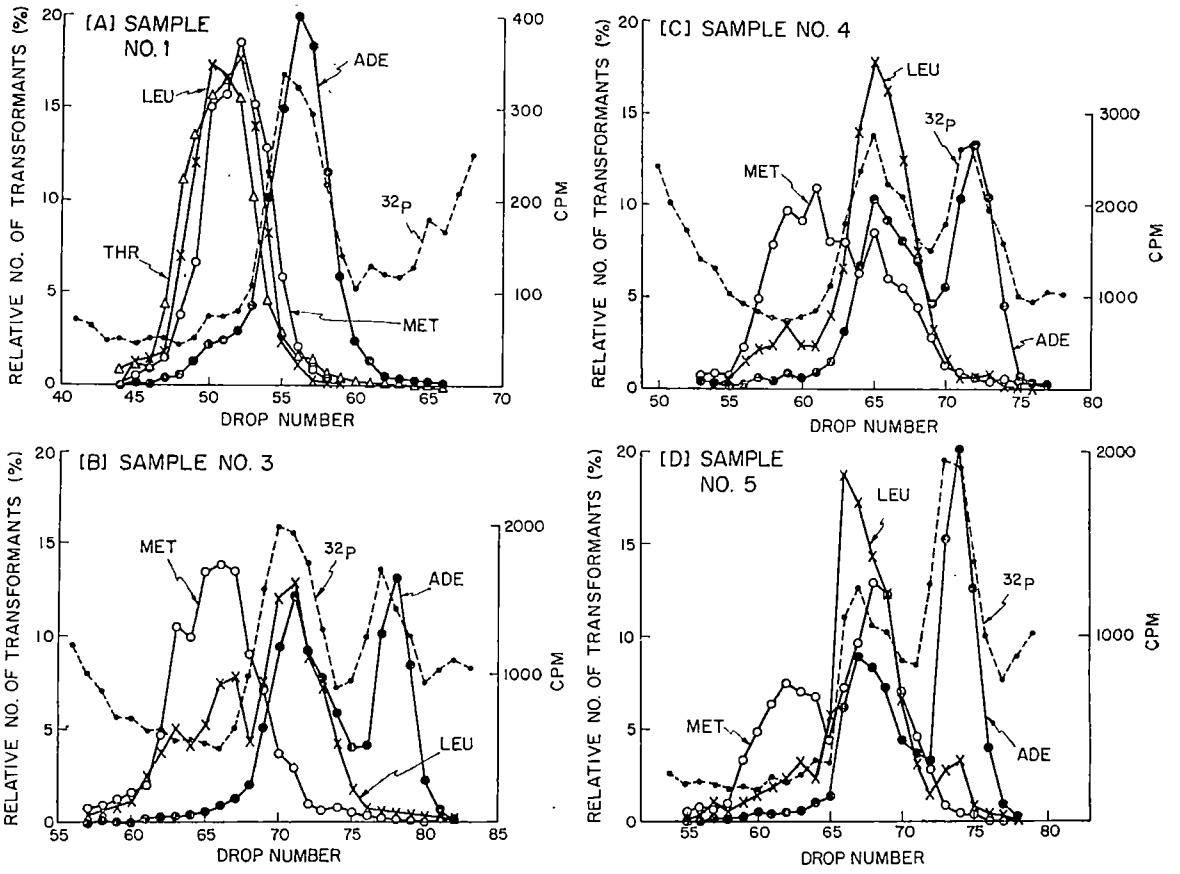

Fig. 6. Distribution of DNA from various samples indicated in Fig. 5 in CsCl density gradient centrifugation and analysis of transforming activities. Lysates of germinated spores prepared from samples in Fig. 5 were mixed with CsCl, centrifuged in a Spinco '*SW*39' rotor, and fractionated as described in the text. 40 per cent of each fractionation was used for assay of ^{32}P-radioactivity and the rest was analysed for transforming activity of various markers. The recipient strains used were two triple mutants: Mu8u5u16 (*leu-met-ade*) for No. 1, No. 3, No. 4 and No. 5 samples for leucine, methionine and adenine markers and Mu8u5u5 (*leu-met-thr*) for No. 1 samples for threonine marker. The relative number of transformants (ordinate) is the relative value (per cent) of the transformants of each fraction to the total number of transformants for each marker

of gene replication. If it does, the gene sequence on the chromosome should reflect the sequence of the function necessary for the reorganization of spores to become growing cells. In this respect, a positive effect of gene replication on the production of enzymes has been observed in *B. subtilis*[11], *Escherichia coli*[12], and yeast[14]. A unique messenger RNA produced at a stage of spore germination of *B. subtilis* also deserves attention[15]. The present system also allows us to separate physically DNA of the starting region of the chromosome from the rest, which should be useful for the structural examination of the replicating region of the chromosome.

The dichotomous replication of the bacterial chromosome demonstrated here should be operating also in the exponential growth phase in a Penassay medium[9], and presents several points of interest. An obvious advantage of the dichotomous replication model is that the generation time required for chromosome replication can be reduced to half, even if the rate of DNA replication at each replication point remains constant. In this connexion, the generation time in a Penassay medium (20 min) is approximately half that in a standard medium (35–40 min). Secondly, the initiation of chromosome replication does not necessarily require completion of previous chromosome replication. An attractive idea has been that in circular chromosomes the re-initiation of chromosome replication at the origin is triggered by the previous replication point reaching the terminus adjacent to the origin. The case of cure from a thymine-less condition[10] also indicates that such a requirement is not absolute. Thirdly, dichotomous replication is as well regulated a system as the ordinary single-fork replication. Apparently, re-initiation of the chromosome is repressed until the first replication point reaches the middle region of the chromosome. Fourthly, the germination process gives the best synchrony of chromosome replication so far reported and could be used in various studies. For example, the sequential increase of the enzyme level[11] in *B. subtilis* may gain better resolution. Finally, dichotomous replication should provide another convenient method for the mapping of markers on the chromosome.

Considering our previous work on marker frequency analyses[5], dichotomy is not expected during spore germination in an unenriched medium. During the progress of the present work, evidence for synchronous replication of tryptophan and methionine markers during spore germination in an unenriched medium was reported, where the ratio *tryp/met* did not indicate dichotomy[16].

As we have reported previously, unlike strain *W*23, strain *W*168 is an apparent non-polar strain which shows no difference in marker frequencies between DNA from exponential and stationary phase cells[2]. Recently, this apparent non-polar behaviour of strain *W*168 has been shown to arise from a less rigid regulation of chromosome replication rather than from a difference in the mode of replication (origin and direction of replication)[9]. Thus, when the spore DNA of *W*168 was used as the standard for marker frequency analysis, exactly the same polarity as in strain *W*23 was observed. The present results give direct evidence for the conclusion.

In summary, in *Bacillus subtilis* an excellent synchrony of chromosome replication has been observed during spore germination in an enriched medium. The system allows us to demonstrate the existence of dichotomous replication of the chromosome, in which three replication points per chromosome should exist.

PETIOLE BLEEDING SAP IN THE EXAMINATION OF THE CIRCULATION OF NITROGENOUS SUBSTANCES IN PLANTS

By Dr. J. S. PATE and W. WALLACE
Botany Department, The Queen's University of Belfast
AND
Dr. J. VAN DIE
Centre for Plant Physiological Research, Wageningen, Holland

THE sap which bleeds from the stump of a decapitated plant is usually regarded as arising from cut xylem vessels and has been used in studying export to the shoot of organic and inorganic compounds of nitrogen from the roots of plants[1–4].

These investigations have recently been extended by collecting bleeding sap simultaneously from the cut petioles of a plant. Such exudates are also considered to originate from the xylem, since they do not usually contain sugars, and in qualitative composition they resemble the bleeding sap collected from similar plants at ground-level. Analysis of petiole exudates may then be used to examine the composition of the xylem sap at different levels of the stem and to outline the part played by stem tissues in the initial assimilation of materials delivered from the root.

Four species have been investigated—tomato (*Lycopersicon esculentum* Mill.), balsam (*Impatiens glandulifera* Royle), field pea (*Pisum arvense* L.) and cocklebur (*Xanthium pennsylvanicum* Willr.). High root temperatures and short pre-treatments in a saturated atmosphere encourage an immediate exudation from cut petioles. The first drop of bleeding sap is discarded to minimize contamination from cut cells, and that collecting over only the following 0·5–1-h period is used. Sap analysis includes quantitative determinations of amino-acids and amides[5], measurements of conductivity and the concentrations of selected inorganic ions[2].

Tomato. In this species the level of organic nitrogen in the bleeding sap does not change significantly between lower petioles, but increases markedly from the middle to the upper petioles (Fig. 1). There is no parallel increase in the conductivity of the sap over the upper region of the stem. The amide glutamine accounts for 50–60 per cent of the organic nitrogen recovered in all exudates.

Balsam. This species also shows a substantial increase in levels of organic nitrogen in exudates from successive petioles up the stem, and a similar gradient is observed in exudates from the axillary shoots. More than 90 per cent of the organic nitrogen in petiole exudates is present as glutamine. Where free nitrate is recovered, its concentration tends to decrease towards the top of the stem, that is, a concentration gradient reverse to that of glutamine. On the other hand, phosphate-levels in petiole exudates show little variation along the length of the stem.

Field pea. The nitrogen recovered from the bleeding sap of nodulated plants raised in nitrogen-deficient media is entirely organic in form, and the amounts and relative proportions of the individual amides and amino-acids vary with the age and nutritional status of the host plant[1,5]. If petiole bleeding saps are studied at different stages in the life of the plant a progressive decrease in concentration of amino nitrogen is always observed from the oldest to the youngest petioles (compare tomato and balsam). In a typical analysis (Table 1) asparagine may show an eight- to ten-fold decrease in concentration from base to top of the stem, while much smaller concentration gradients are recorded for glutamine, homoserine, aspartic acid and the minor constituents of the bleeding sap.

Cocklebur. This species contrasts with the field pea in showing practically no organic nitrogen in petiole bleeding sap. Plants fed with varying amounts of nitrate all show free nitrate in their bleeding sap and tend to exhibit a decrease in concentration of nitrate from the lowest to the highest petioles.

All species mentioned here clearly exhibit gradients in the concentrations of the solutes present in exudates recovered from successive petioles up the stem. Since the volumes of bleeding saps are approximately proportional to the areas of xylem cut on the petiole surfaces, gradients in solute concentration must result from lateral exchange rather than from large differences in the rates of flow of water and solutes through different parts of the plant. The concentrations and gradients, of course, refer only to the defoliated plant, but there is evidence in at least two of the species (tomato[6] and field pea (Pate, unpublished

In each column the value on the left represents the concentration (μg N/ml.) of an amino compound, and that on the right the percentage that it represents of the total nitrogen recovered from the four common amino compounds (aspartic acid, asparagine, glutamine and homoserine).

results)) that a similar phenomenon may occur in the transpiring plant, despite the faster flow and lower solute concentrations to be expected in such a system.

It is interesting that several workers have described a lateral transfer of inorganic ions from wood to bark of various species of trees[7–9]. The investigations of Kursanov *et al.*[10] are also relevant in that they show a selective accumulation of organic substances by fibrovascular bundles. In the present work, lateral exchange with the transpiration stream is also envisaged as being selective, and may even involve a simultaneous accumulation of some solutes but release of others from living cells of the stem.

These exudate analyses, together with the results of other studies, reveal characteristic patterns of nitrogen assimilation in each of the species examined. The simplest situation is that encountered in *Xanthium*, in which the initial step in assimilation is the delivery of nitrate to centres of transpiration in the shoot. Practically no organic nitrogen moves in the xylem, and when nitrate is removed from the external medium it quickly disappears from the bleeding sap (Wallace, unpublished results). These observations suggest that roots do not function as major sites of nitrate reduction, and that there is no appreciable recycling of nitrate between the various pathways of translocation (compare studies on phosphate recirculation by Biddulph[11]). The absence of free nitrate in *Xanthium* leaves (Wallace, unpublished results) suggests that they are very active in reducing nitrate, and that the derived amino compounds are in part exported to other organs. In contrast, petioles and internodes are usually rich in stored nitrate, and these reserves are the last to be used when plants are removed to nitrogen-deficient media.

A slightly different type of circulatory system can be associated with nitrate-fed plants of balsam. Here, both organic and nitrate-nitrogen are regular constituents of the bleeding sap. The organic nitrogen leaving the root might result from a reduction of part of the incoming nitrate in the root, while that released from stem tissues might be derived from metabolism of nitrate accumulated in the stem axis. The marked upward concentration gradient in glutamine, and downward gradient in nitrate, would imply that older leaves receive greater amounts of nitrate via the transpiration stream, while younger leaves may utilize the amino group of amides as the major source of nitrogen. Of course, young leaves might also import other protein amino-acids through their phloem connexions with older organs.

Considerable information is available on the metabolism of nitrogen-containing substances in the tomato plant. Glutamine, γ-amino butyric acid and glutamic acid are the main components moving upwards from the root[2], and these have been shown to result primarily from the amination of α-ketoglutaric acid to glutamic acid[12]. The root system of tomato is relatively inactive in reducing incoming nitrate. In consequence, the level of organic nitrogen in bleeding sap is low (15–30 p.p.m. nitrogen) when nitrate is the sole source of nitrogen, but high (up to 200 p.p.m. nitrogen) when plants are fed with ammonium salts.

Nitrate reduction in the tomato has been shown to take place largely in photosynthesizing tissues[13], and the upward gradient in bleeding sap nitrogen probably results from an export of amino-acids recently synthesized in the mature leaves. Such an export may take place in both xylem and phloem elements (compare work on bean plants[14] showing a movement of photosynthetic products in elements of the secondary xylem).

Recent work on the tomato has shown that certain amino-acids may be progressively absorbed by surrounding tissues as they ascend the stem with the transpiration stream[15]. Selective absorption of this type may involve living cells in the immediate vicinity of the conducting vessels[6], and may well allow a direct exchange of solutes with the phloem and a rapid equilibration of solutes with the storage tissues of the stem.

The nodulated legume differs from the other species in that a substantial part of the carbohydrate produced in the shoot is immediately translocated to the root and utilized in the fixation of atmospheric nitrogen by root nodules[16]. A proportion of the derived amides and amino-acids is then exported in the transpiration stream[17]. Only a limited spectrum of amino compounds moves upwards in the xylem, and considerable metabolic rearrangement must occur in stem and leaves before a full complement of amino-acids is available for protein synthesis. The abundance of amides in bleeding sap suggests that they may be used in many of the synthetic and transamination activities in the shoot. Metabolism in the legume shoot is apparently complicated by an active and selective accumulation of incoming nitrogenous materials into stem tissues. Hence, younger leaves are supplied with xylem fluids with only a fraction of the concentration of amino nitrogen entering the lowest leaves. Transpirational delivery, in fact, favours older organs close to the root, and the deficiency of nitrogen going into younger organs and meristems may well be made up by redistribution through the phloem. Such an effect can, indeed, be demonstrated if amino compounds labelled with carbon-14 are fed to intact shoots via the transpiration stream. Accumulation of labelled material into the lower leaves and internodes is then found to be greatly in excess of present requirements in storage, and some 20–30 per cent of the label entering such tissues is released within 24 h and exported to meristems and actively expanding organs at the top of the shoot. Some of the materials sequestered by older parts of the plant are transferred direct and unchanged to the phloem, while others are metabolized and assimilated *in situ* into protein. This protein is then broken down and a proportion of the resulting amino-acids released for transport to other organs higher up the shoot.

We thank Prof. D. J. Carr, Botany Department, Queen's University, for his advice. Two of us (J. S. P. and W. W.) also acknowledge the support of the Agricultural Research Council in these investigations.

LETTERS TO THE EDITOR

ASTRONOMY

Colour on the Moon

FOR more than half a century there have been reports of colour on the Moon. Few of these confirm one another in detail.

During the past three years, applied commercial photography techniques have been used in an attempt to establish what colours, if any, occur on the Moon, and in what regions.

Using 'Tripack' colour films, including 'Daylight' Kodachrome Types 1 and 2, high speed Ektachrome and *E*3 Ektachrome as well as colour negative materials, on a small telescope, no clearly defined colour was detected.

After fruitless tests by other methods, it was found that 'colour correcting masks'[1] (transparent film positives, having about 70 per cent of the contrast shown in the negatives) applied to high-contrast negatives made from suitable transparencies yielded, on colour paper, clear local variations in colour for different parts of the lunar surface. It was further found that the regional distribution of colour differences was reproducible from phase to phase, and month to month, as well as at different image scales on the telescope. It was later found that using high contrast black and white film on the telescope, and making exposures through tricolour filters on to separate frames, gave negatives which, when enlarged and masked, enabled a colour print to be made having substantially greater colour saturation than those made from 'Tripack' transparencies. This method confirmed the pattern of regional colour distribution

The two black and white prints (Figs. 1 and 2) are made from the red filter and green filter negatives, respectively, of the direct separation set described here. To deduce the colours present, one may say that, where both prints are light in tone, then the lunar feature is light; and where both are dark, the Moon is dark. But, where the red filter print is light and the green filter print dark, this indicates a red region (yellow greatly amplified becomes reddish in this process). From this we see that M. Serenetatis is redder (yellower) than M. Tranquillitatis with a clear-cut boundary; other clearly red regions are M. Frigoris, the north-west corner of M. Imbrium, the north-west corner of Sinus Iridum, the outer rays and interspersed material of Copernicus, the northern rays of Kepler, the floor of Plato, as well as the floors of craters for about 300 miles around Alphonsus. The three dark spots in Alphonsus are also brownish. The four very dark patches lying between the Hyginus cleft and Copernicus are blue.

It is interesting to compare these prints, using visible wave-lengths, with the two black and white prints made by W. H. Wright[2] in 1926, using invisible ultra-violet and infra-red. The colour distribution is virtually identical. Furthermore, Miethe and Seegert[3], in 1911, using ultra-violet and orange light, also obtained essentially the same regional distribution of colour.

A photoelectric photometer was used with tricolour filters to read those areas on the Moon having the most sharply defined colour differences. These readings gave a value of approximately 1·0 per cent blue/yellow colour difference. This was confirmed by tricolour densitometer readings from actual colour transparencies, which, allowing for the slight increase in colour contrast of these materials, gave values of the same order. It was then found that these slight colour differences could just be seen on the transparencies.

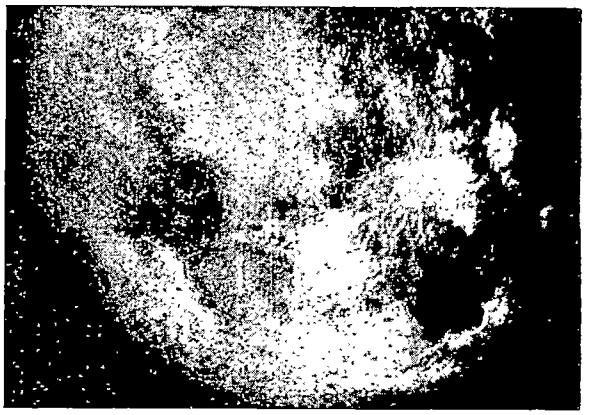

Fig. 1. Red filter

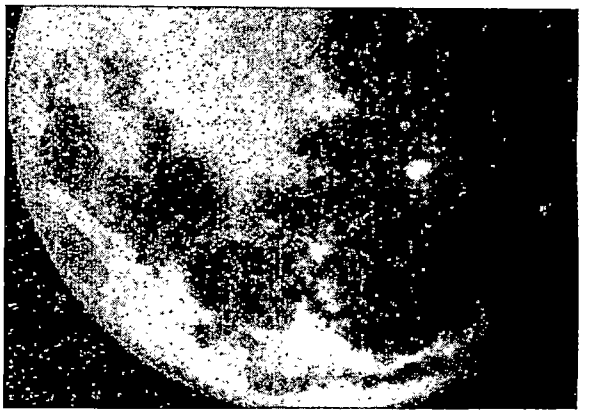

Fig. 2. Green filter

Tricolour reflexion densitometer readings from colour prints derived from the 'masked' separation negatives showed a gain in colour contrast of the order of 50–100 times. Full colour prints describe and define the distribution of colour far more completely than separate black and white prints or a verbal description.

During the course of this work it was observed that considerable colour variations in *integrated* light from the Moon occurred, having no relation to phase or zenith distance. Frequently the Moon was recorded on colour film as a sandy yellow, but even 24 h later, on the same film, might be recorded as a silvery blue. This has been confirmed on the tricolour photometer. Under 'blue Moon' conditions there appears to be an excess of blue light which swamps the basic yellow surface. The ultra-violet reflexion is also enhanced. The increase in blue content may be as much as four times. Under 'blue Moon' conditions the terminator remains relatively yellow.

Efforts have been made to correlate these blue/yellow variations in integrated lunar colour with terrestrial meteorological conditions, but without success. It has been observed that colour transparencies exposed in clear sunlight never show variations of this order for a given filtration suitable for the emulsion batch in use, provided exposures are not made within about 2 h of sunset or sunrise. The observed night-time lunar effect has been shown by experiment to be equivalent to exposing film to a sunlit subject with, and without, a Wratten *CC*50 yellow filter.

These variations of the order of four times for the blue content are absolute variations, and not shown as a result of the fifty times amplification derived from the masking procedure. Tricolour photometer readings obtained early on any particular night's observation, for a Moon not less than 30° above the horizon, have so far shown no detectable hue drift over a period of up to 4 h.

It appears that it is only possible to obtain clear colour prints from transparencies (or separation negatives) exposed under relatively 'blue Moon' conditions.

Over the past three years some 30 per cent of observations showed 'blue Moon' conditions, which do not appear to be statistically less frequent with the approach of the year of the Quiet Sun; for four nights in January 1964 the following were observed, photographed and recorded photoelectrically: January 21 and 26, yellow Moons; January 24 and 28, blue Moons. The photographic record was obtained on a single length of 35 mm Kodachrome II film, processed in one piece by Kodak, Ltd. Tests on standard test objects, including grey scales, for the 'Tripack' colour films used show negligible hue shifts for the full range of exposures used in the telescope.

On a Possibility of measuring the Einstein-shift Photoelectrically

Willmore's[1] method of tracking artificial Earth satellites optically by photoelectric observations seems to be suitable for providing methods of measurement in astronomy with new objectivity and convenience.

The method sets one or more slits in the focal plane of a telescope instead of the reticle, which, as soon as an object appears on them, emit, by a multiplier, an electric signal. Such a system could be appropriate for substituting Repsold's impersonal micrometer; I am now carrying out experiments along these lines. The main problem with this effort is the improvement of accuracy. Fea and Newton[2] have also adopted the method with regard to satellite observations. The accuracy of their device is better than 2 sec of arc. Some of the points of view which led the authors to this figure are discarded when using a star instead of the fast-moving satellite, and the others, partially, referring to the equipment, are worth an attempt towards improvement.

Having made the photoelectric methods an equal partner of the conservative astrometric methods one could make further attempts to examine the effect of the deflexion of starlight by the Sun's mass, resulting from the theory of relativity; but in the past observations made by several astronomers did not accord with theory. Recently, Schmeidler[3] published a short summary of those efforts.

The use of photoelectric methods should result in faster and surer measuring methods, and also very faint stars might be recorded because of the sensitivity of the multiplier tube being greater than that of the photographic layer.

In principle the suggested method would measure the places of the shifted stars directly during the eclipse and not thereafter on a photographic plate. Nevertheless one should determine the places and proper motions of the unshifted stars some months before or (and) later, in the same manner.

For measuring the R.A. of a star it would be sufficient to allow the star to trail across a slit and to record the time of crossing. However, the time available is too short to measure the R.A. of all stars of the field, but one might use several slits and multipliers. The positions of the slits have to be calibrated by crossings of fundamental stars. The time and the star signals would be registered on a multichannel recorder.

More difficulties are met in measuring the declinations. One or more slits should be provided parallel to the equator. A slow motion of the slits through the focal plane, that is, an adequate slow motion of the entire instrument in declination, could replace the motion in hour angle of the device above. This motion having no natural correlation to time we meet the necessity of recording the momentary position of the slits or the instrument, too. We might do this by recording the readings of a level, but since a level should be subject to very slow motions and there is no instrument good enough to make such registration, we should use, for example, some kind of pendulum device with an electronic transducer, such devices being capable of measuring fractions of seconds of arc. While measuring the declination in this manner the instrument should follow the apparent movement of the firmament.

PHYSICS

Electron Paramagnetic Resonance in Spinach Chloroplasts at Low Temperature

Photo-induced electron paramagnetic resonance signals in green plant material have been investigated for many years[1–4]. The description of the parts played by these unpaired electrons in the energy conversion processes of photosynthesis still remains a challenge. This communication describes the initial results of an approach based on the examination of the electron paramagnetic resonance signals at low temperature. It is hoped that the interpretation of the results is simplified in frozen systems by the possibility of excluding mechanisms that proceed with negligible rate in this state, for example, enzymatically catalysed reactions. Thus the observed changes in electron paramagnetic resonance signal intensity are expected to occur near the beginning of the energy conversion sequence in photosynthesis.

The electron paramagnetic resonance spectrometer used in these measurements utilizes a cylindrical TE_{011} mode transmission cavity with balanced barretter mixer detection[5] and operates at a frequency of about 11 gc/s. Magnetic modulation at a few hundred c/s is used for first or second derivative display. The cavity is surrounded by a glass Dewar and its top is cooled with a suitable liquid. Two separate 500-W tungsten projection lamps with water filters, interference filters, and coupled shutters are used to illuminate the sample simultaneously from front and back.

The 'whole' spinach chloroplasts were prepared by the method described by Pon[2]. The samples were run in 3 mm internal diameter quartz tubes after dilution with buffered sucrose solution to a suitable optical density. The optical transmission coefficients were measured in a flat 3-mm cell at a wave-length of 666 mμ with 20 mμ band-width. The light hitting the surface of the sample in the cavity has a wave-length of 700 mμ with about 20 mμ band-width and an intensity of 10^{16} quanta/cm²/sec. The chloroplast concentrations used corresponded to 1 per cent transmission at 666 mμ and 10 times this concentration. Neglecting scattering and assuming that the intensity decreases exponentially with sample penetration the 1 per cent transmission results in a maximum light intensity variation of 5 : 1 with the 2-light system. The

Table 1. Characteristics of the Three Electron Paramagnetic Resonance Signals in Spinach Chloroplasts at −40° C

Signal	g-value	Width (max. slope)	Rise time	Decay time in dark
S	2·004 ± 0·001	20 ± 2 œ	—	—
R_1	2·003 ± 0·001	9 ± 1 œ	<1 sec	sec
R_2	2·003 ± 0·001	8·5 ± 1 œ	min	h

low concentration proved useful for verifying kinetic studies while the high concentration was used for line shape and g-value measurements. The peak of the second derivative is monitored for kinetic measurements and the first derivative is used for the other studies. Potassium nitrosyl disulphonate crystals were prepared[6] and the magnetic field was calibrated at −40° C with the nitrosyl disulphonate ion in a water–methanol mixture using the room temperature g-value and hfs splitting[7]. Sample temperature is read by thermocouples attached to the top and bottom of the cavity.

At temperatures in the range −35° C to −50° C we found three electron paramagnetic resonance signals that can be distinguished by a combination of g-values, line shape and kinetic behaviour. We label the signals R_1, R_2 and S. The composite and individual signals are shown in Fig. 1, and Table 1 lists their characteristics. In some samples the S signal displayed partially resolved fine structure. No fine structure is observed with the R signals. Rough microwave saturation measurements at −40° C indicate that R_2 and S are inhomogeneously broadened lines with half maximum cavity input powers of about 10 mW and less than 1 mW respectively. We used typically about 6 mW input, about 3 œ modulation amplitude and time constant of 1 sec.

The broad signal S arises from the chloroplast sample and is present when the sample has been cooled in the dark from 0° C to −40° C. Although partially obscured by the overlapping R signals, no change could be detected in the relatively clear low field peak of S after many minutes of illumination. Our experimental uncertainty is too large to distinguish the R_1 and R_2 signals by g-value

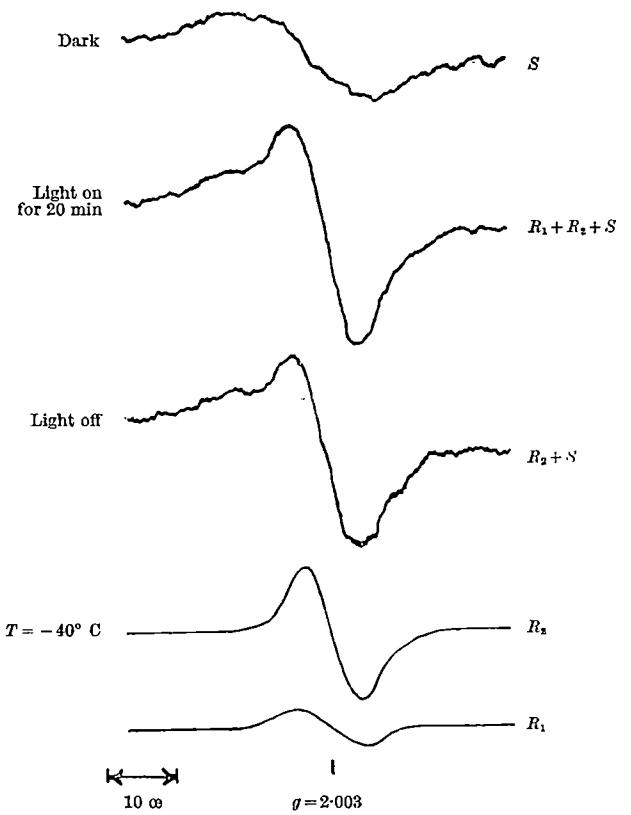

Fig. 1. Electron paramagnetic resonance signals in spinach chloroplasts at −40° C. R_1 and R_2 are obtained by subtractions of smoothed curves

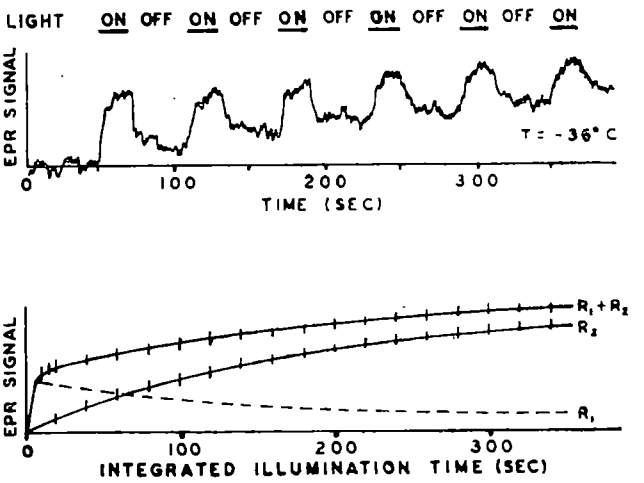

Fig. 2. Electron paramagnetic resonance signal rise and decay in spinach chloroplasts at −36° C with intermittent light and radical concentrations as a function of total illumination time

or line shape differences. That there are two R signals is made evident by kinetic data as shown in Fig. 2. The results are obtained with intermittent light having a typical 'on' time of 20 sec and 'off' time of 40 sec, while the peak height of the second derivative is continuously recorded. With a constant S signal and equal linewidths for R_1 and R_2, this method measures the relative concentration of the R_1 and R_2 electrons. When the light is turned on a composite R signal appears in a time that is instrument limited. When the light is turned off this R signal decays in several seconds to a value that we call R_2. The difference between the R signal and R_2 is designated the R_1 signal. The R_2 signal persists for many hours at low temperature but disappears in several seconds when the sample is warmed to 0° C or higher. The R_1 signal still exhibits a fast decay at −196° C. When intermittent light is incident on the sample kept at a temperature of about −40° C a slow build-up of the R_2 signal over a period of several minutes is observed while the R_1 signal becomes progressively smaller. The data also consistently show a slow rise in amplitude of the total R signal following the initial fast rise.

The interpretation of our results at this stage must be tentative. The radical S appears to be completely uncoupled from the light reaction in spinach chloroplasts at low temperature. The radicals R_1 and R_2 are intimately associated with the chlorophyll light receptors. R_1 reaches its maximum concentration very rapidly (less than 1 sec) after the light hits the chloroplasts and disappears in a few seconds when the light is turned off. It faces two modes of disappearance. It may: (*a*) return to its original 'non-electron paramagnetic resonance' state in which case it can return to its radical form when the light is turned on, or (*b*) it is converted or trapped into an R_2 radical and 'used up' so long as the low temperature is maintained. The behaviour of the R_2 radical is most interesting. A portion of the R_2 concentration comes from the slow rise of the total R signal and the remainder may be ascribed to the conversion or trapping of R_1 radicals. In the 10 different spinach chloroplast samples that have been examined these two proportions appear to be equal. At 10-min integrated illumination time the average ratio of the slow rise contribution to the amount of R_1 used up is 1·08 with a mean deviation of 0·15 and extreme values of 0·8 and 1·3. Thus the conversion of a single R_1 radical seems to give rise to 2 R_2 radicals. It is possible that R_1 initiates a reaction leading to 2 R_2 or perhaps the R_2 radicals are formed in pairs by two different, but coupled, light reactions; one proceeding via R_1 and one by a different route. Experiments at a set of temperatures down to −196° C are being undertaken with

the expectation that changes in relative values of the rate constants will define the mechanism more clearly.

This investigation was aided by contract *Nonr*–4028(00), *NR* 304–473, between the Office of Naval Research and Pomona College, and by a National Institutes of Health grant 2*G*–945.

Measurement of the Emission of Low-energy Electrons in an Irradiated Vacuum Cavity Chamber

The residual current in an ionization chamber, when the pressure is reduced to very low values, has been attributed by Greening[1] to the transfer of slow electrons between the electrodes. He correlated several experimental studies[2–9] in order to estimate the number of low-energy electrons emitted from unit area of the wall of a vacuum chamber under irradiation. For graphite the emission was about 5×10^5 electrons/cm²/rad ($2{\cdot}5 \times 10^{-4}$ e.s.u./cm²/rad) and for elektron metal about $1{\cdot}0 \times 10^6$ electrons/cm²/rad (5×10^{-4} e.s.u./cm²/rad), when irradiated by radium γ-rays. From some measurements at reduced pressure in ionization chambers Burlin[10] also made an approximate estimate of the slow electron emission and obtained a value of 5×10^{-4} e.s.u./cm²/rad from graphite.

The magnitude of the slow electron emission from a copper surface irradiated by γ-rays has been measured directly. A spherical copper vacuum chamber, with the radii of inner and outer electrodes being 3·13 cm and 5·08 cm respectively, was irradiated in the γ-ray field from a 2,000-curie telecobalt 60 unit. The wall thickness of the outer electrode, 2·64 mm of copper, was sufficient to establish electron equilibrium.

The saturation characteristics of this vacuum chamber have already been reported[11] and are represented diagrammatically in Fig. 1. The plateau value of the current when the outer electrode is positive represents the case where all the electrons emitted from the central electrode reach to the outer electrode but all the electrons emitted from the outer electrode are repelled back to the outer electrode, that is, it represents the slow electron emission from an area $4\pi a^2$, where a is the radius of the central electrode. Similarly the plateau value of the current when the outer electrode is negative represents the emission from an area $4\pi b^2$, where b is the radius of outer electrode. Hence the difference between the two current plateaux represents the low-energy electron emission from an area $4\pi(a^2+b^2)$, and this is true even if the plateaux are displaced due to radiation attenuation or other effects. The current was measured on a vibrating reed electrometer. The input resistor was calibrated by means of a standard capacitor using a capacitor leak method and was $(0{\cdot}95 \times 10^{10}) \pm 1$ per cent ohms. The electrometer was calibrated to ± 1 per cent by means of a Weston standard cell and a potential divider. The difference between the current plateaux was found to be $0{\cdot}155 \pm 3$ per cent e.s.u./sec, which corresponds to an average slow electron emission of $(6{\cdot}96 \times 10^{-4}) \pm 3$ per cent e.s.u./sec/cm² from the chamber walls.

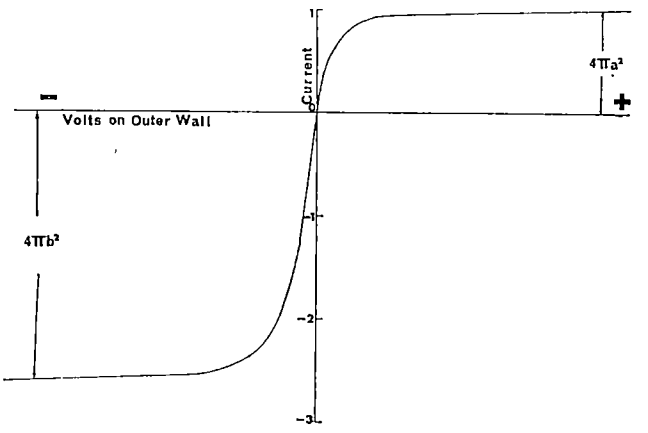

Fig. 1

There are two possible methods of determining the absorbed dose rate in the chamber walls. First, it can be calculated from the known exposure rate of the telecobalt 60 unit. This would involve a detailed knowledge of the radiation field and extremely complex corrections for the absorption and scattering in the chamber walls. In fact, these corrections would render this measurement of the slow electron emission rather inaccurate, and therefore this method was rejected. The second method is to fill the chamber with air at atmospheric pressure and use it as a cavity ionization chamber. The absorbed dose rate may then be determined using the Bragg–Gray[12] equation:

$$E_m = \frac{1}{f_m} W J_m$$

where E_m is the average absorbed dose rate in the chamber walls; f_m is the mass stopping power ratio of the gas to the solid for electrons; W is the average energy associated with the production of one ion pair in the gas; J_m is the ionization current per unit mass of gas.

The values for the average energy associated with the production of one ion pair, W, recommended by the International Commission on Radiological Units and Measurement[13] has been adopted (namely, 33·7 eV) and is assumed to be accurate to ± 1 per cent. To calculate the mass stopping power ratio for the high-energy electrons crossing the air cavity by the theory of Spencer and Attix[14] it is necessary to know the energy of an electron which will, on average, just span the cavity. The average path-length across a cavity formed by two concentric spheres can be shown to be:

$$\frac{4}{3}\frac{(b^3 - a^3)}{(b^2 + a^2)}$$

which in this case yields a value 3·76 cm. When allowance is made for the foreshortening of the electron range due to elastic scattering, an electron of 55·5 keV would traverse this distance[15]. The stopping power ratio, f_m, was then calculated as 1·32 from the Spencer–Attix theory, which recent experiments[15–17] have verified as accurate to at least ± 3 per cent in this particular case. The input resistor of the electrometer, measured on a Tinsley Wheatstone bridge, was $(1{\cdot}008 \times 10^6) \pm 0{\cdot}1$ per cent, giving a value of the ionization current of 497 $\pm$ 2 per cent e.s.u./sec corrected to N.T.P. The density of air was taken as 0·001293 gm/cm³ at N.T.P. Substitution in the Bragg–Gray equation then yielded an average absorbed dose rate in the chamber walls of $1{\cdot}56 \pm 6$ per cent rads/sec.

Thus dividing the average slow electron emission by the average absorbed dose rate yields a value of $4{\cdot}46 \times 10^{-4}$ e.s.u./cm²/rad or $0{\cdot}93 \times 10^6$ electrons/cm²/rad for the emission of low-energy electrons from copper, the surface of which was clean but oxidized, irradiated by 60 cobalt γ-rays. Allowing a maximum error of ± 5 per cent in

the volume to surface ratio, the maximum error in the value is ± 14 per cent and the most probable error ± 5 per cent. This result supports Greening's interpretation of the residual current in ionization chambers at very low pressures. Although Greening did not claim a high degree of accuracy for his estimates, this measurement of the low-energy electrons emitted from the walls of an irradiated vacuum cavity chamber is in remarkably close agreement with his estimates.

We thank Mr. D. E. A. Jones for allowing us to use the radiation facilities at Mount Vernon Hospital, Northwood, and Prof. J. F. Fowler and Mr. J. Yarwood for their advice. This work was supported by the Department of Scientific and Industrial Research.

Tests with Solid Brushes on the Canberra Homopolar Generator

Early in 1963 a programme was begun with the view of establishing whether or not solid brushes could be used instead of liquid metal jets to collect the required current (1·6 million amp) from the rotors of the Canberra homopolar generator. Within the first few weeks of investigation it became clear that there were no insuperable problems. Many pilot tests were conducted and details of the design will be published later. Since then, brush gear has been designed, manufactured and installed, and large-scale tests have been made with this gear in the homopolar generator. The behaviour of these brushes has been very satisfactory.

The homopolar generator was designed to produce a roughly sinusoidal current pulse lasting for nearly 2 sec with a peak of 1·6 million amp. In the initial tests[1], this current was drawn from the rotors by means of sheet jets of sodium–potassium alloy. The brushes have been designed for the same duty as the NaK jets, namely, to carry 1·6 million amp from the rims (outer brush units) of the mild steel rotors, at a rubbing speed of up to 33,000 ft./min. The inner brush units were designed to take the same current from an auxiliary copper slip ring clamped to the rotor, with a rubbing speed of 11,000 ft./min. Both sets of brushes were required to carry current for about 2 sec.

The arrangement of the generator for these tests was different from that used for the initial tests. The lower rotor was used, the upper rotor being clamped. The inner brush units were bolted to contact blocks which, in turn, were bolted to copper segments clamped to the bottom pole face. The outer brush units were bolted to an annular copper ring around the rotor and were staggered to run on a band 2·5 in. wide on the rotor rim. Both sets of brushes were brought into contact with the rotor for the duration of the pulse only, this being done by means of compressed air. A complete outer brush set consists of 864 brushes of 1 cm² arranged in 72 units. Thus the peak current per brush is 1,850 amp. The inner set consists of 576 brushes, 2 cm thick by 0·5 cm wide, arranged in 36 units, the peak current in each brush being 2,780 amp. The brush material is a standard high copper grade (Morganite *CM1S*). The brush wear-rate appears to be about 0·0001 in. per pulse for the outer brushes and about one-twentieth of that for the inner brushes. The load holding each brush on to the rotor rim and slip ring was 8 lb. The contact voltage drop between the outer brushes and rotor was about 0·75 V at peak current, the inner ones being half this.

In order to facilitate tests, the decision was made to install only one-half on each set of brush units and proportionately to decrease peak current to 0·8 million amp. Maximum surface speed of the rotors used was 22,000 ft./min.

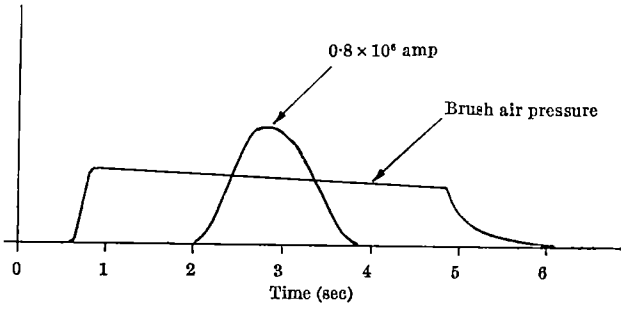

Fig. 1

During the tests, 137 current pulses were taken, 30 of which had 0·8 million amp peaks. Further, of these 30, four were taken from an initial rotor surface speed of 22,000 ft./min, and another 21 taken from an initial speed of 17,000 ft./min. The shape of the current pulses and the corresponding outer brush actuating air pressures are shown in Fig. 1. During these tests the machine and all its ancillary equipment functioned well for a total running time of more than 50 h. There has been no sign of damage to the brush track on the rotor rim so far.

The appearance and performance of the homopolar generator with brushes is clean, neat and impressive. These tests have demonstrated that large energy stores of this type are a safe practical engineering proposition, at least up to the conditions of the tests and probably up to the full design conditions. Life tests on the generator are continuing.

I thank Sir Mark Oliphant and my colleagues and the technical staff of the Brush Group for their help and advice.

GEOLOGY

Some Radiometric Rock Ages and the Problem of the Southward Continuation of the East Greenland Caledonian Orogeny

The work of Lauge Koch and others has established that a powerful Caledonian orogeny occurred in what is now the coastal region of East Greenland, north of Scoresby Sound. Whether this orogenic belt continues down the east coast of Greenland and joins the Caledonian mountain

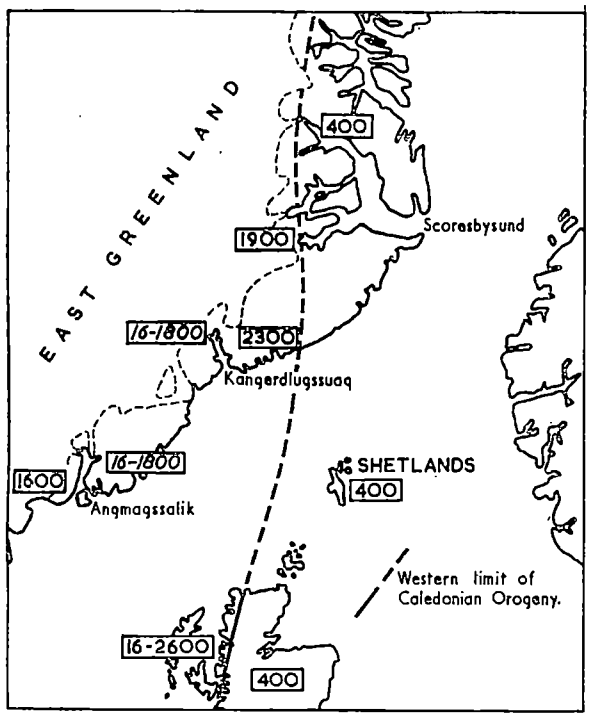

Fig. 1. Radiometric ages from East Greenland and Scotland in millions of years. The relative positions of the two sides of the Atlantic are those suggested by Bullard (Royal Society Symposium on Continental Drift, 1964). For Greenland, figures in ordinary type are from potassium/argon data and those in italics from rubidium/strontium

belt of eastern North America has been an open question but can now be answered by means of radiometric age determinations. The metamorphic basement rocks between Kangerdlugssuaq and Angmagssalik, which have a dominantly east–west structure[1], do not seem to fit into the idea of their having been involved in a north–south Caledonian orogenic belt; but if the effects of a Caledonian orogeny did not obliterate the earlier structures, this hypothesis would have to be accepted as a possibility.

With the view of deciding whether or not the metamorphic rocks south of Scoresby Sound have suffered from a Caledonian orogenic event ending about 400 m.y. ago, we have investigated the radiometric ages of rocks from certain critical areas. For some 200 miles south of Scoresby Sound, the coastal mountains (including the highest within the Arctic Circle) are cut from Tertiary basalt lavas which largely hide the basement complex. The most north-easterly exposures of the basement rocks in this area are in Nansen Fjord, 50 miles east-north-east of Kangerdlugssuaq (Fig. 1). These rocks are the most critical for the problem of the position of the Caledonian orogeny, and a granulitized biotite-gneiss collected from this point in 1935 has been investigated. The potassium/argon age of biotite from this rock proves to be 2,360 m.y. There is only a very small amount of rubidium in the biotite and a rubidium/strontium age could not be obtained. A hornblende from the basement complex at Kangerdlugssuaq has also been investigated and gives an age of 2,720 m.y. by potassium/argon, while biotites from the same rocks give 1,600–1,800 m.y. by rubidium/strontium. The ages of the rocks in this region are clearly high, but further work is required to understand the precise meaning of the divergent results.

The first exposed basement rocks south of Scoresby Sound apparently have ages comparable with the Scourian and Laxfordian rocks of Scotland. The ages of rocks from some parts of the Angmagssalik district (Fig. 1) also prove to be around 1,600 m.y., that is, comparable with the age of the Laxfordian, while in other parts the rubidium/strontium ages ranged from 1,600 to 1,800 m.y. Some of the Angmagssalik rocks are post orogenic from their textures and were thought to be perhaps Caledonian in age[2], but these also give ages around 1,800 m.y. For rocks from Gaase Fjord, a branch of Scoresby Sound, Kulp and Haller[3–5] have obtained rubidium/strontium ages of 2,300 m.y., while the potassium/argon age was found to be 1,900 m.y. These rocks, like those at Kangerdlugssuaq and Angmagssalik, lie to the west of the Caledonian orogenic belt (Fig. 1).

The chief ages determined so far from central East Greenland are shown on the map (Fig. 1). It is clear that the Caledonian orogenic belt must pass out to sea south of Scoresby Sound and north of Kangerdlugssuaq. If we accept the relative positions of Greenland and Europe, before the formation of the Atlantic, which have recently been obtained by Bullard[6] from estimates of the best fit of the 100 fathom line off the Greenland and European coasts (Fig. 1), it is seen that the East Greenland Caledonian orogenic belt passes, without change in direction, into the British Caledonian belt. The East Greenland metamorphic rocks between Kangerdlugssuaq and Angmagssalik, which lie west of the Caledonian belt, prove to be comparable in age to the Lewisian rocks of north-west Scotland, which similarly lie to the west of the Scottish Caledonian belt, and which they also resemble in general petrological character.

We thank Mr. D. C. Rex for carrying out the analytical work for the potassium/argon age determinations. A more detailed account of the ages obtained for these and other rocks from the East Greenland area will be given in the near future.

Grain Growth Fabrics in the Cambrian Dolomites of Skye

Grain growth, as defined by metallurgists, is a process of migration of grain boundaries by which the grain mosaic adjusts itself to the requirements of minimum surface tension. Harker and Parker[1], Smith[2–4], and others, have demonstrated that the occurrence of grain growth in metals may be detected by the study of the intergranular relationships within the metal mosaic. It has also been shown that such a study may be made on any random section through the granular medium.

Bathurst[5,6] suggested that grain growth may be of a considerable importance in the diagenesis of calcareous rocks, but no quantitative study of this problem has been made.

In the course of investigation of the Cambrian dolomites of Sleat (Isle of Skye, Scotland), I conducted a series of observations on the intergranular relationships shown by these rocks in thin sections and photomicrographs. The average grain size of the mosaics examined varied from less than 20μ to 350μ, the grains did not show any preferred orientation. Following the procedure used in the metallurgical research, I recorded the frequency and shape of the triple junctions between the grains and measured the interfacial angles of these junctions: 200–300 triple junctions were analysed in each of the 32 sections investigated. The results obtained indicated the existence of two main types of textures: (1) those in which features attributable to grain growth were recognized; (2) those in which the

geometry of the mosaic suggests that no adjustment to the requirements of minimum surface tension has occurred.

The grain mosaics of the first type yield an interfacial-angle frequency distribution with a maximum in the range of 100°–140° (Fig. 1*a* and *b*). The proportion of triple junctions with three obtuse angles may reach 50–60 per cent of the total. Junctions with two straight angles are uncommon, usually less than 10 per cent of the total. The boundaries at the junctions are usually concave away from the smallest angle. The occurrence of three straight boundaries at junctions with three unequal angles is rare and so are boundaries which are concave towards the smallest angle. All these features correspond closely to those reported from metals in which grain growth was induced experimentally.

Mosaics of the second type yield an interfacial-angle frequency distribution with two maxima: one in the *r* range of 160°–180° and the other between 80° and 100° (Fig. 1*c* and *d*). Triple junctions with three obtuse angles are uncommon and rarely exceed 10 per cent of the total. At 40–50 per cent of the junctions having one acute angle the boundaries are either concave towards the smallest angle (that is, in the sense opposite to that expected to result from the surface tension adjustment), or are perfectly straight.

These mosaics, which obviously are not controlled by grain growth, fall into two main sub-groups.

The first one includes mosaics or parts of mosaics which originated as 'drusy growth', 'sparry calcite' or 'granular cement' in the sense implied by Sander[7] and Bathurst[5,6]. These mosaics are medium-to-coarse grained (100–350μ average grain size) and display a very high proportion of straight boundaries. Straight boundaries are thermodynamically more stable than the curved ones and thus the 'energy barrier' which must be overcome to start the migration of the boundaries is high. It is possible also that the migration was further hindered because of the relatively large original size of the grains (that is, low surface energy).

The other sub-group includes fine- and very fine-grained mosaics in which the straight boundaries are less frequent, whereas the junctions with three obtuse angles appear more frequently (at times up to 20 per cent of the total) than in the first sub-group. This seems to suggest that, though some grain growth may have taken place, the process of adjustment to the requirements of minimum surface tension has not proceeded to completion. One of the reasons for this 'locking' of the boundaries may lie in the presence of impurities. Indeed, in most of these samples the amount of insoluble residuum exceeded 15 per cent.

It has been found that, near planes of dislocation, the fine-grained rocks of this sub-group often pass into a rock with patchy texture. The coarse-grained patches which appear within the fine-grained matrix display all the features indicative of grain growth (Fig. 1*e*). It appears, therefore, that the tectonic stress may have supplied the energy necessary for the 'unlocking' of the boundaries.

The results outlined here indicate that grain growth (in the strict metallurgical sense) occurs in calcareous rocks. The occurrence or absence of a grain-growth stage in diagenesis may be established by quantitative study of the grain mosaic geometry—based on the metallurgical methods.

I thank Prof. C. S. Smith (Massachusetts Institute of Technology) and Prof. J. Sutton (Imperial College of Science and Technology) for their advice.

Graptolites from the Kashmir Himalayas, also a Note on the Discovery of Fossils in the Muth Quartzite

In continuation of our note[1] "Graptolites in the Indian sub-continent", field work was recommenced by one of us (V. J. G.) earlier in 1964 and resulted in further graptolite discoveries. The doubt conveyed in our previous note in referring the graptolites we illustrated to *Didymograptus* (?) was well founded because examination of these by Dr. C. J. Stubblefield revealed sicular structures of Monograptid type and he refers the figured specimens to *Monograptus* cf. *vulgaris* Wood and to *M.* cf. *colonus* (Barrande) of Lower Ludlow (Silurian) age. Additional graptolites collected this year from 3 ft. higher in the succession he refers to *Monograptus* cf. *dubius* (Suess), a species which, in Europe, ranges from Wenlock to Lower Ludlow in age. Further Monograptids were found associated with an internal mould of *Cardiola* cf. *interrupta* Broderip 30 ft. below *M.* cf. *dubius*; in Europe this lamellibranch species ranges from Wenlock to Ludlow. Thus we surmise that these 30 ft. of mudstones are of Lower Ludlow age, but possibly include some Wenlock.

These Silurian fossils are all preserved in weathered buff mudstones. They occur in the area mapped by Middlemiss[2] as Older Silurian and (?) Cambrian lying below those rocks in which he had found Upper Silurian shelly fossils.

The previously recorded occurrences of *Monograptus* nearest to Kashmir are in the Northern and Southern Shan States of Burma and, according to species determinations made by the late Miss G. L. Elles[3], they indicated a Lower Llandovery age.

The Muth Quartzite of Kashmir has been considered to be unfossiliferous since its first description by Stoliczka[4] more than a century ago. It overlies the fossiliferous division called by Middlemiss (ref. 2, p. 213) Upper Silurian rocks and underlies the Lower Carboniferous *Syringothyris* Limestone Series. Stoliczka[4] assigned an Upper Silurian age to it whereas Griesbach[5] regarded it as Carboniferous; Hayden[6] and Burrard and Hayden[7] considered it to be probably partly Silurian and partly Devonian. According to Middlemiss (ref. 2, p. 217), "No fossils

have been found it it; so that as in the case of Spiti and other areas its exact age cannot be known; the only limits being Upper Silurian below and Lower Carboniferous above. It may therefore be of either of these ages, or it may be Devonian, or represent any two or all three of them".

The fossils now found are well preserved and occur in profusion though extraction is difficult. We have identified the trilobite *Phacops rana* Green; the brachiopods *Athyris spiriferoides* (Eaton), *Meristella atoka* Girty, and *Spirifer* sp.; a gastropod as *Diaphorostoma* sp. and a lamellibranch as *Modiolomorpha* sp. This fauna indicates a Devonian age—thus proving the age of a part at least of the Quartzite.

Further work is in progress on both the new Silurian and Devonian faunas. *Note added in proof.* We have now learned that I. Strachan, J. W. A. Bodenhausen, T. de Booy and C. G. Egeler have announced (*Geol. en Mijnb.*, 43, 380; 1964) the finding of early Silurian graptolites in Nepal.

CRYSTALLOGRAPHY

Electron Diffraction Study of Evaporated Beryllia

When beryllia flakes, supported on thin carbon films to form electron microscope specimens, are strongly irradiated with an electron beam, they disintegrate and small crystals condense on the surrounding carbon film. Willis, Austerman and Dearborn[1] reported that the condensed material gives electron diffraction ring patterns which they identify as being those of the high-temperature β-BeO phase examined by Smith, Cline and Frechette[2]. These latter authors suggest that the β-phase is cubic, $a_0 = 4{\cdot}76$ Å, with a non-trivial structure. According to Austerman[3], more recent work has suggested that the structure may be hexagonal or tetragonal.

The ring patterns of Willis *et al.* contain rings attributable to both the β-phase and the low-temperature α-phase. The absence of the (002) ring on α-BeO could be assumed to result from preferred orientations of the crystals.

In the course of an investigation of the disintegration of BeO crystals under electron irradiation in our *JEM-6A* electron microscope we have made observations on the crystals condensed on the supporting film which parallel those of Willis *et al.* However, we have found that under certain ill-defined conditions of electron irradiation, the condensed crystals take the form of comparatively large, thin crystal plates (linear dimensions of a few thousand Å) from which we have obtained fragmentary single-crystal patterns by selected-area diffraction methods.

From some areas we have obtained almost complete rotation patterns, given by a crystal or a set of parallel crystals bent around one axis.

Interpretation of these patterns shows clearly that the predominating ring pattern comes from a single substance rather than from a mixture of the α and β phases. The rotation pattern is readily interpreted in terms of a hexagonal unit cell with $a_0 = 5{\cdot}40$ Å and $c_0 = 4{\cdot}62$ Å, the accuracy of determination being in each case about 0·5 per cent. The rotation is about the c-axis. On the zero layer line, $l = 0$, the $hk0$ arcs are present only for both h and k even. The same may apply for $l = 2n$ because weak spots with h or k odd on layer lines with $l = \pm 2$ may be due to secondary scattering. Because the a dimension is very close on twice that for α-BeO (2·70 Å) and the c-dimension is very nearly equal to the (100) spacing (4·68 Å) the principal α-BeO rings appear to be present in the ring patterns (apart from the 002), and the rings not attributable to α-BeO have radii showing simple arithmetic relationships which could suggest a cubic structure.

The relationship between this hexagonal phase and the high-temperature β-BeO phase of Smith *et al.* remains obscure. The strong preferred orientation thought to be present in the high-temperature phase could possibly limit the pattern of the hexagonal phase to lines which could be indexed as cubic, and the report that the high-temperature phase could be hexagonal is suggestive. An identification of this sort would remove doubts that the observed hexagonal phase is actually BeO, since the possibility must be considered that it results from reaction of the BeO with the gases present or the carbon supporting film.

The existence of a structure derived from α-BeO with commensurate unit cell dimensions (except for a 6 per cent increase in c-axis) is of particular interest in relation to the anisotropic expansion of the lattice of BeO irradiated in a nuclear reactor at moderate temperature[4]. The relatively great expansion in the c-direction commonly observed could be explained if a primary effect of irradiation was the formation of small nuclei of this hexagonal phase.

This work was supported by a research contract from the Australian Atomic Energy Commission.

METALLURGY

Effect of Grain Boundaries on the Diffusional Growth of Oxides on Metals

Several mechanisms[1-3] for the growth of thin films of oxides on metals have yielded equations of the form $y^3 = kt$, where y is the film thickness, k a rate constant, and t, time. However, none of these mechanisms can be satisfactorily extended to the case of thick films formed on such metals as titanium, zirconium and tantalum[4]. It is proposed that this so-called 'cubic' oxidation can result from a combination of diffusion along grain boundaries and normal bulk diffusion in relatively thick oxide films.

The usual high-temperature protective oxidation of metals obeys a parabolic kinetic law, $y^2 = k't$, and the mechanism universally accepted for this law is that proposed by Wagner[5]. The oxide is assumed to grow by the diffusion of defects across the film. Constant defect concentrations at the metal–oxide and oxide–gas interfaces provide a gradient of chemical potential inversely proportional to film thickness. It is assumed in this mechanism that diffusion occurs across the bulk of the oxide film and that grain boundaries in the oxide film can be safely ignored.

In laboratory determinations of diffusion coefficients the possibility of grain boundary effects, especially at moderate temperatures, is generally appreciated[6]. The significance of grain boundary effects can be examined by

two methods derived from the mathematical solutions of the equations appropriate to diffusion into a semi-infinite body from a planar source. The more usual method is to plot the logarithm of the concentration of the diffusing species as a function of the distance from the source. However, since growing oxide films have a constant concentration difference across them, this method is not applicable. The alternative is to determine the distance from the source at which a given concentration-level is found at successive times. For bulk diffusion the distance is proportional to $t^{1/2}$, but for grain boundary diffusion the function is $t^{1/4}$ (refs. 7 and 8). It has been generally appreciated that these two laws ($t^{1/2}$ and $t^{1/4}$) are limiting cases. Hitherto it has not been possible to appreciate the intermediate kinetic behaviour when grain boundary diffusion is playing some part but is not completely dominant.

Two papers have recently been published[9,10] presenting results of the numerical integration of the differential equation governing diffusion from a constant planar source into a semi-infinite solid containing a grain boundary perpendicular to the surface. These permit a closer examination of this intermediate behaviour, which can conveniently be discussed in terms of the parameter $\beta = \frac{D'}{D}\frac{\delta}{2}\frac{1}{\sqrt{Dt}}$, where D' is the diffusion coefficient in the grain boundary of width δ, D the coefficient of bulk diffusion, and t, time. This parameter can be regarded as a measure of the relative significance of grain boundary to bulk diffusion. If $\beta < 0{\cdot}1$ grain boundary effects are negligible and the $t^{1/2}$ law applies. When $\beta > 10$ grain boundary effects are dominant and the law becomes $t^{1/4}$. By using the published results for $\beta = 1$ and $\beta = 5$ (ref. 9) it has been demonstrated that the exponent of t decreases smoothly, as might be expected from $\frac{1}{4}$ to $\frac{1}{2}$ as β increases from approximately 0·1 to 10 and that values close to $\frac{1}{3}$ correspond to values of β between about 1 and 5, that is, when the effects of grain boundaries are comparable to those of bulk diffusion.

Since β is itself a function of time ($\propto t^{-1/2}$) the value of the exponent of t for $0{\cdot}1 < \beta < 10$ is not strictly a constant. However, the exponent increases from $\frac{1}{4}$ to $\frac{1}{2}$ as β is varied by two orders of magnitude, and this corresponds to a variation of four orders of magnitude of time. Hence, in practice, where time-intervals rarely cover even two orders of magnitude, the variation will be small and could easily be obscured by the scatter of experimental results.

To apply the above kinetic behaviour to the growth of oxides on metals with the usual assumption of the Wagner oxidation mechanism (constant concentrations of the diffusing defects at the metal–oxide and the oxide–gas interfaces) the oxide thickness should be equated to the penetration from the surface to a constant concentration contour. The published figures[9,10] relate solely to the penetration at the grain boundary, whereas oxidation measurements, as usually determined by weight gain or volumetric methods, provide a mean thickness of oxide film. The difference between the mean thickness and maximum grain boundary penetration is seen[9,10] to depend on both β and the concentration difference. For fairly small values of β and for the small concentration differences associated with defects in oxides this discrepancy between penetration and mean thickness is not expected to be large. It should also be noted that the model for the mathematical analysis involves only a single grain boundary, and hence is strictly only applicable if the boundaries are sufficiently far apart to exert independent influence. Grain size in oxide layers is typically of the same order of magnitude as the thickness and therefore this condition does not apply. However, one effect of multiple boundaries will be to make the mean thickness closer to the grain boundary penetration. Mathematical analysis of the multiple grain boundary model has not been evaluated but to a first approximation the effect of multiple boundaries will be to increase the concentration within the grains and that other boundaries will have relatively little effect on the penetration at a boundary itself. This lends some support to the application of the kinetics of grain boundary penetration to oxidation.

Since grain boundary diffusion kinetics arise from a combination of penetration along a boundary and lateral spreading away from the boundary some modification due to multiple boundaries is to be expected. In general terms it can be seen that the effect of material reaching the grains from more than one boundary will be to reduce the tendency of material to diffuse laterally away from grain boundaries. The magnitude of this effect is expected to increase as grain size is reduced, and in the limit of infinitely small grains diffusion would be characterized by the grain boundary diffusion coefficient alone. At this limit a parabolic law would again apply. The distance from a grain boundary enters the calculations as a reduced dimensionless parameter which incorporates $t^{-\frac{1}{2}}$ and therefore the effect of the grain boundary spacing in the multiple grain boundary model is also expected to be time-dependent. In the early stages with thin oxide films the boundaries are comparatively widely spaced and act independently with the kinetics of the mathematical model. However, the mean thickness will be comparatively less like the grain boundary penetration than in the later stages where the oxide thickness is similar to the grain size. At this stage, however, the mathematical model is inadequate. These two effects, the initial difference between mean thickness and grain boundary penetration and the later significance of grain boundary interaction, both act in the same sense to make oxidation behaviour somewhat closer to parabolic than the mathematical model of grain boundary diffusion indicates.

The boundary conditions used for the numerical integration correspond to a uniform concentration of diffusant over a planar source surface. For gaseous oxidation with growth proceeding by anion diffusion this should be appropriate provided the outer interface remains reasonably planar. For growth by cation movement this condition requires that the metal–oxide interface is planar and has high surface diffusion rates (with little surface diffusion at the gas–oxide interface). The boundary conditions would have to be modified if these assumptions do not apply.

To take account of grain boundaries the kinetic equation for the diffusional protective growth of oxides on metals has to be generalized to $y^n = kt$, where n takes the value 2 for negligible effect of boundaries but may be as high as 4 for complete dominance of grain boundary diffusion. The effect of grain boundaries may not be constant during oxide growth and the value of n may similarly change.

Not only does a consideration of grain boundaries in an oxide film provide a satisfactory mechanism for cubic and similar growth laws but it also suggests new possible mechanisms for the effect of alloy additions on oxidation characteristics and such phenomena as breakaway oxidation. It is hoped to explore these and give a more thorough analysis of the effect of grain boundary diffusion at a later date.

CHEMISTRY

Vapour Pressures of Xenon (77°–180° K) and Krypton (77°–130° K)

For the evaluation of recently measured low-temperature adsorption data we required the vapour pressure curves of krypton and xenon from 77° K to about 20° K above their respective triple points. We therefore undertook a critical review of the literature in order to try to define for each gas the vapour pressure curve that is best substantiated by the reported values. We found that the vapour pressure data for krypton published by various authors[1–6] are generally in good agreement with each other. Most reported values lie within ± 1 per cent of the curve given by the vapour pressure equations of Freeman and Halsey[6], which can therefore be used with some confidence.

On the other hand, the vapour pressure data for xenon[3,6–9] show more serious inconsistencies, and the use of the equations recommended for solid xenon in different temperature regions results in a sharp change in the slope of the curve of $\ln p$ against $1/T$ when changing over from one equation to the next, although it is clear that no corresponding phase change of the condensed xenon occurs.

We have therefore examined the available vapour pressure data for xenon and compared them with the vapour pressure curve, which can be calculated from calorimetric data[10], in an attempt to find a satisfactory smooth curve from 77° K to 180° K. The vapour pressure equations considered are given in Table 1.

The *FH* equation for liquid xenon deviates quite considerably, especially towards 180° K, from those of *HO* and *MW*, which agree with each other within 0·5 per cent. For solid xenon, the temperature regions of the two available vapour pressure equations (*FH* and *PD*) do not overlap ; extrapolation of the *PD* equation yields an intersection point at 111·5° K, where, however, solid xenon exhibits no phase change.

A first indication of the reliability of the slopes of the vapour pressure equations near the triple point is obtained from Table 2 in which the Clapeyron melting enthalpies calculated from the difference in slopes of the vapour pressure equations at the triple point are compared to the calorimetrically measured values[10,11]. It is inferred that it is probable that the slopes of *HO* (and therefore of *MW*) and of *FH* for the solid are close to the true ones, whereas the slope of the *FH* liquid equation is erroneous. For krypton the two *FH* equations yield a value which is in reasonable agreement with the calorimetric one.

Table 1. Vapour Pressure Equations for Xenon

Vapour pressure equation (p) (mm Hg)	Stated temperature range in which equation valid (°K)	Authors and abbreviations used in text
$\log_{10} p = 7{\cdot}2488 - \frac{720{\cdot}7}{T}$	160·56–166·2	Freeman and Halsey[6] (*FH*)
*$\log_{10} p = 6{\cdot}9903 - \frac{678{\cdot}49}{T}$	160·8–166·0	Heuse and Otto[7] (*HO*)
$\log_{10} p = 26{\cdot}08413 - \frac{1{,}040{\cdot}76}{T} - 8{\cdot}25369 \log_{10} T + 0{\cdot}0085216\, T$	161·7–289·2	Michels and Wassenaar[8] (*MW*)
$\log_{10} p = 7{\cdot}7371 - \frac{799{\cdot}1}{T}$	110·0–160·56	Freeman and Halsey[6] (*FH*)
$\log_{10} p = 8{\cdot}044 - \frac{833{\cdot}33}{T}$	70 – 90	Podgurski and Davis[9] (*PD*)

* Equation obtained from their data with the method of least squares.

Table 2. Comparison of Calorimetric and Clapeyron Melting Enthalpies

	Calorimetric (cal/mole)	Clapeyron from *FH* equations (cal/mole)	Clapeyron from *FH* and *HO* equations (cal/mole)
Kr	390·7 (ref. 11)	401	—
Xe	548·5 (ref. 10)	359	552

The calorimetric data of Clusius and Riccoboni[10] are extensive, and have been used to calculate a calorimetric vapour pressure curve with the equation:

$$\log_{10} p = 4{\cdot}464 + 2{\cdot}50 \log_{10} T - \frac{L_0}{4{\cdot}576T} - \frac{\int_0^T \frac{c_p}{T}\,dT}{4{\cdot}576} + \frac{\int_0^T c_p\,dT}{4{\cdot}576T} - \frac{Bp}{4{\cdot}576T}$$

The last term is only significant above 120° K. It is a correction term for the non-ideal behaviour of the saturated vapour which is assumed to obey the equation of state, $pV = RT + Bp$, where:

$$B = \frac{9}{128}\frac{RT_c}{p_c}\left(1 - 6\frac{T_c^2}{T^2}\right)$$

from the Berthelot equation. In Fig. 1 it is shown how, using a value for the latent heat of sublimation of xenon at 0° K (L_0) of 3,780 cal/mole, which is also the value recommended by Hollis Hallett[12], the calorimetric vapour

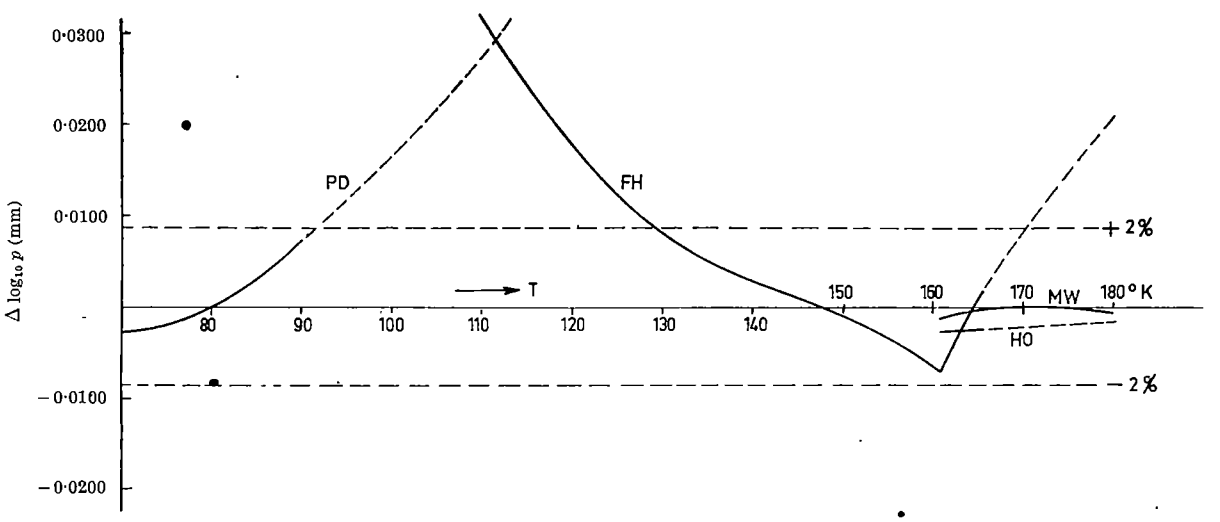

Fig. 1. Deviation of experimental xenon vapour pressure equations from calorimetric vapour pressure curve. ●, Liang (ref. 3); – – –, equation extrapolated outside experimental temperature region or stated region of validity

pressure curve deviates from the vapour pressure data available between 77° and 180° K.

It can be seen that for liquid xenon the *MW* and *HO* vapour pressure equations agree well with the calorimetric curve. For solid xenon the *PD* equation is in agreement within its stated experimental accuracy in the experimental temperature region but when extrapolated to higher temperatures it begins to deviate seriously. The *FH* equation agrees (within 2 per cent) with the calorimetric equation only at temperatures above 130° K. The value given by Liang[3] falls off by 5 per cent. It is possible that this deviation is due to uncertainty in the thermal transpiration correction as has been discussed by Podgurski and Davis[9].

We therefore recommend that, until more precise vapour pressure measurements are available, the calorimetric vapour pressure curve should be used for the vapour pressure of solid xenon. The estimated error is ± 2 per cent at any temperature between 70° and 161° K. The vapour pressure is most easily calculated from the values given by the *PD* or *FH* equation and by the application of the correction curve given by Table 3. For the vapour pressure of liquid xenon either the *MW* or, below 180° K, the *HO* equation can be used.

Table 3. CORRECTIONS TO BE APPLIED TO THE *PD* OR *FH* EQUATIONS TO OBTAIN THE VAPOUR PRESSURE OF SOLID XENON

T (°K)	*p* (mm Hg)	$\text{Log}_{10}(p)$
70	$1{\cdot}39 \times 10^{-4}$	*PD* + 0·0028
80	$4{\cdot}24 \times 10^{-3}$	*PD* + 0·0000
90	$5{\cdot}99 \times 10^{-2}$	*PD* − 0·0072
100	$4{\cdot}95 \times 10^{-1}$	*PD* − 0·0164
110	2·76	*PD* − 0·0275 *FH* − 0·0320
120	11·5	*FH* − 0·0173
130	38·2	*FH* − 0·0085
140	106	*FH* − 0·0030
150	258	*FH* + 0·0010
160	562	*FH* + 0·0067

We thank the O.E.C.D. High Temperature Reactor Project *Dragon*, the sponsors of our low-temperature adsorption investigations, for permission to publish this communication.

Water Content of Black Soap Films

IN a recent investigation of the thickness of black soap films, Corkill *et al.*[1] determined the water content of the films by measuring the absorption of radiation at 2·93μ by placing a number of black films in an infra-red beam. In order to calculate the amount of water from the infra-red absorption, it is necessary to know the molar extinction coefficient at 2·93μ. Since the absorption is so strong, Corkill *et al.* measured the extinction coefficient with very thin cells (using a gold leaf spacer) and claim that the value of 133 obtained by this method was identical with the extinction coefficient obtained by measuring the optical density of water in deuterium oxide. There is no reason to suppose that the extinction coefficient should be identical for pure water and dilute water in deuterium oxide, and a re-determination was considered desirable, particularly as the value of 133 quoted by Corkill *et al.* is very different from the earlier value of 55 obtained by Fox and Martin[2].

The full experimental details for the determination of the molar extinction coefficients will be given elsewhere[3]; but it is found that the value for water in D_2O is 131, in good agreement with Corkill *et al.*, but that the value for pure water in thin films is 81. This difference between pure water and water in D_2O is reasonable and will be discussed later[3]. Taking the value of 81, the amount of water in the black soap films examined by Corkill *et al.* will be larger by a factor of 1·62 than the values quoted by these authors. Thus for a film drawn from an aqueous solution of $C_{10}H_{21}N(CH_3)_3C_{10}H_{21}SO_4$ (8×10^{-4} M) + NaBr (0·5 M) said to be 72 Å thick with a water core of 29·4 Å, the corrected water core thickness would be 47·6 Å. However, this calculation is open to objections. The extinction coefficient is certainly a function of the composition of the water phase, in the same way as the Raman intensities for the water vibration band are a function of the solute concentration and type in aqueous solutions[4,5].

We thank Dr. W. A. Senior for his advice.

Nucleation and Morphology of Chymotrypsinogen Crystals

IT has been suggested recently[1] that the morphology of enzyme crystals grown from solutions at various supersaturations[2] may be interpreted in terms of the basic mechanisms of nucleation. Little is known of either the nucleation mechanism or the solid-state properties of enzymes, since most are notoriously unstable even under mild conditions. The work presented here is a preliminary examination of the nucleation of bovine α-chymotrypsinogen from solution. This enzyme has been selected because it is available commercially in a particularly pure form and something is known of its solid-state structure. From X-ray diffraction data[3] the molecule is said to be spherical with a radius of 21 Å. It consists of approximately 246 amino-acid units[4] and has a molecular volume of 17,100 ml./mole[5].

If an aqueous solution of chymotrypsinogen is allowed to evaporate on a glass slide at a temperature of about 20° C very small crystallites are produced. Using carbon films and platinum shadowing it is possible to examine the morphology of replicas by low-magnification electron microscopy, some typical examples being shown in Figs. 1, 2 and 3. The crystals are generally in the size-range 1–10μ and the morphology shows several apparently familiar features with some unusual details. Fig. 1 indicates a collapsed pyramid structure similar to that known for several synthetic polymers in which chain folding is the dominant growth mechanism, and Fig. 3 shows dendritic growth with a marked central groove. Despite a search of many such crystals with high-resolution electron microscopy we have been unable to detect screw dislocations or regular growth steps. Although the absence of these features seems to indicate that chain folding is not the normal growth mechanism it could also

Figs. 1, 2 and 3. Electron micrographs of bovine α-chymotrypsinogen crystals grown from aqueous solution (platinum shadowed replicas. × c, 8,600)

have been caused by collapse of the crystals during the shadowing procedure.

Slow evaporation of a solution of the enzyme in the hemispherical well of a microscope slide has, however, given further evidence of the growth mechanism. Around the edges of the well clearly defined whiskers were formed (Fig. 4). The thickening of the whiskers at the base seems similar to the phenomenon observed by DeVries and Sears[6] for growth of Al_2O_3 whiskers from the vapour phase. These authors observed that the whiskers grew from a region of low super-saturation at the tip to a region of high super-saturation at the base where rapid growth ceased. The thickening in that case was postulated as occurring when the super-saturation was critical with respect to two-dimensional surface nucleation.

Fig. 4. Optical micrograph of the edge sector of evaporated enzyme solution (Reichert microscope. × c. 330)

In the present case it seemed that the whiskers might have grown with a central screw dislocation possibly instigated by heterogeneous nucleation. Closer inspection of Fig. 4 does, however, indicate that the whiskers are, in fact, hollow (at least in some places) and do not grow by a screw mechanism. Side branches apparently occur at massive dislocation junctions.

Since the relation between heterogeneous and homogeneous nucleation of the enzyme is reminiscent of features observable for less-complicated crystals, a more quantitative approach can be formulated. If it is assumed that at low super-saturations the enzyme undergoes heterogeneous nucleation and whisker growth, and at higher super-saturations generates a vast number of crystallites by homogeneous nucleation, then the critical super-saturation for the latter process can be calculated (approximately) from the geometry of the crystallization pattern on the microscope slide and the maximum metastable concentration. In solubility investigations of chymotrypsinogen we find that the solubility decreases with increase in temperature. The metastable limit from the temperature solubility studies occurs at a super-saturation ratio of about 1·15. The critical (homogeneous) super-saturation is consequently approximately 1·6. Applying classical concepts to the homogeneous process the interfacial energy is 0·4 erg/cm^2 and the critical radius 123 Å.

From the foregoing calculation, though crude, it would appear that the interfacial energy is considerably lower than that of chain-folded synthetic polymers[7] and this may indicate a more random configuration of the chymotrypsinogen molecule. The morphology and nucleation study are, therefore, in accord with the view that bovine α-chymotrypsinogen crystals probably grow by accretion of globular material which is randomly oriented (but specifically located) within the crystal. Such observations are in agreement with the available X-ray results.

Polarography of Quinazoline

THE polarographic behaviour of quinazoline displays special features which are not shown by the related compounds quinoxaline, phthalazine and 1,5-naphthyridine.

The anomaly is found in the *p*H-dependence of the limiting current. In neutral and alkaline solution the wave has the height of a normal two-electron wave. Between *p*H 6 and *p*H 1·5 the wave splits into two and the sum of the height of these two waves diminishes to less than 10 per cent of the height in neutral solution. In more acid solution the height of the waves increases and in 40 per cent perchloric acid ($H_0 \sim -2{\cdot}5$) it reaches approximately the height found in alkaline solution.

Whereas the wave-height of quinazoline at *p*H 6 is proportional to the square-root of the height of the mercury reservoir (diffusion controlled wave), the wave-height at *p*H 1·5 is independent of the height of the mercury reservoir, indicating that the wave-height is mainly governed by the rate of a chemical reaction.

4-Methylquinazoline and 2,4-dimethylquinazoline do not show this dependence of wave-height on *p*H; nor do 4-methoxy-, 4-mercapto-, 4-methylmercapto-, 4-chloroquinazoline, and 3,4-dimethylquinazolinium iodide. 3-Methylquinazolinium iodide, however, shows a similar feature in all solutions where the polarograms can be measured before hydrolysis of the ring.

Quinazoline also displays anomalies in other respects. The base strength ($pK_a = 3{\cdot}5$) is higher than expected (1·5, ref. 1) and the ultra-violet spectrum of the cation shows a hypsochromic shift compared with that of quinazoline. These anomalies have been explained by assuming that quinazoline in acid solution adds water with formation of an abnormal cation, 4-hydroxy-3,4-dihydroquinazolinium ion.

A dependence of wave-height on *p*H, similar to that of quinazoline, is found in the polarography of pyridine aldehydes[2,3]. This is attributed to the fact that the aldehyde groups in the protonated pyridine aldehydes at *p*H near unity are mainly in the hydrated state, which is not reducible.

The polarographic behaviour of quinazoline is thus explained by assuming that the reducible species in acid solution is the normal quinazolinium ion, whereas the abnormal cation, 4-hydroxy-3,4-dihydroquinazolinium ion, is not reducible. According to this the polarography of quinazoline (Q) is governed by the following equilibria and the rate of these reactions:

$$\begin{array}{ccc} Q + H_2O & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & Q,H_2O \\ \Downarrow + H+ & & \Downarrow + H+ \\ H^+Q + H_2O & \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} & H^+Q,H_2O \end{array}$$

with the four equilibrium constants:

$$K_1 = (Q,H_2O)/(Q)(H_2O) \quad (1)$$

$$K_2 = (H^+Q,H_2O)/(H^+Q)(H_2O) \quad (2)$$

$$K_3 = (Q)(H^+)/(H^+Q) \quad (3)$$

$$K_4 = (Q,H_2O)(H^+)/(H^+Q,H_2O) \quad (4)$$

The wave-height at *p*H > 2·5 is chiefly determined by the equilibrium concentration of the reducible, unprotonated quinazoline. This is shown by the fact that a similar curve with inflexion at the same *p*H (3·6) is found, when the extinction at 310 mμ of quinazoline is plotted against *p*H. The absorption at 310 mμ is mainly caused by quinazoline, whereas the abnormal cation has very little absorption at 310 mμ.

At *p*H 1 the wave-height is essentially governed by the rate of the dehydration of the irreducible, abnormal cation to the reducible, normal cation. The rate is the sum of an uncatalysed and an acid-catalysed reaction rate. The acid-catalysed dehydration is mainly responsible for the increase in wave-height between *p*H 0 and H_0 about − 2. In more acid solution the equilibrium concentration of the normal cation increases, and this, together with the presence of some unhydrated, doubly-protonated cation, is also of importance for the wave-height.

The assumption of the irreducibility of the abnormal cation is substantiated by the fact that 3-methyl-4-hydroxy-3,4-dihydroquinazoline is polarographically irreducible and only yields an anodic wave.

4-Chloroquinazoline is polarographically reducible and yields two two-electron waves in neutral solution. By controlled potential reduction the first wave was shown to be caused by a reduction to quinazoline. In acid solution at 25° C the compound is rapidly hydrolysed to the irreducible 4-quinazolone, but at − 5° to − 10° C the compound is stable enough for polarographic investigation in 40 per cent alcohol. At *p*H 1, 4-chloroquinazoline yields a two-electron wave followed by two one-electron waves; the sum of the heights of the one-electron waves is equal to the height of the two-electron wave. The two one-electron waves are found at the same potentials as those of quinazoline, but the wave-height of quinazoline under the same conditions is very much smaller. This indicates that the quinazolinium ion formed in the reduction of 4-chloroquinazoline is reduced before it has time to be hydrated.

From (3) and (4) it follows that:

$$pH = pK_3 + \log (Q)/(H^+Q) = pK_4 + \log (Q,H_2O)/(H^+Q,H_2O) \quad (5)$$

The experimental results show qualitatively that $(Q) \gg (Q,H_2O)$ and $(H^+Q) \ll (H^+Q,H_2O)$, and thus at the experimentally determined:

$$pK_A(3{\cdot}6)\ (Q) \simeq (H^+Q,H_2O) \quad (6)$$

Introducing (1), (2) and (6) into (5) one gets:

$$pK_A = pK_3 + \log (H_2O) + \log K_2 = pK_4 + \log (H_2O) + \log K_1 \quad (7)$$

pK_3 has been estimated to be 1·5 (ref. 1) and pK_4 has been measured at 7·77 (ref. 4). From these the values $K_1 \simeq 1{\cdot}5 \times 10^{-6}$ and $K_2 \simeq 2$ are obtained. According to this estimate about 99 per cent of the protonated quinazoline is present as the abnormal cation. From this value and the ratio of the limiting current at *p*H 1·3 and the diffusion current at *p*H 7 (and assuming the same diffusion coefficients for the different forms of quinazoline) one can calculate[5] the rate of the dehydration at *p*H 1·3; $k_{-2} = 0{\cdot}2\ sec^{-1}$. The value of k_{-1} at *p*H 10 has been found[4] by a method of flow technique to be $0{\cdot}077\ sec^{-1}$.

The uncertainty of the estimate of k_{-2} is mainly due to the difference between pK_2 and the estimated value 1·5. pK_2 is probably equal to or greater than pK of pyrimidine (1·3); spectroscopic data (concentration of normal cation ~ 0 per cent)[4] seem to exclude more than 2 per cent of the normal cation in the equilibrium at *p*H about 1. This means that k_{-2} with a high probability has a value between 0·1 and 0·4 sec^{-1} at *p*H 1·3.

BIOCHEMISTRY

Crystalline β-Nigerose

Since its isolation from the partial hydrolysate of nigeran by Barker *et al.*[1], nigerose (3-O-α-D-glucopyranosyl-D-glucose) has been obtained from various sources. In each case, octa-acetate of the sugar was readily obtained in crystalline form, but the free sugar was highly hygroscopic and had hitherto not been successfully crystallized. We were able to prepare this sugar with a fairly good yield by the acetolysis of dextran[2] and we have now crystallized the free sugar.

When 390 g of the dextran from *Leuconostoc mesenteroides* B[3] (in our earlier report[2] the name of the strain was incorrectly given as *L.m.* NRRL, *B*–421) was acetolysed, fractionation on a charcoal column yielded 41 g of crude nigerose. When this amorphous nigerose was dissolved in 80 per cent methanol and allowed to stand at room temperature for about ten months, during which the solvent was evaporated, a part of the syrup showed crystalline appearance. A small portion of the crystallized part was added, as a nucleus, to a solution of 10 g of nigerose in 80 per cent methanol. Crystallization occurred very slowly and, after a week, 3·5 g of fine crystalline product was obtained (Fig. 1). The yield of the crystal was not satisfactory as compared with other common sugars, and crystallization took at least several days and sometimes several months.

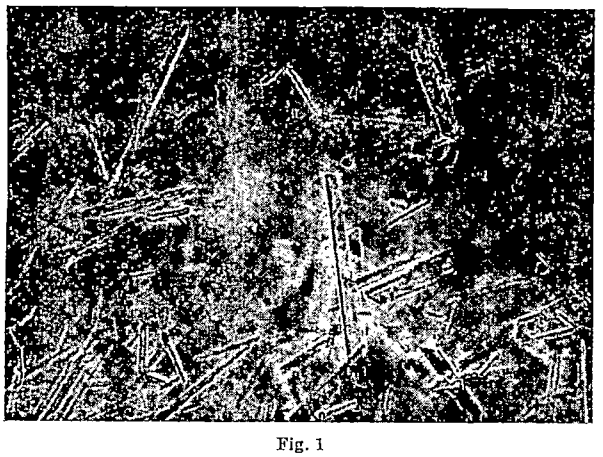

Fig. 1

On drying *in vacuo* at room temperature or at 100° C in atmospheric pressure, the crystal was less hygroscopic. Recrystallized nigerose had a melting point of 156° C (uncorrected) and $[\alpha]_D^{19} = +125° \rightarrow 138°$ (17 h) (approximately 2·0 in water). (Observed values were: C, 42·32; H, 6·43 per cent; values calculated for $C_{12}H_{22}O_{11}$: C, 42·11; H, 6·48 per cent). The upward mutarotation indicated that this crystalline nigerose was the β-anomer. Complete acid hydrolysis of this crystalline nigerose gave D-glucose equivalent to 99·8 per cent of the theoretical value. Acetylation with pyridine as a catalyst produced only β-nigerose octa-acetate, which showed no depression of melting point on admixture with the known specimen; m.p. 150° C, $[\alpha]_D^{2} = +83°$ (approximately 2·1 in chloroform). The infra-red spectrum (KBr disk) of this crystalline nigerose showed the absorption peak at 842 cm^{-1} (α-linkage)[4] and also at 892 cm^{-1} (β-anomer)[4]; the latter was not observed in amorphous nigerose[4,5]. Furthermore, no absorption peak around 1,650 cm^{-1} (free water or water of crystallization)[4] was observed in the above spectrum. The X-ray diffraction data (interplanar spacing (Å), CuK_α radiation: relative intensity as percentage of strongest line, estimated visually) were: 7·34 : 30, 7·08 : 20, 4·46 : 50, 4·29 : 20, 4·18 : 100, 3·81 : 20, 3·53 : 10, 3·34 : 10, 3·12 : 10.

From the above properties, it is now confirmed that this crystalline product is anhydrous β-nigerose.

We thank the Department of Pharmacology, of this University, for microanalysis, and Dr. J. Masui for X-ray diffraction measurements.

Alpha-Amylase Activity of Varieties of English Wheat

One criticism of English wheat is its often very high and variable α-amylase activity. It is well known that as the wheat grain begins to germinate its α-amylase activity increases very rapidly. Conditions during a wet harvest are such that many samples of English wheat yield flours which are unsuitable for bread production by reason of this high activity.

In a recent examination of 109 flours milled from wheats supplied by the National Institute of Agricultural Botany grown at its headquarters and sub-stations, the α-amylase activity ranged from 1–141 Farrand units[1] with a mean of 7. Some samples of flour gave activities which one would normally associate with wheat containing weathered and prematurely sprouted grain, although based on their visual appearance they were bright and free from sprouted grain.

In particular, one variety of winter wheat, 'Professeur Marchal', gave flours the activity of which ranged from 15–141 units, with a mean of 72.

Flour from 'Cappelle Desprez', grown and harvested under the same conditions as the former variety, had activities ranging from 6 to 12 units, with a mean of 8.

Since much English wheat is bought and sold on its appearance, it is important to wheat buyers to know which varieties are likely to produce samples of unusually high α-amylase activity and yet appear to be bright and attractive. It would therefore be worth while to make a detailed examination of present and future varieties of wheat from this angle.

Chemical Analysis of Proteins Low in Aromatic Amino-acids

Methods for protein estimation in common use such as ultra-violet absorption and the method of Lowry *et al.*[1] rely on the presence in the molecule of the aromatic amino-acids tyrosine and tryptophan, and if these are present in low concentrations, estimates of protein will be subject to error. Our *in vivo* investigations into blood coagulation[2] have revealed that the active moiety, serum thrombotic accelerator[3], which plays an important part in this mechanism, is low in aromatic groups. This deficiency was first indicated from the ultra-violet absorp-

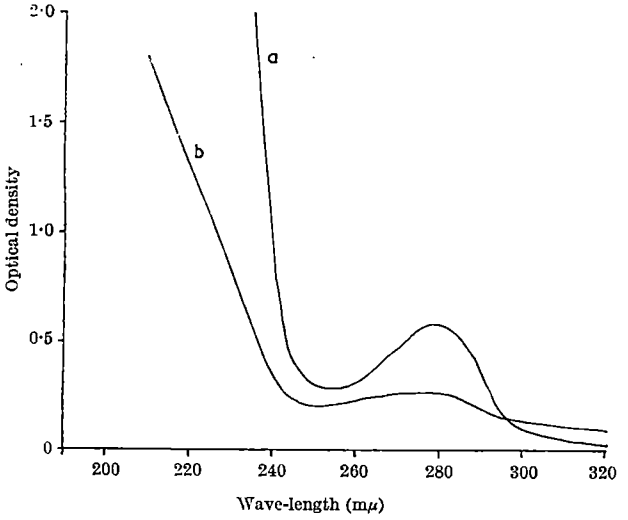

Fig. 1. Ultra-violet absorption spectra of (*a*) bovine serum albumin (1·3 mg/ml.) and (*b*) serum thrombotic accelerator (1 mg/ml.). Optical density was measured in a Unicam *SP* 500 spectrophotometer using 1 cm silica cells

tion spectrum of the serum thrombotic accelerator, which revealed a depressed peak at 280 mμ when compared with the corresponding spectrum of serum albumin (Fig. 1).

From the divergence between these spectra it was concluded that the error, using the method of Lowry *et al.*, would be large and this was confirmed as the isolation of serum thrombotic accelerator proceeded, since variable results were obtained with this method. The micro-biuret technique of Goa[4] was therefore substituted since the colour production depends only on the presence of peptide bonds in the protein molecule, except that the formula for the quantitative 'Benedict' reagent of Varley[5] and not that of Goa[4] was used in our estimations because of the greater stability of the former over a period of time. One disadvantage of the method is that the quantity of protein required (300 μg/ml.) is greater than in the method of Lowry *et al.* (30 μg/ml.).

Our investigations also required the estimation of the bound carbohydrate in the serum thrombotic accelerator for which we used the anthrone procedure of Goa[6] with some modifications. The low tryptophan content of the serum thrombotic accelerator proved to be advantageous, since this amino-acid is known to interfere with the anthrone reaction[7], and application of this latter procedure to serum proteins has therefore produced values for hexose which have varied, for example, serum albumin[8,9]. The colour production between anthrone and carbohydrate is normally measured at its maximum absorption peak of 630 mμ; however, the additional reaction due to the presence of tryptophan produces a second maximum at 530 mμ and interference at 630 mμ, resulting in a lower reading at the latter wave-length.

The absorption curve produced by the anthrone reagent and galactose is compared in Fig. 2 with those produced by the reaction of anthrone with albumin, fibrinogen and the serum thrombotic accelerator, respectively. It will be seen that no correction for tryptophan interference was necessary with the serum thrombotic accelerator since the colour production followed closely that of a pure sugar, whereas an additional absorption at 530 mμ with a concomitant reduction at 630 mμ occurred with fibrinogen and albumin.

Björnesjö[10] attempted to correct this interference by the use of a nomogram incorporating readings at 530 mμ and 630 mμ, and concluded that the error produced by tryptophan could reach 15–20 per cent. This author also emphasized the importance of standardizing the conditions of the reaction, and his observation that the optimum colour development occurred at 90° C over a period of 16 min was confirmed by us. We adopted the practice, originally described by Scott and Melvin[11], of layering the protein solution over the cooled anthrone reagent and then mixing very rapidly so as to dissipate heat quickly. We confirmed that this order of addition, as opposed to that of reagent to the protein solution, was important for maintaining the yellow colour of the blank solution as well as preventing precipitation of the anthrone.

The final method used incorporating these modifications is as follows: The proteins are precipitated with 0·2 ml. phosphotungstic acid (5 per cent in 2 N HCl) per ml. of solution, followed by centrifugation at 1,000 r.p.m. for 2 min. The supernatant is poured off, and after washing the precipitate with 95 per cent ethanol it is dissolved in one drop of 5 N NaOH and made up to 2 ml. Boiling-tubes containing 4 ml. freshly-prepared anthrone reagent (British Drug Houses, 0·2 per cent in concentrated sulphuric acid) are cooled in an ice bath, and the test samples carefully layered on top of the anthrone by running down the side of the tube which is immersed at an angle of 45° in the bath. This position is held for a few moments so that any heat produced at the interface is dissipated, and then the tube is rapidly swirled while still immersed so as to mix the reagent and sample, the swirling being continued until the contents of the tube are cooled. The tubes are kept in the ice bath until all have been similarly treated, and after being placed in a water bath at 90° C for 16 min are transferred back to the ice bath in order to cool rapidly. A period of 10 min is allowed for the tube contents to warm up to room temperature and the colour is then read in the spectrophotometer at 630 mμ against the blank, which consists of 2 ml. distilled water treated in the same manner as the samples. The blank should be clear and yellow after heating while the test solutions turn green. Standards should be run every time using an equimolecular mixture of galactose and mannose at 25 μg/ml. and 50 μg/ml. respectively.

It is felt that this method incorporates the most important practical details from a number of different anthrone procedures, and we feel that these together with our experiences of the various methods for protein estimation mentioned here will be useful to others working with proteins low in aromatic amino-acids. We would further emphasize the importance of obtaining an ultra-violet

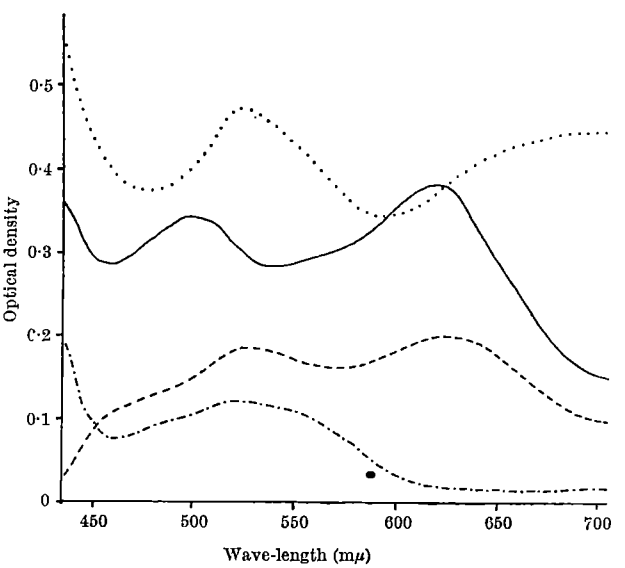

Fig. 2. Absorption spectra in the visible region of the colour produced between anthrone reagent and various plasma proteins, compared with that produced between anthrone and galactose. . . . ., Fibrinogen (4 mg): — — — —, serum thrombotic accelerator (1 mg); — . — . — . bovine albumin (6 mg); ——, galactose (50 μg)

absorption spectrum on the protein before a method for its estimation is chosen, and an absorption curve in the visible region on the anthrone colour, so that if necessary a correction can be made for tryptophan interference.

Influence of Excreted Substance from Leaves on Decomposition of Zineb, a Dithiocarbamate Fungicide

A variety of substances are excreted by leaves[1], and have a direct influence on the germination of fungus spores[2] and on the activity of copper fungicides[3]. Since the fungicidal activity of the dithiocarbamate fungicides depends largely on their mode of decomposition and this in turn depends on environmental conditions[4], we examined the influence of the foliar excreta.

Leaves of grape (var. 'Trebbiamo'), potato (var. 'Majestic'), sugar beet (var. 'Maribo P.'), and apple (var. 'Golden Delicious') were collected. Four samples, each of 100 cm² surface, of each species were prepared by cleaning with a dry cotton plug and immersing for 3 h in 100 ml. of distilled water. Care was taken to exclude petioles. After 3 h one part of each liquid sample was mixed with a previously prepared 4 per cent suspension of zineb (zinc ethylene-*bis*-dithiocarbamate), in a ratio of one part of zineb to nine parts of wash-water, yielding 0·4 per cent zineb suspension. These operations were repeated on three consecutive days with the only difference that samples of the first day were chromatographed immediately after mixing wash-water and zineb; samples of the second day were mixed with zineb and maintained for 3 h at 26° C and those of the third day were mixed and maintained for 5 h before being chromatographed. As a control zineb suspension was mixed in every case with distilled water (one part of 4 per cent zineb with nine parts of distilled water).

Descending chromatograms were prepared on Whatman No. 1 paper with a mixture of distilled water, ethanol and butanol (1 : 1 : 1 mixture for 24 h at laboratory temperature). After drying, the chromatograms were developed with a spore suspension of *Aspergillus niger* in diluted peach juice ($7{\cdot}5 \times 10^5$ spores/ml.). 1·34 ml. of this suspension was distributed on 100 cm² paper. After 72 h incubation at 27° C the zones of inhibition were evident on the paper as white spots.

Neither of the wash-waters without zineb gave inhibition spots, whereas all those suspensions with zineb did so at $R_F = 0$, that is, at the start, corresponding to zinc-ethylene-*bis*-dithiocarbamate.

A second inhibition spot with $R_F = 0{\cdot}86 - 0{\cdot}89$ was evident with the following suspensions: (*a*) Chromatograms prepared immediately after mixing zineb and wash-water: zineb in distilled water, light spots in all four replications; in grape wash-water, light spots in two replications; in potato, in sugar beet, and in apple wash-water, no spots. (*b*) Chromatograms prepared 3 h after mixing zineb and wash-water: distinct spots with distilled water and with all wash-waters in the four replications. (*c*) Chromatograms prepared 5 h after mixing zineb and wash-water: only zineb in potato wash-water gave inhibition spots in all four replications. There were two distinct spots at $R_F = 0{\cdot}86 - 0{\cdot}88$ and at $R_F = 0{\cdot}70 - 0{\cdot}72$.

Table 1. *p*H Values of the Wash-waters obtained using Different Kinds of Leaves, with and without Zineb

	Mean	*S.E.*
Sugar beet wash-water	6·79	0·07
Sugar beet wash-water + zineb	7·11	0·24
Potato wash-water	6·94	0·05
Potato wash-water + zineb	7·76	0·03
Grape wash-water	7·27	0·09
Grape wash-water + zineb	7·51	0·04
Apple wash-water	7·38	0·02
Apple wash-water + zineb	7·56	0·01
Zineb alone	7·26	0·01
Distilled water	6·10	0·72

It is evident that the substances excreted from the leaves affect the decomposition and activity of the zineb sprayed on the leaf-surface; as a rule, the activity is enhanced. The small differences in the R_F-values suggest that the decomposition products are similar, with the exception of the product of the potato wash-water.

Comparison of the chromatographic results with the *p*H values (Table 1) suggests that the more distinct inhibition spots of the potato wash-water are due to its higher *p*H value, and this agrees with Thorn's suggestion[4] that decomposition of zineb is enhanced by an alkaline environment, where it produces ethylenethiurame-monosulphide. In fact, in other trials carried out by us (unpublished) the R_F values of the ethylenethiurame-monosulphide were 0·84–0·88.

Chloroplast Ribosomes

Previously[1] we have found ribosomes in chloroplasts of *Chenopodium album* and *Clivia miniata*. As shown by electron microscopy and biochemical methods, ribosomes located in the matrix of chloroplasts are 180–200 Å in diameter and possess a sedimentation coefficient of about 70 *S* in the presence of 10^{-2} M Mg^{2+}. The work described here is concerned with the isolation of chloroplast ribosomes from a number of higher plants and investigation of some of their chemical and physico-chemical properties.

Chloroplasts were isolated from leaves of eight species of higher plants (before flowering) belonging to six families: *Clivia miniata* (Amaryllidaceae), *Beta vulgaris* and *Chenopodium album* (Chenopodiaceae), *Galinsoga parviflora* (Compositae), *Triticum vulgare* (Gramineae), *Lamium album* (Labiateae), *Phaseolus vulgaris* and *Pisum sativum* (Leguminosae). Wheat and pea seedlings, 7–10 days old, were also used.

The isolation of chloroplasts was carried out by differential centrifugation, the rate of precipitation of nuclear and chloroplast fractions being particular for each plant. The details of the procedure were described previously[1].

Chloroplast and cytoplasmic ribosomes were isolated as described previously[1] with the only modification that the former were purified not only by reprecipitation but

also by 0·5 per cent sodium deoxycholate treatment to remove chloroplast material rich in lipids which are present in the ribosome fraction.

The amount of protein was estimated by Lowry's method[2]; RNA was determined spectrophotometrically[3]. The nucleotide composition of RNA was estimated according to Spirin and Belozersky[4]. Sedimentation was carried out in a Spinco model *E* ultracentrifuge at 37,020 r.p.m. RNA ultra-violet absorption spectrum was measured in 1-cm quartz cells in an *SF*-4 model spectrophotometer.

An investigation of the chloroplast fraction in light and phase microscopes showed that 'intact' particles (chloroplasts with undamaged membrane) comprised 60–80 per cent of the fraction[5]. RNP particles isolated from chloroplasts of all the plants examined displayed an absorption spectrum with λ_{max} at 260 mμ and λ_{min} at 240 mμ. The $\lambda_{max}/\lambda_{min}$ ratio was 1·40–1·65. The ultra-violet spectrum of chloroplast ribosomes was similar to that of cytoplasmic ribosomes. The protein and RNA content of the chloroplast RNP particles was 60–40 per cent of protein and 40–60 per cent of RNA. With regard to its nucleotide composition, RNA of chloroplast ribosomes was of the so-called *GC*-type, the coefficient of specificity being 1·15–1·21 and purines prevailing over pyrimidines. The nucleotide composition of the chloroplast ribosomal RNA in various plant species was the same, differing insignificantly from that of cytoplasmic ribosomes (Table 1). Similar results concerning the nucleotide composition of the spinach chloroplast RNA were obtained by Lyttleton[6]; the coefficient of specificity amounted to 1·17–1·19. Only RNA of ribosomes isolated from *Euglena gracilis* chromatophores belongs to the *AU*-type, the specificity coefficient being 0·88–0·89 (ref. 6). In the analytical ultracentrifuge in the presence of 10^{-2} M Mg^{2+}, all preparations of chloroplast ribosomes investigated gave a single main peak with a sedimentation coefficient of about 70 *S*. All preparations also displayed a 17–20 *S* component and in some experiments very small peaks of dimers and sub-units were also discovered. Under these conditions the main components of the cytoplasmic ribosome fraction were also particles with a sedimentation coefficient of about 70 *S*. Together with the main component a small peak of dimers was always observed in this fraction. The slow component in the fraction of cytoplasmic ribosomes was absent in most experiments (Table 2). In experiments on spinach chloroplast ribosomes Lyttleton[6] and App and Jagendorf[7] found sedimentation coefficients to be close to our values. According to Lyttleton[8] the slow component in the chloroplast ribosome fraction is a water-soluble protein devoid of RNA which is related to the chloroplast photosynthetic function. In a magnesium-free medium chloroplast ribosomes dissociate into sub-units similar to those of cytoplasmic ribosomes (Table 3). This process is reversible, and the addition of Mg^{2+} to the medium results in the re-synthesis of initial ribosomal particles. If the concentration of Mg^{2+} ions increases to 3×10^{-2} M, particles with a sedimentation coefficient of about 70 *S* remain the main structural component (Table 4). Extrapolation of sedimentation coefficients obtained for chloroplast and cytoplasmic ribosomes of pea and bean to infinite dilution gives 79–81 *S*. Thus, chloroplast ribosomes do not differ from cytoplasmic ribosomes isolated from the same plants and belong to the type of 80 *S* particles common to all higher plants and animals.

Table 1. Nucleotide Composition of RNA of Chloroplast and Cytoplasmic Ribosomes

Ribosomes	G	U	C	A	Pur/Pyr	G+C/A+U	G±U/A+C
	(mole per cent)						
Chenopodium album							
Chloroplast	28·5	21·3	25·3	24·7	1·14	1·17	0·99
Cytoplasmic	30·3	20·4	23·9	25·3	1·25	1·18	1·03
Lamium album							
Chloroplast	28·2	20·7	25·3	24·8	1·15	1·17	0·96
Cytoplasmic	28·9	22·0	24·5	24·5	1·15	1·15	1·04
Phaseolus vulgaris							
Chloroplast	29·2	20·8	24·3	25·6	1·21	1·15	1·00
Cytoplasmic	29·4	21·2	24·4	25·1	1·19	1·16	1·02
Pisum sativum							
Chloroplast	29·8	21·2	24·8	24·2	1·17	1·20	1·04
Cytoplasmic	30·1	20·8	24·8	24·3	1·19	1·21	1·03

Mean values are given calculated from 8–10 individual estimations in each of 2–3 parallel hydrolysates of ribosomal preparations. Pur, Purine bases; Pyr, pyrimidine bases; G, guanylic acid; U, uridylic acid; C, cytidylic acid; A, adenylic acid.

Table 2. Sedimentation Coefficients ($S_{20,w}$) of Chloroplast and Cytoplasmic Ribosomes (Mg^{2+}, 10^{-2} M)

Source of ribosomes	Chloroplast ribosomes				Cytoplasmic ribosomes			
	Slow comp.	Main comp.	Additional components		Slow comp.	Main comp.	Additional components	
Beta vulgaris	17·5	71·1	—	—

Modified Phycoerythrin from *Porphyridium cruentum* treated with *p*-Chloro-mercuribenzoate

Phycoerythrin, one of the biliproteins in red algae, which plays a part in photosynthesis, exhibits various absorption bands in the visible absorption spectrum[1,2]. Recent investigations have shown that these bands are independent of each other. Among three absorption bands at 500, 545 and 565 mμ of phycoerythrin from *Ceramium rubrum*, the two bands at 500 and 545 mμ disappear on reduction with sodium hydrosulphite[3]. O'hEocha and O'Carra presented evidence that the 500 mμ band behaves independently of the other two[4]. Furthermore, the 565 mμ band disappears on the addition of *p*-chloro-mercuribenzoate (PCMB) to phycoerythrin isolated from *Ceramium rubrum*[3] and *Porphyridium cruentum*[5]. These results indicate the existence of different chromophores absorbing at different wave-lengths.

Further investigation in this laboratory has revealed that phycoerythrin could be split into two units, each of

which contains different chromophores. This communication is concerned with the separation of a modified component of phycoerythrin, which has a single absorption band at 545 mμ, from PCMB-treated *Porphyridium cruentum*. An interaction of this component with glutathione will also be reported.

During the course of investigation on the effect of SH-blocking agent PCMB on energy transfer in *Porphyridium cruentum*, a gradual increase of an orange fluorescence has been observed. Since a decrease of the fluorescence by PCMB is accompanied by the disappearance of the 565 mμ absorption band in phycoerythrin free from the cells either in ruptured cells or in isolated form[5], this observation is an unexpected result. In spite of the reverse change of the fluorescence, the same loss of the 565 mμ absorption band occurs in PCMB-treated cells. This is shown in Fig. 1 by absorption spectra of cell suspension before and after treatment with PCMB (Fig. 1, *A* and *B*). In this measurement, the cells of *Porphyridium cruentum* separated by centrifugation from culture medium and suspended in 0·1 M phosphate buffer at *p*H 7·0 were saturated with PCMB (California Corp. Biochem. Research) and left standing overnight before measuring the absorption spectrum. Opal glass was used in a Cary spectrophotometer model 14.

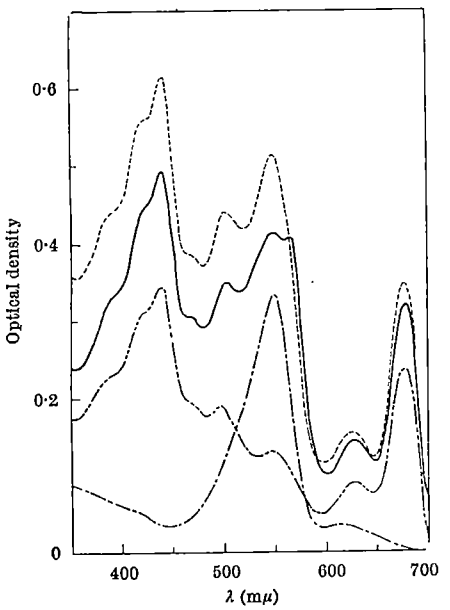

Fig. 1. Absorption spectra of (*A*) intact cells (——), (*B*) cells saturated with PCMB (- - - - - - -), (*C*) modified phycoerythrin (— - — - —) separated from the cells, and (*D*) cell residue (— - - — - - —)

The above suspension with PCMB was centrifuged at 10,000*g* for 10 min. A resulting fluorescent supernatant exhibited a single absorption band at 545 mμ, a small absorption at 615 mμ probably being due to phycocyanin (Fig. 1, *C*). The absorption spectrum of a greenish-brown cell residue re-suspended in the same buffer solution revealed that a component absorbing at 500 mμ remains in the cells (Fig. 1, *D*). This result indicates that the modified fluorescent component of phycoerythrin having a single band at 545 mμ was released from the cells and was responsible for the increase of fluorescence in the cells treated with PCMB.

It is known that phycoerythrin splits into smaller units in more alkaline media[6–8]; but the spectral characteristics of these units have not been examined. Very recent work by Vanghan[9] also shows that phycoerythrin is composed of sub-units. Previous investigations have shown that a change in protein structure can be induced by the blocking of protein SH-groups[10,11]. The dissociation of the phycoerythrin molecule into units in the cell and the release of the one unit from the cell is probably the result of PCMB changing the intermolecular protein structure and the permeability of cell membrane.

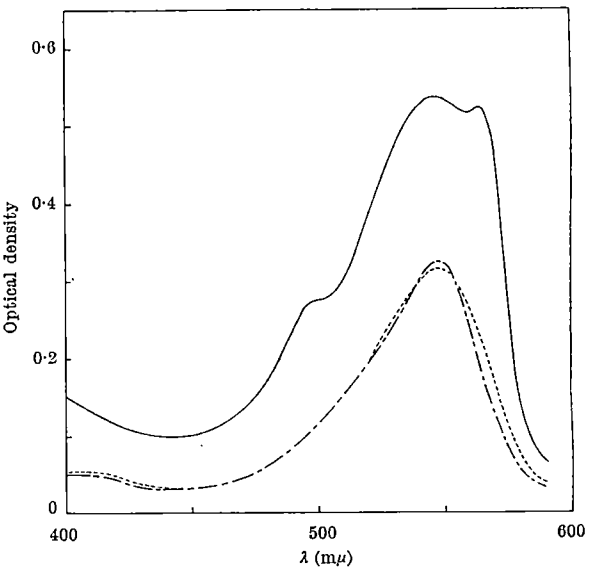

Fig. 2. Absorption spectra of native phycoerythrin (——) and modified phycoerythrin without (— - — - —) and with (- - - - -) glutathione (5×10^{-3}M) in 0·1 M phosphate buffer at *p*H 7

The absorption spectrum of the modified fluorescent segment of phycoerythrin is compared in Fig. 2 with that of native phycoerythrin which has three absorption bands at 500, 545 and 565 mμ. Native phycoerythrin was isolated from *Porphyridium cruentum* in the same method as reported previously[3], except that the cells were sonicated by means of a Raytheon sonic oscillation, model *DF*-101 (200 W, 10 kc/s), instead of freezing and thawing. Since the 565 mμ band disappears on blocking SH-groups of native phycoerythrin with PCMB, the possible presence of the inactive 565 mμ chromophore in this modified unit was examined. Treatment with glutathione (C. F. Boehringer and Soehne *G.m.b.H.*, Mannheim, Germany) did increase the absorption at 565 mμ region, reducing the absorption at 545 mμ, to some extent (Fig. 2). A striking change occurred in the fluorescence. As shown in Fig. 3, action spectra of the fluorescence at 575 mμ of the same solution as in Fig. 2 show a considerable increase of the fluorescence in the presence of glutathione. The action spectra were measured on an Aminco-Keirs spectrophosphorimeter equipped with an RCA *IP*21 photomultiplier. This shows that the 545 mμ chromophore becomes efficient in producing the fluorescence though its absorption does not increase. According to the previous investigation[5], the 565 mμ chromophore is highly fluorescent in native phycoerythrin, accepting an energy absorbed by the 500 and

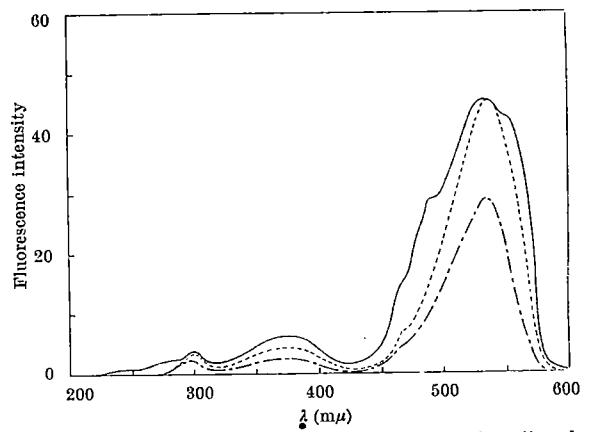

Fig. 3. Action spectra of the fluorescence at 575 mμ in native phycoerythrin (——) and modified phycoerythrin without (— - — - —) and with (- - - - - -) glutathione (5×10^{-3} M)

545 mμ chromophores. Therefore, in the glutathione-treated modified component the highly fluorescent 565 mμ chromophore regenerated in a small amount possibly contributes to the high yield of fluorescence through energy transfer from the 545 mμ chromophore.

This investigation indicates the existence of at least two main units in phycoerythrin from *Porphyridium cruentum* : one contains the 500 mμ chromophore and the other contains the 545 and 565 mμ chromophores. In the latter, SH-groups of protein interact with the 565 mμ chromophore. It would be possible that these units are composed of smaller sub-units. Further investigations on sub-unit structure of phycoerythrin are at present in progress.

PHYSIOLOGY

Uptake of Labelled Precursors of Melatonin by the Epiphysis of *Xenopus laevis*

THE hormone, melatonin, was first isolated from bovine pineal glands by Lerner *et al.* in 1958 (ref. 1). Its only biological activity appeared to be to cause contraction of the melanocytes in Amphibia. Since that time melatonin has been found in pineal tissue of other mammals[2–4] and birds[5]; but there has been, as yet, no demonstration of its presence in amphibian pineal glands.

Axelrod and Weissbach[6] have shown that melatonin is synthesized from 5-hydroxytryptamine (5HT) by *N*-acetylation followed by *O*-methylation. The enzyme which catalyses this final step, 5-hydroxyindole *O*-methyl transferase, has been found only in pineal tissue. The donor for the methyl group is *S*-adenosyl methionine.

If the epiphysis of *Xenopus* is producing melatonin, then it is predictable that the cells of this organ should incorporate labelled 5HT and also methionine labelled in the methyl group. In the experiments reported here young adult *Xenopus*, 3–4 months after metamorphosis, were used. The wet weight of each animal was approximately 5 g. The labelled precursors used were 5-hydroxytryptamine-3′-^{14}C creatinine sulphate and ^{14}C-methyl methionine (supplied by the Radiochemical Centre, Amersham).

The first experiment was undertaken to see if labelled 5HT was incorporated into cells of the epiphysis. 5 μc. of the precursor was injected into the dorsal lymph sac of each of six frogs, which were placed in black painted plastic containers measuring 17·5 cm long × 11·5 cm wide × 5 cm deep, with transparent plastic lids. All animals were kept in constant light provided by a 60-W pearl bulb placed 1 m above the containers.

Table 1. Comparison of the grain counts made in areas of 10μ² over the epiphysis with those over the optic lobes in 5 animals injected with ^{14}C-methyl methionine and killed at different periods after injection. These results were subjected to a *t*-test and the difference between the mean count over the epiphysis and that over the optic lobe was in each case highly significant (P, 0·0001)

Time after injection (h)	Mean grain count over epiphysis	Mean grain count over optic lobe
2	27·8	15·6
6	56·7	33·1
24	75·7	38·2
72	81·4	40·9
168	55·0	31·9

Animals were decapitated 5 min, 6 h, 12 h, 24 h, 3 days and 1 week after injection. The brains were quickly dissected out, fixed, and prepared for autoradiography which was carried out using the stripping film technique with Kodak '*AR* 10' films. A similar series of experiments was performed using ^{14}C-methyl methionine.

In both cases incorporation into epiphysial cells of labelled precursors was observable. Fig. 1 shows a radioautograph over the epiphysis of an animal injected 3 days previously with ^{14}C-5HT that clearly demonstrates the uptake of the compound by the cells of the organ. Grain counts over the epiphysis and over the adjacent areas of the brain are given in Table 1, and again uptake of labelled precursor, this time ^{14}C-methyl methionine, is demonstrated.

The fact that there is a blood-brain barrier in higher vertebrates, which does not operate in the pineal region[7], suggests that the greater uptake of ^{14}C-5HT in the epiphysis of *Xenopus* as compared with other parts of the brain may not be in itself significant. However, what is significant is that 5HT is taken up at all, and in such large quantities.

The following experiments give a strong indication that both methionine and 5HT are incorporated into the same compound. It would be supposed that if the epiphysis of *Xenopus* is producing melatonin, stores of this hormone would become depleted in animals kept on a white background. There is a synchronous decrease in the amounts of both radioactive precursors detectable in the pineals of animals kept in white containers as compared with those kept in black ones. These results will be fully discussed elsewhere.

It has been demonstrated by these experiments that both ^{14}C-5HT creatinine sulphate and ^{14}C-methyl methionine are taken up by cells of the epiphysis of *Xenopus laevis*. The experiments do not prove that melatonin is made by the organ, but this would certainly seem probable.

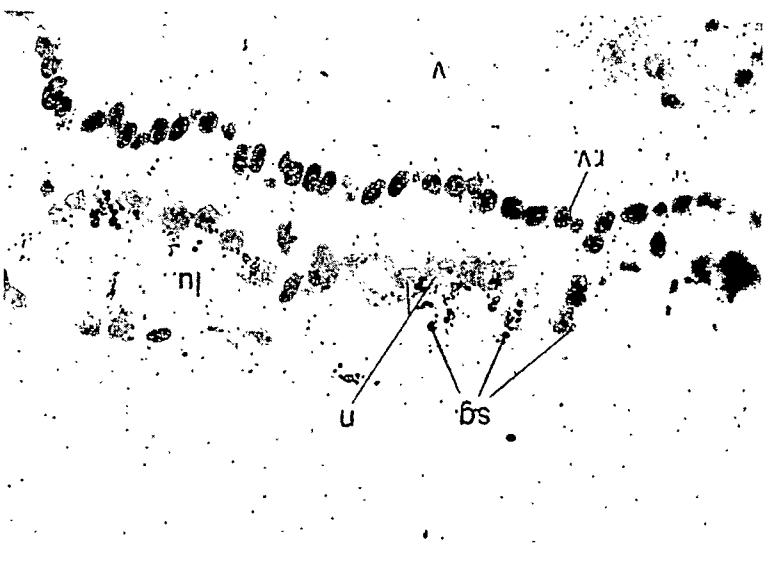

Fig. 1. Autoradiograph of the epiphysis of a young adult frog 3 days after injection of 5-hydroxytryptamine-3′-^{14}C creatinine sulphate. *lu*, Lumen of epiphysis; *n*, nuclei of epiphysial cells; *rv*, roof of third ventricle; *sg*, silver grains; *v*, third ventricle

This work was performed during the tenure of a research studentship from the Department of Scientific and Industrial Research.

Grants from the Gilbert Foyle Educational Trust and the Haberdashers' Co. were used towards the cost of radioactive chemicals. I thank Dr. P. C. J. Brunet for his advice.

Marked Decrease of DNA in the Nuclei of the Adrenal Medulla of Rats exposed to Cold

Exceptions have been made to the concept of constancy of DNA per nucleus, established by Boivin[1] on the basis of biochemical determinations and nuclear counts, and confirmed by others[2] on the basis of histophotometric measurements.

Many of them have been explained as being caused by instrumental errors, polyploidy, polyteny or synthesis of DNA in preparation for mitosis (see Bonucci[3] and Hale[4]). Others so far resist critical scrutiny. The great majority of the variations reported are small (around 10–15 per cent). This work is concerned with determinations of the DNA content of the nuclei of the adrenal medulla of rats exposed to cold. A decrease of DNA, of the order of 40 per cent, could be demonstrated by three different methods.

Adult male albino rats, 'Italico' strain, bred in our department, weighing 250–330 g, were kept at +4° C for 15 h/day for a total period of 100 or 300 h.

A second group of rats, after exposure to cold for 300 h, was kept at room temperature (15°–20° C) for 10 days. Another group of animals was used as control. Suprarenal glands were fixed in neutral formalin and embedded in paraffin. Sections 15μ thick were stained by the Feulgen method.

The absorption of the DNA-Feulgen complex was measured at 546 mμ on whole nuclei by means of an integrator 'scanning' histophotometer, designed on the basis of Jansen's[5] model. The nuclei of the normal adrenal medulla showed a DNA content slightly higher than that of the diploid nuclei of the kidney. After exposure to cold, the DNA content of the nuclei of the adrenal medulla showed an average diminution (with respect to the controls) of 22·2 per cent after 100 h, and 39·6 per cent after 300 h. In the animals which had been exposed to cold and then kept again at room temperature for 10 days, the nuclear DNA content was found to return to the normal and in some nuclei was significantly above the normal values.

The variations in the DNA content of nuclei obtained by cytochemical methods, in order to be considered as the expression of physiological changes of the cells, must satisfy the following criteria[6,7]: (1) that DNA has not been synthesized in preparation for a mitotic division; (2) that the number of chromosomes be known; (3) that no errors have been made in the measurements.

As regards the first criterion, mitoses are not seen in the cells of the adrenal medulla after the 30th day of life (Mitchell)[8]. Synthesis of DNA *de novo* in our adult animals can, therefore, be ruled out.

As to the second criterion, it is evident for the above reason that a direct chromosomal count is not feasible.

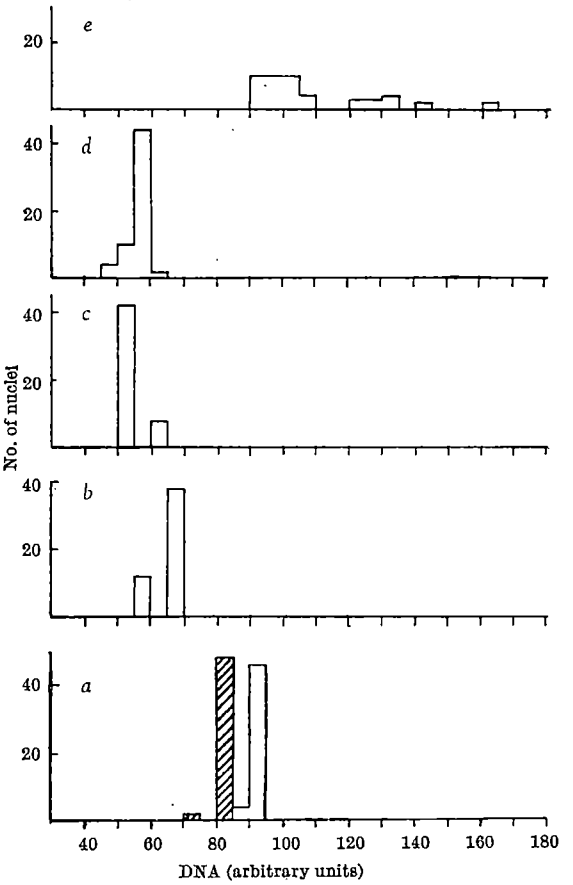

Fig. 1. Histograms of DNA content obtained by histophotometry in arbitrary units. *a*, From the nuclei of renal tubules (cross-hatched) and of the adrenal medulla in normal conditions; *b*, from the nuclei of the adrenal medulla after exposure to cold for 100 h; *c*, from the nuclei of the adrenal medulla after exposure to cold for 300 h; *d*, as *c*, smears of nuclei; *e*, from the nuclei of the adrenal medulla of rats kept for 10 days at room temperature, after exposure to cold for 300 h

However, if the observed decrease in DNA is due to a reduced chromosome number, it implies that 40 per cent of the chromosomes disappear during exposure to cold and are formed again (without mitosis) during the period in which the DNA content is restored to the normal value; an unlikely hypothesis.

As to the third criterion, the measurements made with our instrument are free from errors arising from the distribution of the DNA-Feulgen complex and from the shape of the nuclei. It is also possible to exclude errors arising: (*a*) from being 'out of focus', since the differences observed using smeared nuclei are coincident with those observed using sections; (*b*) from possible discrepancies in the absorption curve of the DNA-Feulgen complex (on the basis of tests made); (*c*) from variations in the time of hydrolysis or from changes in *p*H and SO_2 content of the Schiff reagent (since sections of control suprarenal gland and normal kidney and of experimental adrenal gland were stained in the same way on the same slide).

In order to confirm the data obtained by means of the histophotometric method, two other methods have been used: (1) Measurements of the dry mass by means of the interference (Baker-Smith) microscope on isolated adrenal nuclei, suspended in saline. After treatment with DNase, the loss in dry mass, considered as equivalent to the nuclear content of DNA, in rats exposed to cold is on the average 37·5 per cent less than in control animals. (2) Chemical determinations of DNA on medulla homogenates, by the micromethod of Steele *et al.*[9], based on the diphenylamine reaction of Dische[10] and the count of the nuclei. The results show that the nuclei of the adrenal medulla of rats exposed to cold have less DNA (on average

25 per cent less after 100 h; 34 per cent after 300 h) than those of control rats.

In either case, the results are in agreement, qualitatively and quantitatively, with those obtained by histophotometry. This agreement, together with the DNA diminution, clearly shows that the latter is not due to errors in measurement, but is real. On the other hand, the reaction of Dische on the acid-soluble fraction of the homogenates of adrenal medulla does not give rise to difference in colour development between control extracts and those from cold-exposed animals. This fact eliminates the possibility that the observed difference in DNA content may be due to a loss of DNA present in a depolymerized form in the nucleus *in vivo*.

Since the DNA content is restored to normal or supranormal values after withdrawal of the stimulus, it is presumably a reaction of the nucleus to a functional stimulus of exceptional intensity.

I thank Prof. E. Puccinelli and Prof. C. Pellegrino for advice. This work was supported by a grant from Consiglio Nazionale delle Ricerche.

Increase in Length of Skeletal Muscle during Normal Growth

RECENTLY I attempted to answer the question of how mammalian striated muscle fibres increase in length during normal post-natal growth. Aronson[1] has shown that the length of the sarcomeres of the muscles of the tarsonemid mite increase during development. He also suggests that the exceptionally long sarcomeres in this mite result from an early determination of the number of sarcomeres in a given fibre.

The investigation described here was carried out on the biceps brachii muscle of the mouse. This muscle is ideal for this purpose because its fibres run from tendon to tendon and are all approximately the same length. It is now well established that the length of the sarcomeres of striated muscle fibre decreases as the muscle shortens during contraction[3,4]. Therefore, in order to fix the muscle at a standard length the animals were killed and pinned to a cork board with the forelegs stretched out horizontally. They were then kept for 48 h at 4° C to allow the muscles to go into rigor mortis in this outstetched position. The purpose of maintaining the mouse carcasses at this low temperature was three-fold: to cause the muscle to go into rigor very slowly and avoid any violent contractions of the fibres that sometimes occur when muscle goes rapidly into rigor[5]; to reduce any decomposition; and to prevent the precipitation of the sarcoplasmic proteins[6]. After 48 h the muscles were excised and their length from tendon to tendon was measured with an ocular micrometer using transmitted light. These muscles were then fixed in Flemming's solution without acetic acid[7], sectioned longitudinally and stained with Mallory's triple stain. The length of the muscle was measured after sectioning to ascertain whether any contraction in muscle length had occurred due to the histological procedure used. No change in length was in fact noted in any of the muscles examined.

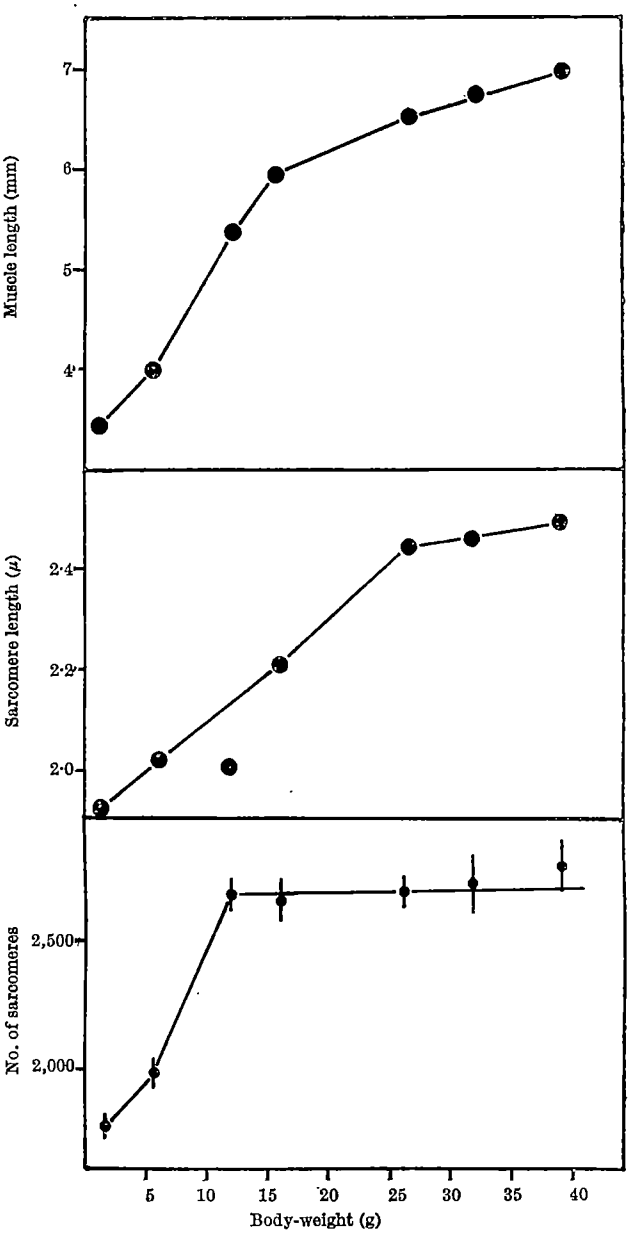

Fig. 1

The sections were then projected using a microscope fitted with a ground glass projection screen which was calibrated with an ocular micrometer. The number of *A* bands per 20μ length of fibre was then determined. These measurements were made on 6 fibres for each muscle and the average sarcomere length was calculated. An estimate of the total number of sarcomeres along the length of the muscle was then obtained from the average sarcomere length and the muscle length. This procedure was carried out on the biceps of mice ranging in size from newly born animals to adults.

The results of these measurements plotted against body weight are given in the three graphs of Fig. 1. It can be seen in Fig. 1 that the length of the muscle (top graph) increases with increase in body weight in a way that one might expect; increasing rapidly initially until the animal weighs approximately 15 g. After 15 g is exceeded the muscle lengthens at a slower rate. However, the average sarcomere length (middle plot) increases steadily until the animal weighs approximately 25 g. The lower plot shows the estimates of the number of sarcomeres along the length of the muscle (2 × the standard error is

given with each point). From this graph it is concluded that the number of sarcomeres along the long axis of this muscle increases only initially, that is, until the animal attains a body-weight of approximately 10 g. I have shown in earlier investigations[2,6] that embryonic differentiation of the biceps branchii of the mouse is not complete until the animal is approximately 8–10 g. Therefore this initial period of increase in the number of sarcomeres along the length of the muscle represents the completion of differentiation. After differentiation is complete then it would seem that the number of sarcomeres along the long axis of the muscle is fixed and no further increase takes place. My findings do in fact agree with Aronson's, who found that the post-embryonic elongation of striated muscle is due to the increase in length of each sarcomere and not due to the increase in the number of sarcomeres along the length of the muscle.

I thank Prof. J. N. R. Grainger for his interest in this work, and also the Agricultural Institute of the Republic of Ireland for the research fellowship they made available.

HÆMATOLOGY

Plasma Angiotensinase Activity in Human Hypertension

Angiotensin is the pressure-active component of the renal pressor system and is suspected of playing a part in cases of human hypertension accompanied by primary or secondary renal lesions. The angiotensin-level results on one hand from its rate of synthesis by renin, on the other from its uptake by tissues and its inactivation by 'angiotensinase'. Angiotensinase activity results from a peptidasic enzyme system which has not yet been shown to be specific.

Blood or plasma angiotensinase activity has been measured with methods varying widely in principle; the level in hypertensive patients has been reported to be decreased[1], normal[2], and elevated[3–5]. These contradictory results led us to apply to 52 hypertensive patients a previously described method[6] based on: (*a*) the incubation of angiotensin with untreated plasma under standard conditions of time, temperature, *p*H, buffer and substrate concentration; (*b*) the assay of residual pressor activity in a rat preparation. Since the principle was strictly physiological, the results may have more significance than those obtained by measuring the degradation of a chemical or radioactive element of the angiotensin molecule. The degree of inaccuracy inherent to bioassays was reduced to 15 per cent by duplicating all assays, multiplying injections to each rat, using normal plasma as an extra control, and discarding less-than-ideal animal preparations.

Table 1. Mean Plasma Angiotensinase of 25 Normals and 52 Hypertensives. Normal Range is 80–120 per cent

Diagnosis	No. of patients	Mean ± *S.E.M.*	*P*
Normal	25	100 ± 2	
Essential hypertension	27	105 ± 4	> 0·05
Renal artery stenosis	14	109 ± 6	> 0·05
Malignant hypertension	11	115 ± 8	> 0·05

From the results shown in Table 1, it appears that the increase observed in the three hypertensive groups was not statistically significant according to the '*t*' test. No correlation was found between the angiotensinase-level and the blood-pressure reading at the time of sampling. Blood was obtained from one essential hypertensive patient every 3 h for 30 consecutive h to learn about the stability of the plasma enzyme-level; for an average value of 105 per cent, the standard deviation of the 11 samples was ± 7; considering the error due to technique, these fluctuations were of a minor degree. Two patients with renal artery stenosis in whom renal surgery was beneficial were examined before and after the operation; the post-operative plasma angiotensinase of one remained elevated, whereas it reverted to normal in the other.

These results confirm those of Klaus *et al.*[2], who observed a plasma angiotensinase increase of only 6 per cent in a group of 65 essential hypertensives. Those and the present results are not compatible with the production of a specific angiotensinase as an adaptive mechanism to prevent chronic hyper-angiotensinæmia.

We gratefully acknowledge the encouragement of Prof. R. M. Archibald, the technical aid of Mrs. Judith Lawson, the referral of patients by Dr. J. M. Bryant and Dr. A. I. Vagnucci, and the gifts of 'Hypertensin' by Dr. R. Gaunt, Ciba, Summit. The work was supported in part by U.S. Public Health Service grant *HE* 07473.

Solubility of Fibrin Clots in Solutions of Heparin

Heparin has been shown to retard both the beginning and the general course of polymerization of purified fibrinogen[1]. Evidence will be presented that this anticoagulant, in solutions of low ionic strength, in addition to inhibiting the polymerization of fibrinogen, is able to depolymerize and thus dissolve preformed clots.

(*A*) *Effect of heparin on the polymerization of activated fibrinogen.* Saline solutions of four different preparations of bovine fibrinogen (34–54 mg/ml.) isolated by the method of Laki[2] and of two preparations of human fibrinogen (64 and 46 mg/ml.) obtained by ammonium sulphate precipitation of fraction I0 of Blombäck and Blombäck[3] (kindly supplied by Dr. A. M. Fisher of the Connaught Laboratories of Toronto) were mixed 1 : 1 with 2 M sodium bromide, *p*H 5·3. To these mixtures a thrombin solution of 100 N.I.H. units/ml. was added to a final concentration of 10 units/ml. and the samples kept at room temperature (24° C) for 3 h. One-tenth ml. from each mixture was then gently added to 9·9 ml. of each of several heparin solutions varying in concentration from 10–100 for human or 100–500 μg/ml. for bovine fibrinogen samples in 15 mm × 100 mm tubes. A small clot-like structure appeared immediately after the addition. The tubes were then stoppered and attached horizontally on a Kahn shaker with their long axis parallel to the motion of the machine. They were

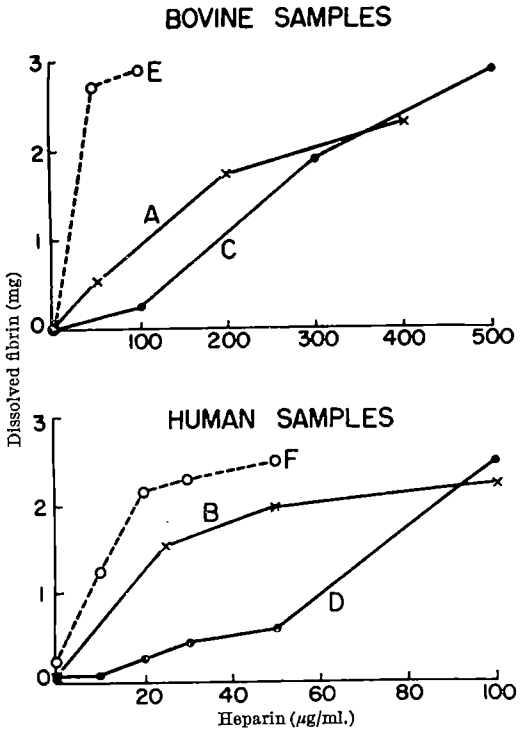

Fig. 1. Prevention of clotting of activated fibrinogen and dissolution of preformed fibrin by heparin. All graphs represent amounts of protein dissolved by shaking fibrin in aqueous solutions of heparin at the concentrations indicated on the two abscissæ, for 10 min. In *A* and *B* the parent bovine and human fibrinogens (2·6 mg) were subjected to the action of thrombin in 1 M sodium bromide of *p*H 5·3 for 3 h before being diluted 1 : 100 with the heparin solutions. In *C*, *D* and *E*, *F* the parent fibrinogens (3, 2·6 and 3, 2·6 mg, respectively) were clotted in distilled water left undisturbed for 10 min and then diluted with the heparin solutions. Thrombin was added at 10 N.I.H. units/ml. in the experiments of lines *C* and *D* but only at 1 and 0·5 units in those of *E* and *F*, respectively

shaken for 10 min after which they were centrifuged at a relative centrifugal force of 3,020*g* (5,000 r.p.m.) for another 15 min in order to separate the supernatant from the remaining undissolved clot, if any. The protein content of the supernatants was then determined by reading the absorption at 280 mμ in a Beckman *DB* spectrophotometer against a blank of 0·01 M solution of sodium bromide containing the same amount of heparin as each sample being tested. The protein concentration was read from a fibrinogen dilution curve which was prepared from a fibrinogen solution of known concentration. Lines *A* and *B* in Fig. 1 indicate that heparin solutions of low ionic strength ($\Gamma/2 = 0{\cdot}01$) are able to keep in solution smaller or greater amounts of fibrin depending on the heparin concentration. Comparison of the concentrations of heparin needed to keep in solution the same amount of activated fibrinogen shows that human samples are considerably more sensitive to the antipolymerizing action of heparin than are bovine preparations. Concentrations of heparin above 500 μg/ml. are even able to prevent the initial formation of a clot.

(*B*) *Effect of heparin on preformed fibrin clots.* Saline solutions of five preparations of bovine fibrinogen and two preparations of human fibrinogen containing 12·5–15 mg protein/ml. were buffered with 0·01 M imidazole at *p*H 7·3. 0·2 ml. volumes of these solutions were added into 15 × 100 mm tubes containing 9·0–9·8 ml. of distilled water and thrombin at a final concentration of 10, 1 or 0·5 N.I.H. unit/ml. Ten min after the formation of a clot 0·1–0·5 ml. of a heparin solution containing either 1 or 10 mg/ml. was added so that the final volume in each tube was 10 ml., while the final heparin concentration varied from either 10–100 or from 100–500 μg/ml. for human and bovine fibrinogen samples respectively. Immediately after heparinization the tubes were shaken on the Kahn shaker, as previously described, for 10 min and the amount of clot dissolved was determined by reading the absorption of the supernatant at 280 mμ after centrifugation of the mixtures. The blanks in each case were identical to the test samples except that they lacked fibrinogen. Curves *C* and *D* were obtained when the concentration used to clot the fibrinogen was 10 N.I.H. units/ml., while only 1 or 0·5 unit thrombin/ml. was added to the samples of curves *E* and *F* respectively. It is apparent that heparin is capable of dissolving preformed clots and that the amount of clot dissolved is proportional to the heparin concentration. It is also obvious that the clots produced with less thrombin, although of about the same protein content as those formed with higher concentrations of the enzyme, require considerably less heparin to be dissolved. Comparison of curve *C* versus *D* indicates that clots formed from human fibrinogen are more easily dissolved than clots from bovine fibrinogen.

Dissolution of the clots did not occur when (*a*) the clot was first wrapped on a glass rod and then shaken in the aqueous heparin solutions; (*b*) heparin was dissolved in saline instead of in distilled water—in such instances even concentrations of 1·2 mg heparin/ml. were ineffective; (*c*) fibrinogen was clotted in physiological saline containing 10 mM calcium chloride instead of in distilled water. Removal of the calcium-containing saline by repeated careful washings of the clot with distilled water, taking care not to increase its compactness, did not make the clot more soluble. On the other hand, clots formed in saline but in the absence of calcium chloride dissolved in heparin almost entirely, after washing.

Heparin has been claimed to activate the fibrinolytic system[4]. For this reason, 3,000 anti-Schwert-Takenaka units/ml. of pancreatic trypsin inhibitor[5] ('Iniprol', Choay Laboratories, Paris, France) were added to the aqueous solution of thrombin before the addition of fibrinogen. The presence of this excessive amount of fibrinolytic inhibitor did not affect the dissolving action of heparin, thus excluding the possibility that the lytic action was due to activation of the fibrinolytic system. Further proof against the idea of fibrinolytic action is the fact that addition of sodium chloride to a concentration of 1·7 per cent (double the physiological), or calcium chloride to 10 mM or neutralization of heparin by hexadimethrine bromide ('Polybrene'), resulted in the appearance of a new clot.

(*C*) *Effect of heparin on the solubility of fibrinogen.* Addition of 100 μg heparin/ml. to cloudy 1 : 9 dilutions of citrated human or bovine fibrinogen with distilled water resulted in redissolution of the fibrinogen and clearing of the turbidity of the mixture. Addition of 10 mM calcium chloride to the clear solution made it more cloudy than it was prior to the addition of heparin. Addition of sodium chloride to this suspension to a concentration of 0·9 per cent redissolved the floccules.

The evidence presented indicates that heparin in solutions of low ionic strength breaks the bonds holding the fibrin monomers together in clots. A solubilizing effect is also exerted on suspensions of fibrinogen of very low salt concentration. Calcium and hexadimethrine bromide reverse the solubilizing effect of heparin on both fibrinogen and fibrin. Sodium chloride neutralizes the effect of heparin on fibrin. However, due to the fact that saline itself solubilizes fibrinogen the effect of sodium chloride on the solubilization of fibrinogen by heparin is not clear. The fact that heparin is unable to dissolve clots formed in the presence of calcium indicates that the bonds broken by heparin are not covalent. This is similar to the effect of numerous other substances (like sodium bromide, urea, monochloroacetic acid, etc.) which at high concentrations are able to break hydrogen bonds and reverse the polymerization process which has taken place in the absence of the activated fibrin stabilizing factor or calcium[6]. The great difference in solubility between clots formed with 10 and clots formed with 1 or 0·5 N.I.H. units of thrombin activity/ml. indicates that the resistance of a clot to

heparin depends among other parameters on the amount of thrombin that generated the fibrin.

Hæmoglobin : Reversal of Oxidation and Polymerization in Turtle Red Cells

Hæmoglobins from the turtle, *Chelydra serpentina*, the frog, *Rana catesbeiana*, and certain strains of mice have been shown to polymerize *in vitro*[1]. Polymerization to an octamer began after hæmolysis and was completely inhibited by either *N*-ethylmaleimide or iodoacetamide. Experiments to be described here indicate that oxidized and polymerized hæmoglobin appears to be a frequent constituent in high concentrations in the red cells of some species of turtles. This polymerization and oxidation of hæmoglobin can be reversed by incubation of the cells with plasma, and appears to involve the formation of double molecules linked by one or more disulphide bridges. Disulphide bonds are suggested both by the finding that very low concentrations of mercaptoethanol dissociate already formed polymer and by the inhibition of polymerization by −SH reagents.

Freshwater turtles, *Pseudemys scripta elegans*, were purchased from Lemberger and Co., Oshkosh, Wisconsin, or captured in July in Bastrop County, Texas. Blood was collected and prepared as previously described for turtles[1]. Methæmoglobin was determined as described by Dubowski[2]. The following procedure was used to determine the presence of polymer because iodoacetamide inhibits polymerization but has no effect on polymer already formed[1]. Hæmoglobin (3·0 ml. of a 1·25 per cent solution in ~ 0·1 per cent NaCl), freshly prepared at 4° C, was reacted with 34·2 mg iodoacetamide and incubated at 25° C for 1 h. This solution was dialysed against 0·1 M phosphate buffer, *p*H 6·9, and run on a Spinco model *E* analytical ultracentrifuge as described elsewhere[1]. Red cells were incubated with glucose as described by Beutler and Baluda[3]. ACD–*A* solutions were used in the acid–citrate–dextrose incubations[4].

Six specimens from Texas were bled on the third day after their capture. Each possessed methæmoglobin, the values of which ranged from 5·2 to 60·3 per cent with an average of 30·1 per cent. Methæmoglobin levels in other turtles ranged from 50 to 90 per cent after 3 or more months in captivity. Polymerized hæmoglobin was present in every sample in which the methæmoglobin-level was more than 20 per cent. A typical sedimentation pattern is shown in Fig. 1. Small amounts of polymerized hæmoglobin may have been present in solutions containing less methæmoglobin, but are difficult to detect by ultracentrifugation.

Table 1. Incubation of Red Cells from a Single Turtle, *Pseudemys scripta elegans*, with Various Media at 4° C for Ten Days

Sample	1	2	3
		Vol. (ml.)	
Red blood cells	1·25	1·25	1·25
Plasma	3·00	3·00	—
0·8 per cent NaCl + heparin	0·75	0·75	—
ACD–*A* solution	—	0·75	—
0·15 M phosphate buffer *p*H 7·52	—	—	2·25
10^{-4} M methylene blue*	—	—	0·60
0·17 M glucose*	—	—	0·90
	Methæmoglobin values		
Initial methæmoglobin (per cent)	50·2	50·2	50·2
Final methæmoglobin (per cent)	6·1	34·4	10·1

* In 0·15 M phosphate buffer, *p*H 7·52.

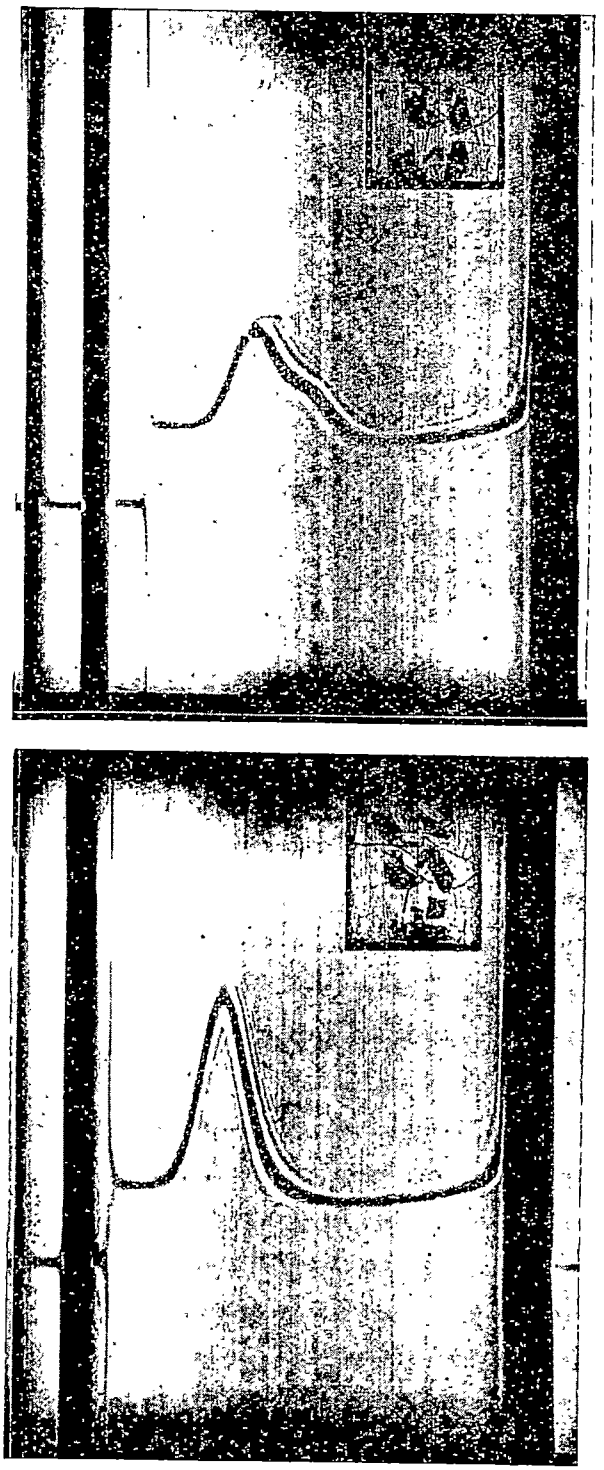

Fig. 1. Sedimentation patterns of freshly-prepared hæmolysates of the turtle, *Pseudemys scripta elegans*, before and after plasma incubation at 4° C for ten days. 64 min after reaching speed of 52,640 r.p.m.; hæmoglobin concentration is 1·25 per cent in 0·1 M phosphate buffer, *p*H 6·92. The sedimentation constants are corrected to water at 20° C. Above: before plasma incubation, showing the presence of two components with sedimentation constants of 4·1 and 6·6. The methæmoglobin concentration is 50·2 per cent. Below, after plasma incubation, showing the presence of a single component with sedimentation constant of 4·1. Methæmoglobin concentration is 6·1 per cent

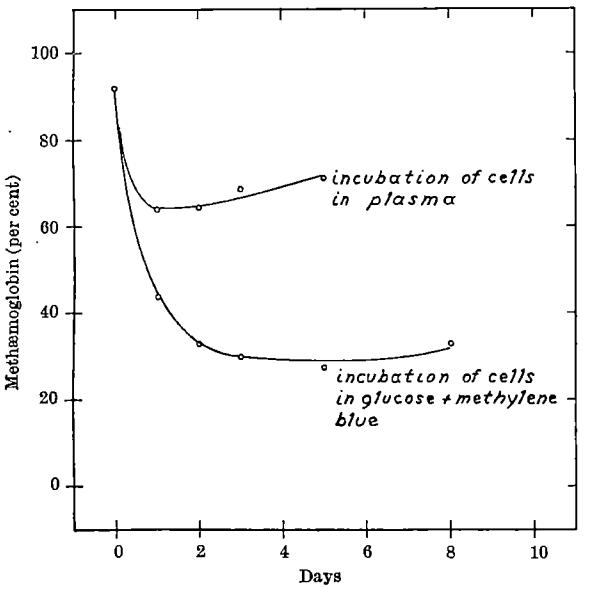

Fig. 2. Reduction of methæmoglobin by incubation of red cells of the turtle, *Pseudemys scripta elegans*, in plasma and in glucose–methylene blue medium at 4° C

Samples of freshly-obtained red cells containing 50·2 per cent methæmoglobin were incubated for 10 days in various media at 4° C (Table 1). Sedimentation patterns (Fig. 1) show that incubation of the cells with plasma resulted in the almost complete disappearance of the 7*S* component. The methæmoglobin content was reduced to 6·1 per cent. In other experiments plasma incubation completely reduced all methæmoglobin. Similar results were obtained with glucose–methylene blue incubations. Incubation in 0·8 per cent NaCl reduced the methæmoglobin and polymer content only slightly. Reduction of methæmoglobin by plasma incubation has been reported previously[5]. Fig. 2 shows that this reduction reaches a steady state in 1–2 days. Daily disturbance of the solution lowers the degree of reduction, presumably by increasing oxygen consumption. Glucose–methylene blue incubation appears to be more effective than incubation in plasma when the solution is disturbed. Although methæmoglobin formation is accompanied by polymerization of a portion of the hæmoglobin, the separation of the heavy 7*S* component from the 4*S* component by filtration through 'Sephadex *G*-100' equilibrated with 0·2 M NaCl showed that methæmoglobin formation occurs in both the polymerized and unpolymerized fractions.

The double molecule has been shown to dissociate on treatment with 0·5 M mercaptoethanol[1]. This might have been produced either by the reagent acting as a reducing agent to break disulphide bonds or as a dissociating organic solvent. We have now found that 0·01 M mercaptoethanol is sufficient to bring about the complete dissociation of the 7*S* component in a solution which initially contained more than 50 per cent double molecules. This finding supports the conclusion that —S—S— bonds are probably involved.

Methæmoglobin-levels in animals other than man have received little attention. Human red cells normally contain less than 1 per cent methæmoglobin[6]; the lethal level is probably near 70 per cent[7]. We have found more than 90 per cent methæmoglobin in a freshly-captured specimen of the box turtle, *Terrapene ornata ornata*. Otherwise, the animal appeared healthy. In some species of turtles polymerization accompanies methæmoglobin formation. Nutrition and red cell ageing are factors known to affect methæmoglobin-levels in other animals. We have observed that methæmoglobin-levels in turtles are higher in summer than in spring. The mean life-span of turtle erythrocytes from *Terrapene carolina* has been reported to be 600–800 days[8]. Examination of red cell synthesis in turtles indicates that their systems are different from those found in mammals[9]. Turtles can, under anoxic conditions, shunt blood by the lungs via the ventricular septum and are able to live for long periods of time on energy derived only from anaerobic glycolysis[10]. This may explain in part the tolerance of turtles to high levels of methæmoglobin.

The effect of polymerization on the oxygen affinity of the hæmoglobin is difficult to evaluate because we have not yet been able to isolate as a monomer that fraction which polymerizes without reacting the freshly-prepared hæmoglobin with iodoacetamide or *N*-ethylmaleimide. Each of these reagents is likely to affect the oxygen equilibrium.

Hæmoglobin Types of the Wild House Mouse (*Mus musculus domesticus* Rutty 1772)

Ranney and Gluecksohn-Waelsch[1] described in laboratory strains of the house mouse the hæmoglobin (Hb) types *s* = single and *d* = diffuse which differ in their electrophoretic behaviour. Of 20 inbred strains which were investigated six belonged to the 'single' (Hb^s) and 14 to the 'diffuse' (Hb^d) type[2]. In crosses Hb^d is dominant over Hb^s (ref. 3). Popp[4,5] was able to localize the Hb-gene on chromosome I by discovering its linkage to the genes *p*, *c* and *sh*–1. In addition, there are differences in the solubility and peptide structure of the hæmoglobins within the Hb^s and Hb^d types which, as such, are differentiated by their electrophoretic patterns only[4–7].

From the existence of the two Hb types in inbred laboratory strains of mice, Russell and Gerald[2] concluded that they must also occur in Nature and that Hb^d is probably the commoner of the two; however, the existence of both alleles in wild mice was regarded as necessary to explain their actual distribution in the inbred strains examined.

Popp[5] has indeed found the Hb^s type in 6 from 18 wild mice. We have investigated the hæmoglobin pattern of wild house mice by means of the agar electrophoresis technique[8]. The animals are derived from five fairly closed populations; there is one additional mouse from a different locality (Table 1). The ratio of Hb^s to Hb^d found in our material is about 1 : 1·6, in agreement with Russell and

Table 1. Distribution of Hæmoglobin Types in Five Populations of Wild Mice

Population	Number of mice	Hb^s type	Hb^d type
T I	6	2	4
T II	7	6	1
T III	15	1	14
H I	6	0	6
H II	7	6	1
Additional	1	1	0
Total	42	16	26

Gerald's[2] suggestion that Hb^d may be more widespread in Nature. However, individual populations differed widely from one to another.

Furthermore, studies of mutants[1,5] show that animals with the Hb^s type can arise as mutants from Hb^d lines and possibly vice versa. Mutant strains can also be found with some animals of the single and some of the diffuse type[1,9]. We therefore do not always know for certain that the wild ancestors of laboratory strains already possessed the Hb^s allele. In the strain '*CE*', which originated from a wild mutant (Knight[10]), we found the Hb^s type in animals of the line *CE/J* Han Jena (F_{25}).

Effects of Erythromycin and Tetracycline in Human Bone-marrow Cultures

In a previous publication[1] we have reported that chloramphenicol inhibits hæmoglobin synthesis in human bone-marrow culture. Erslev and Iossifides[2] found that not only chloramphenicol but also tetracycline and erythromycin had similar effects on immature erythrocytes *in vitro*. Because tetracycline and erythromycin do not cause toxic hæmatological reactions in man, this finding would seriously limit the validity of applying this *in vitro* method to the study of the effect of chloramphenicol on erythroid cells *in vivo*. It seemed important, therefore, to extend our experiments and to study the effect of tetracycline and erythromycin on hæmoglobin synthesis in human bone-marrow cultures, using the same methods as were used to study the effect of chloramphenicol.
